This interaction is of clinical importance: be alert for the need to reduce the midazolam dosage in the presence of saquinavir. The authors of the study2 suggest that continuous intravenous midazolam doses should be reduced by 50%, but do not consider dose adjustments to single intravenous doses necessary.2 The same precautions would seem appropriate with triazolam. However, the manufacturer of saquinavir contraindicates the concurrent use of oral midazolam and triazolam.5 They note that no studies have been conducted with ritonavir-boosted saquinavir but that a 3 to 4-fold increase in intravenous midazolam levels would be expected.4 Use of intravenous midazolam with saquinavir is not contraindicated but they...
advise that its use be restricted to an intensive care unit or similar setting so that the appropriate management of respiratory depression is available.8 The UK manufacturer of ritonavir contraindicates its use with clorazepate, diazepam, estazolam, flurazepam, midazolam and triazolam as they are highly metabolised by the cytochrome P450 isoenzymes and therefore may cause extreme sedation and respiratory depression in the presence of ritonavir.8 The US manufacturer of ritonavir contraindicates its use with triazolam and midazolam.9 This interaction is likely to occur at least to some extent with all protease inhibitors and any of these highly metabolised benzodiazepines, and the use of (oral) midazolam and triazolam is largely contraindicated.

The manufacturer of ritonavir notes that zolpidem and ritonavir may be given concurrently with careful monitoring for excessive sedative effects.8

### Benzodiazepines + Proton pump inhibitors

**Gait disturbances (attributed to benzodiazepine toxicity) occurred in two patients given triazolam and lorazepam or flurazepam with omeprazole, and another patient taking diazepam and omeprazole became wobbly and sedated. Lansoprazole, pantoprazole, or rabeprazole appear not to interact to a clinically relevant extent with diazepam. Diazepam serum levels are increased by esomeprazole but the clinical relevance of this is unknown.**

#### Clinical evidence

(a) Esomeprazole

Esomeprazole inhibits the cytochrome P450 isoenzyme CYP2C19 so that the appropriate management of respiratory depression is available. Antipsychotics, Anxiolytics and Hypnotics 735

(b) Lansoprazole

Lansoprazole 60 mg daily for 10 days was found to have no effect on the pharmacokinetics of a single 100-microgram/kg intravenous dose of diazepam.5

(c) Omeprazole

Two elderly patients, both smokers, taking triazolam with lorazepam or flurazepam, developed gait disturbances when they were given omeprazole 20 mg daily. They rapidly recovered when either the benzodiazepines or the omeprazole were stopped.3 A brief report describes a patient taking omeprazole 20 mg daily. They rapidly recovered when either the benzodiazepines or the omeprazole were stopped.3

One study in 8 healthy subjects found that omeprazole 40 mg daily for one week reduced the clearance of a single 100-microgram/kg intravenous dose of diazepam by 54%,6 while another study found that omeprazole 20 mg reduced diazepam clearance by 27%.7 A further study found that omeprazole 40 mg reduced the oral clearance of diazepam by 42% in white American subjects but only by 21% in Chinese subjects.8 Metaboliser status (see ‘Genetic factors’, (p.4)) was also found to be important in another study of this interaction: only extensive metabolisers of CYP2C19 showed a significant decrease in diazepam clearance when given omeprazole.9

(d) Pantoprazole

In a placebo-controlled study in 12 healthy subjects, intravenous pantoprazole 240 mg for 7 days did not change the half-life, clearance and AUC of a 100-microgram/kg intravenous bolus dose of diazepam.10

(e) Rabeprazole

Rabeprazole 20 mg daily or placebo was given to 15 patients (in 3 groups) for 23 days with a single 100-microgram/kg dose of diazepam on day 8. Each group contained at least two poor metabolisers and three extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19 (see ‘Genetic factors’, (p.4)). No significant changes in the pharmacokinetics of the diazepam were seen.11 Another study similarly found that rabeprazole does not affect the pharmacokinetics of diazepam in both poor and extensive metabolisers of CYP2C19.9

#### Mechanism

*In vitro* studies with human liver microsomes suggest that omeprazole inhibits diazepam metabolism because it inhibits the cytochrome P450 isoenzymes CYP3A, and CYP2C19.12 Studies in humans suggest that CYP2C19 may be the most important isoenzyme in this interaction.4 The reaction with lorazepam (and other glucuronidated benzodiazepines) may possibly not be an interaction (so it is suggested) but an adverse effect of giving sedating medications to markedly anaemic patients.4

#### Importance and management

Information is limited, but what is currently known suggests that patients given omeprazole, and possibly esomeprazole, with diazepam may experience increased benzodiazepine effects (sedation, unstable gait etc). If this occurs the benzodiazepine dosage should be reduced. Lansoprazole, pantoprazole and rabeprazole do not appear to interact with diazepam.

Further, an *in vitro* study suggests that omeprazole may possibly interact similarly with midazolam,13 although this needs confirmation. There seems to be no information about other benzodiazepines.

### Benzodiazepines + Quinolones

Ciprofloxacin causes a marked reduction in the clearance of diazepam, but this does not appear to be clinically important in most individuals. Ciprofloxacin appears not to interact with temazepam, and gatifloxacin appears not to interact with midazolam.

#### Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

Ciprofloxacin 500 mg twice daily for 3 days was found to have no effect on the pharmacokinetics of diazepam in a study in 10 healthy subjects.1 However, a later study in 12 healthy subjects found that ciprofloxacin 500 mg twice daily for 5 days increased the AUC of a single 5-mg intra-
venous dose of diazepam by 50%, reduced its clearance by 37% and doubled its half-life. These changes caused no significant alteration in the performance of a number of psychometric tests. It was suggested that the clearance of diazepam was reduced because ciprofloxacin inhibited the cytochrome P450-mediated metabolism of diazepam. Another study by the same group found that ciprofloxacin does not interact with temazepam.

It seems unlikely that any marked increases in diazepam effects (drowsiness etc.) will occur in most patients, but it may possibly be significant in those who have reduced renal or hepatic clearance (e.g. the elderly). This needs confirmation.

(b) Gatifloxacin

Gatifloxacin 400 mg daily for 5 days had no effect on the pharmacokinetics of midazolam in 14 healthy subjects. The pharmacokinetics of gatifloxacin were also unaffected by concurrent use.

### Benzodiazepines and related drugs + Rifampicin (Rifampin)

Rifampicin causes a very marked increase in the metabolism and/or clearance of diazepam and nitrazepam. Rifampicin also causes a marked increase in the clearance of midazolam and triazolam and the non-benzodiazepine hypnotics, zaleplon, zolpidem and zopiclone. Benzodiazepines and related drugs that are metabolised similarly are expected to interact in the same way.

#### Clinical evidence

A. Benzodiazepines

(a) Diazepam

The mean half-life of diazepam was reduced from 58 to 14 hours and the clearance was increased fourfold in 7 patients with tuberculosis who were given daily doses of isoniazid 500 mg to 2.2 g, rifampicin 450 to 600 mg and ethambutol 25 mg/kg, when compared with healthy control subjects. In 21 healthy subjects rifampicin 600 mg or 1.2 g daily for 7 days increased the clearance of diazepam by about threefold.

(b) Midazolam

A pharmacokinetic study in 10 healthy subjects found that rifampicin 600 mg daily for 5 days reduced the AUC of a single 15-mg oral dose of midazolam by 96%, and reduced the half-life by almost two-thirds. The psychomotor effects of the midazolam (as measured by the digit symbol substitution test, Maddox wing test, postural sway and drowsiness) were almost totally lost.

(c) Nitrazepam

A study in healthy subjects found that rifampicin 600 mg daily for 7 days increased the total body clearance of nitrazepam by 83%.

(d) Temazepam

A study found that the pharmacokinetics of temazepam were unchanged by rifampicin.

(e) Triazolam

Triazolam 500 micrograms orally was given to 10 healthy subjects before and after rifampicin 600 mg daily or a placebo for 5 days. Rifampicin reduced the triazolam AUC by 95% and decreased the maximum plasma triazolam levels by 88% when compared with the placebo group. The elimination half-life was reduced from 2.8 to 1.3 hours. Pharmacodynamic tests (drowsiness, sway, Maddox wing, etc.) showed that rifampicin abolished the effects of triazolam.

B. Non-benzodiazepine hypnotics

(a) Zaleplon

A non-randomised, crossover study in healthy subjects found that rifampicin 600 mg daily for 14 days increased the clearance of a 10-mg dose of zaleplon by 5.4-fold, decreasing its maximum serum levels and AUC by 80%.

(b) Zolpidem

In a randomised, placebo-controlled, study, 8 healthy subjects were given rifampicin 600 mg daily for 5 days and then on day 6 they were given a single 20-mg oral dose of zolpidem. It was found that the rifampicin reduced the zolpidem AUC by 73%, reduced the maximum plasma level by about 60% and reduced its half-life from 2.5 to 1.6 hours. A significant reduction in the effects of zolpidem was also seen, as measured by a number of psychomotor tests (digital symbol substitution, critical flicker fusion, subjective drowsiness, etc.).

(c) Zopiclone

In a two-phase study, 8 healthy subjects were given rifampicin 600 mg or a placebo daily for 5 days, with a single 10-mg oral dose of zopiclone on day 6. The rifampicin reduced the zopiclone AUC by 82%, decreased the peak serum levels by 71% and reduced its half-life from 3.8 to 2.3 hours. A significant reduction in the effects of zopiclone was also seen, as measured by the performance of psychomotor tests.

#### Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of several benzodiazepines and the non-benzodiazepine hypnotics, zaleplon, zolpidem and zopiclone, thereby decreasing their levels. The metabolism of midazolam by the cytochrome P450 isoenzyme CYP3A4 in both liver and gut is affected. The enzyme inducing effects of rifampicin seem to predominate if isoniazid (an enzyme inhibitor) is also present. Temazepam undergoes glucuronidation and is therefore unaffected by rifampicin.

#### Importance and management

The documentation of these interactions is limited but what has been reported is consistent with the way rifampicin interacts with many other drugs. The clinical importance of some of these interactions between the benzodiazepines and related drugs and rifampicin has not yet been assessed but what is known suggests that the dosage of diazepam and nitrazepam may need to be increased if rifampicin is given. Be alert for a reduction in the effects of other similarly metabolised benzodiazepines (e.g. chloridiazepoxide, flurazepam).

The effect of rifampicin on oral midazolam, triazolam, zaleplon, zolpidem and zopiclone is so large that they are likely to become ineffective and an alternative should be used instead. Alprazolam is also predicted to interact because CYP3A is involved with its metabolism. Those benzodiazepines that, like temazepam, undergo glucuronidation (e.g. lorazepam, oxazepam) are not expected to be affected by rifampicin and may be useful alternatives.

**Benzodiazepines + Saw palmetto**

No pharmacokinetic interaction is expected between saw palmetto and alprazolam or midazolam.
### Benzodiazepines and related drugs + SNRIs

Visual hallucinations have been seen in one patient given zolpidem and venlafaxine. No important interaction normally appears to occur between venlafaxine and alprazolam or diazepam. The pharmacokinetics of duloxetine were not affected by lorazepam or temazepam.

#### Clinical evidence

A 27-year-old woman who had been taking venlafaxine 37.5 mg at night for a week and terfenadine for a few years started taking zolpidem 10 mg daily. After 2 days, and within 45 minutes of the zolpidem dose, she developed visual hallucinations, which lasted for 2 to 4 hours. A similar episode occurred 2 weeks later when she had discontinued the terfenadine.

A double-blind study in 18 healthy subjects taking venlafaxine 50 mg every 8 hours found that the concurrent use of diazepam 10 mg did not have a clinically significant effect on the pharmacokinetics of either drug, or their major active metabolites (O-demethylvenlafaxine and desmethyldiazepam). Diazepam affected the performance of a battery of pharmacodynamic tests, but the addition of venlafaxine had no further effects.

A study in 16 healthy subjects found that venlafaxine 75 mg twice daily reduced the AUC of a single 2-mg oral dose of alprazolam by 29% and reduced its half-life by 21%, but the performance of psychometric tests were only minimally changed.

#### Mechanism

Uncertain. It has been suggested that a pharmacodynamic interaction between serotonin reuptake inhibition and zolpidem may lead to prolonged zolpidem-associated hallucinations in susceptible individuals.

#### Importance and management

The studies suggest that no special precautions are necessary during the concurrent use of venlafaxine and diazepam or alprazolam, or between duloxetine and lorazepam or temazepam. Similarly, the manufacturer of duloxetine reports that its pharmacokinetics were not affected by lorazepam or temazepam under steady state conditions. However, a pharmacodynamic interaction may occur. Hallucinations have been seen with zolpidem alone, and they have also occurred, rarely, when zolpidem and some benzodiazepines were given with the ‘SSRIs’, below, which are related to venlafaxine. However, adverse effects such as these seem rare and the concurrent use of these drugs need not be avoided, but bear this possible interaction in mind if hallucinations occur.

---

---

### Benzodiazepines and related drugs + SSRIs

There is some evidence to suggest that the metabolism of some benzodiazepines (such as alprazolam, bromazepam, diazepam, and also possibly midazolam, nitrazepam and triazolam) may be reduced by some SSRIs (such as fluoxetine and fluvoxamine). On the whole, no clinically significant interaction appears to occur between other SSRIs and the benzodiazepines or related drugs such as chloral hydrate or zaleplon. There is some evidence to support the suggestion that sedation is likely to be increased by the concurrent use of SSRIs and benzodiazepines. Rare cases of hallucinations have been seen with zolpidem and some SSRIs. Symptoms of the serotonin syndrome have been reported in two patients taking paroxetine and a benzodiazepine.

#### Clinical evidence

(a) Citalopram

The UK manufacturer of citalopram says that no pharmacodynamic interactions have been noted in clinical studies in which citalopram was given with benzodiazepines, although the US manufacturer points out that caution should be used with citalopram and any CNS active drug.

A general study in psychiatric patients found that when data on benzodiazepines was pooled, they caused a modest 23% increase in serum citalopram levels, which is almost certainly too small to be clinically relevant. Alprazolam was the only benzodiazepine to cause an elevation of citalopram levels (by 13%) when analysed alone. In another study, citalopram was found to have no effect on alprazolam plasma levels, although the time to maximum alprazolam concentration was increased by 30 minutes. Similarly, a study in 17 healthy subjects found no pharmacokinetic interaction between triazolam and citalopram, and it was suggested that triazolam and other substrates of the cytochrome P450 isoenzyme CYP3A4 are unlikely to have pharmacokinetic interactions with citalopram.

(b) Fluoxetine

The concurrent use of fluoxetine 60 mg daily has been found to reduce the clearance of alprazolam 1 mg four times daily by about 21% and to increase its plasma levels by about 30%. These changes were accompanied by increased psychomotor impairment. Another study also reported impaired alprazolam metabolism, and another study found that the inhibition of cytochrome P450 isoenzyme CYP3A4 by fluoxetine, although some significant changes in alprazolam pharmacodynamics were found.

Fluoxetine 30 mg, given daily for 1 or 8 days, had no effect on the pharmacokinetics of diazepam 10 mg. A later study by the same group, using 60 mg of fluoxetine suggested that the diazepam half-life and AUC were increased, possibly because the fluoxetine decreased the metabolism of diazepam. However, they concluded that this was not of any clinical significance. Another study found that fluoxetine 60 mg alone did not affect psychomotor performance but fluoxetine 60 mg plus diazepam 5 mg significantly impaired the divided attention tracking test and vigilance test more than with diazepam 5 mg alone. Other studies found that the pharmacokinetics of clonazepam, estazolam, midazolam, triazolam, and zolpidem were not significantly affected by fluoxetine.

In contrast, isolated cases of visual hallucinations lasting up to 7 hours have been reported in patients taking zolpidem who were also taking fluoxetine. Marked drowsiness occurred for a whole day in a patient taking fluoxetine 20 mg daily after being given cloral hydrate 500 mg the night before. She later tolerated cloral hydrate 1 g in the absence of fluoxetine without adverse effects.

(c) Fluvoxamine

In 60 healthy subjects fluvoxamine 50 mg daily for 3 days then 100 mg daily for 7 days, doubled the plasma levels of alprazolam 1 mg four times daily given on days 7 to 10. The alprazolam clearance was more than halved. Psychomotor performance and memory were found to be significantly worsened, even after only one day. A study in 23 Japanese patients found that fluvoxamine increased the plasma levels of alprazolam by 58%. There was wide interpatient variability, possibly associated with differences in the cytochrome P450 isoenzyme CYP2C19 levels in these patients (see ‘Genetic factors’, p.4), although it is unclear exactly what impact this isoenzyme has on the interaction.
Fluvoxamine 50 mg twice daily increased the plasma levels of a single 12-mg dose of bromazepam in 12 healthy subjects by 36% and increased the AUC almost 2.5-fold. Some increased impairment in cognitive function was seen.22 Fluvoxamine has been found not to interact adversely with cloral hydrate.23 Fluvoxamine (50 mg on day one, 100 mg on day 2, then 150 mg daily thereafter) for 16 days decreased the clearance of a single 10-mg dose of diazepam by about 65%. The half-life was increased from 51 to 118 hours, and the AUC was increased threefold.24 Fluvoxamine 50 mg twice daily caused a very small, non-significant, increase in the serum levels and AUC of a single 4-mg dose of lorazepam in 12 healthy subjects.22 A study in 10 healthy subjects14 found that fluvoxamine 50 mg twice daily for 8 days then 100 mg twice daily for 6 days had minimal effects on the pharmacokinetics of a single 10-mg dose of midazolam given on day 12.

In a placebo-controlled study in 12 healthy subjects it was found that fluvoxamine 25 mg twice daily for 14 days had no effect on the pharmacokinetics of a single 20-mg dose of quazepam. However, formation of the metabolite 2-oxoquazepam was decreased, and there was a minor decrease in the sedative effects of quazepam at 4 hours, although these changes were considered to be of little clinical significance.25

(d) Paroxetine

No important changes in the pharmacokinetics of paroxetine were seen. A 12-hour study given paroxetine 30 mg daily were also given diazepam 5 mg three times a day. Adverse events were not increased by the combination.26 In another study it was found that paroxetine did not increase the impairment of a number of psychomotor tests caused by oxazepam.27 In vitro studies using human liver microsomal enzymes have shown that paroxetine is a relatively weak inhibitor of alprazolam metabolism mediated by the cytochrome P450 subfamily CYP3A.28,29 Furthermore, a randomised, placebo-controlled study in 22 healthy subjects reported no evidence for a pharmacokinetic or pharmacological interaction between paroxetine and alprazolam.30 An isolated report describes worsening anxiety, agitation, mild abdominal cramps and diaphoresis in a woman taking paroxetine, shortly after starting clonazepam (dosage stated as one tablet). This toxic response was suggested as being the serotonin syndrome, although in fact many of the usual signs were absent and moreover, clonazepam has actually been used to treat the myoclonus that occurs in the serotonin syndrome. She was effectively treated with lorazepam.31 Another report describes a patient who was admitted to hospital with symptoms of the serotonin syndrome within 6 days of starting daily treatment with paroxetine 20 mg, etizolam 1 mg and brotizolam 250 micrograms. Paroxetine was discontinued on day 6. The serotonin syndrome usually resolves within 24 hours of discontinuing the causative medication but symptoms in this patient continued for a total of 10 days.

In a double-blind study in healthy subjects it was found that paroxetine 20 mg for 9 days had no effect on the pharmacokinetics of zaleplon 20 mg, and psychomotor performance was unaffected by concurrent use.33 An isolated report describes a healthy 16-year-old girl with depression who took paroxetine 20 mg daily for 3 days, and then on the evening of the third night a single 10-mg dose of zolpidem. Within 1 hour she began to hallucinate, then became disoriented and was unable to recognise members of her family. She recovered spontaneously within 4 hours.34

(e) Sertraline

No clinically relevant effects were found in interaction studies in which sertraline was given with a single intravenous dose of diazepam.35,36 One in vitro study in human liver microsomes suggested that sertraline inhibits the metabolism of alprazolam, whereas another suggested no interaction occurred.37 In vivo studies largely demonstrate a lack of interaction. For example, a pharmacokinetic study in 10 healthy subjects found that sertraline 50 to 150 mg daily had no effect on the pharmacokinetics of alprazolam, although some small decreases in a driving simulation score were seen at the 100- and 150-mg doses of sertraline.38 Similarly, sertraline 50 mg daily had no effect on the pharmacokinetics of alprazolam 1 mg daily in 12 healthy subjects, after 2 weeks of concurrent use.39 A study in 13 subjects given daily doses of clonazepam 1 mg with sertraline 100 mg for 10 days found no evidence that the addition of sertraline to clonazepam made the subjects more sedated or less able to carry out simple psychometric tests.39 Sertraline appears to have no clinically significant effects on the pharmacokinetics of zolpidem, but isolated cases of visual hallucinations lasting up to 7 hours have been reported in patients on zolpidem who were taking sertraline.18

Mechanism

The evidence suggests that fluvoxamine inhibits the metabolism of those benzodiazepines that undergo oxidation (e.g. alprazolam, bromazepam, diazepam) thereby increasing and prolonging their effects, but not those that are metabolised by glucuronidation (e.g. lorazepam). Zaleplon is metabolised by aldehyde oxidase and therefore does not interact.

Importance and management

Evidence is limited, but what is known suggests that the dosages of alprazolam, bromazepam, diazepam and other similarly metabolised benzodiazepines such as nitrazepam should be reduced, probably by half, in the presence of fluvoxamine to avoid adverse effects (drowsiness, reduced psychomotor performance and memory). The US manufacturer recommends avoiding the use of fluvoxamine with diazepam as substantial diazepam accumulation could occur. They also note that as fluvoxamine has non-linear kinetics, the effects of higher doses of fluvoxamine such as 300 mg could be substantially greater, particularly with long-term diazepam use.3 The UK manufacturer recommends a 1-mg decrease of fluvoxamine and triazolam.32 Fluvoxamine is unlikely to affect lorazepam and other benzodiazepines metabolised by glucuronidation (e.g. lorazepam, oxazepam, temazepam).31 It seems unlikely that sertraline will affect any of the benzodiazepines and it may therefore be a useful alternative to fluvoxamine. Nevertheless, the manufacturers of sertraline say that it should not be given with benzodiazepines or other tranquillisers in patients who drive or operate machinery.33 The hallucinations seen with the SSRIs and zolpidem appear rare, and re-actions of this kind have been seen with zolpidem alone. The concurrent use of these drugs need not be avoided, but bear this possible interaction in mind if hallucinations occur.

Benzodiazepines + Olestra do not appear to interact with diazepam.

**Benzodiazepines + Olestra**

St John's wort decreases the plasma levels of quazepam, although this did not reduce its effects in one study. Alprazolam appears not to interact, although this needs confirmation. The bioavailability of midazolam was reduced by long-tem but not single doses of St John's wort.

### Clinical evidence, mechanism, importance and management

#### (a) Alprazolam

Alprazolam 1 or 2 mg was given to 7 healthy subjects on the third day of a 3-day treatment period with St John's wort (Soloray): hypericin content standardised at 0.3% 300 mg three times daily. The pharmacokinetics of alprazolam were unchanged by the St John's wort, but the authors note that 3 days may have been an insufficient time for St John's wort to fully induce cytochrome P450 iso-enzymes.

In another study, 16 healthy subjects were given St John's wort extract 120 mg (Hypericum perforatum; hypericin content standardised at 0.3%) 300 mg three times daily for 14 days with a single 15-mg dose of quazepam on day 14. Although St John's wort did not affect the pharmacodynamic effects of quazepam it did decrease the quazepam AUC by 26% and the maximum plasma levels by 29%. This was attributed to the effects of St John's wort on the cytochrome P450 isoenzyme by which quazepam is metabolised.

### Benzodiazepines + Sucre polyster

Sucre polyster (e.g. Olestra) do not appear to interact with diazepam.

#### Clinical evidence, mechanism, importance and management

A single 5-mg dose of diazepam was given to 8 healthy subjects with 18 g of sucre polyster (Olestra). Sucre polyster had no effect on the pharmacokinetics of diazepam.

### Benzodiazepines + Tadalafil

Tadalafil does not alter the pharmacokinetics of midazolam.

#### Clinical evidence, mechanism, importance and management

An open label study in 12 healthy subjects found that while taking tadalafil 10 mg daily for 14 consecutive days, the pharmacokinetics of a single 15-mg oral dose of midazolam were unchanged. Since midazolam is metabolised by the cytochrome P450 isoenzyme CYP3A4, it was concluded that the absence of any interaction shows that tadalafil does not inhibit or induce the activity of this isoenzyme.

Benzodiazepines + Terbinafine

**Clinical evidence, mechanism, importance and management**

Terbinafine 250 mg daily for 4 days had no effect on the pharmacokinetics of a single 7.5-mg dose of midazolam or a single 250-microgram dose of triazolam in 12 healthy subjects. The performance of a number of psychomotor tests was unaffected by concurrent use. No special precautions would seem to be necessary if terbinafine is given with either of these drugs.

2. Varhe A, Olkkola KT, Neuvonen PJ. Fluconazole, but not terbinafine, enhances the effects of terbinafine, and did not experience any sedative effects following the use of terbinafine. It has also been noted that two heavy smokers had a very high clearance of benzodiazepines, such as midazolam, and that the benzodiazepines and non-benzodiazepine hypnotics, such as zolpidem, can cause. However, one study suggested that caffeine intake, and others suggest age, may affect the response to benzodiazepines, so the picture is not altogether clear. Whether any of these interactions has much clinical relevance remains to be determined.

**Benzodiazepines and related drugs + Tobacco**

Smokers may possibly need larger doses of some benzodiazepines and zolpidem than non-smokers.

Some studies have suggested that smoking does not affect the pharmacokinetics of diazepam, chloridiazepoxide, clorazepate, lorazepam, midazolam, or triazolam, but others have found that the clearance of alprazolam, clorazepate, diazepam, lorazepam, oxazepam, and zolpidem is increased by smoking, but not all the changes were significant. The Boston Collaborative Drug Surveillance Program reported a decreased frequency of drowsiness in smokers who took diazepam or chloridiazepoxide, which confirmed the findings of a previous study. It has also been noted that two heavy smokers had a very high clearance of midazolam and did not experience any sedative effects following the use of zolpidem.

Benzodiazepines + Vinpocetine

Vinpocetine does not appear to interact adversely with oxazepam. Vinpocetine may improve short-term memory impairment induced by flunitrazepam.

**Clinical evidence, mechanism, importance and management**

No changes in the steady-state plasma levels of oxazepam 10 mg three times daily were seen in 16 healthy subjects who took vinpocetine 10 mg three times daily for 7 days. There would therefore seem to be no reason for taking special precautions if these two drugs are given together.

A study in 8 healthy subjects found that vinpocetine 40 mg three times daily for 2 days did not significantly improve flunitrazepam-induced impairment of memory, although the combination did appear to significantly improve patients ability to sleep.

Benzodiazepines and related drugs + Xanthines

Aminophylline, theophylline and caffeine appear to antagonise the effects of the benzodiazepines (mainly sedative effects, but possibly also anxiolytic effects), and aminophylline and theophylline appear to reduce the levels of alprazolam. The effects of zopiclone may be similarly antagonised.

**Clinical evidence**

A. Benzodiazepines

In a comparative study, two groups of patients were given alprazolam 500 micrograms twice daily for 7 days. One of the patient groups had 6 patients who had chronic obstructive pulmonary disease (COPD) and were taking theophylline, and the other group had 7 patients with chronic heart failure or atherosclerotic disease (one patient also with COPD) and were not taking theophylline. On day 7, those taking the theophylline were found to have lower trough serum alprazolam levels of 13.25 nanograms/mL, while in the other group the levels were 43.92 nanograms/mL.

A patient who was unrousable and unresponsive having been given diazepam 60 mg given over 10 minutes and nitrous oxide/oxygen anaesthesia, rapidly returned to consciousness when given aminophylline 56 mg intravenously. Other reports confirm this antagonism of diazepam, by lower doses of aminophylline (60 mg to 4.5 mg/kg intravenously). Caffeine, to a lesser extent theophylline and aminophylline, counteract the drowsiness and mental slowness induced by a single 10- to 20-mg dose of diazepam. Flunitrazepam, lorazepam, and midazolam also appear to be affected; however, there is some controversy about whether or not theophylline and aminophylline antagonise the effects of midazolam.

There is also some evidence to suggest that caffeine and clonazepam or triazolam have mutually opposing effects.

B. Non-benzodiazepine hypnotics

Zopiclone appears to counter the stimulant effects of caffeine more easily than caffeine counters the sedative effects of zopiclone. No pharmacokinetic interaction occurred between zolpidem and caffeine (given as one cup of coffee containing caffeine 300 mg), and the hypnotic effects of zolpidem were unchanged.
The plasma levels of buspirone are markedly increased by itraconazole. Ketoconazole is predicted to interact similarly.

Clinical evidence
In a placebo-controlled study, 8 healthy subjects were given buspirone 10 mg, before and after taking itraconazole 100 mg twice daily for 4 days. It was found that the buspirone maximum plasma levels and its AUC were increased 13-fold and 19-fold, respectively, by itraconazole. These increased buspirone levels caused a moderate impairment of psychomotor performance (digital symbol substitution, body sway, drowsiness, etc.) and an increase in adverse effects.

Mechanism
Itraconazole is a potent inhibitor of the cytochrome P450 isozyme CYP3A4, by which buspirone is metabolised. Itraconazole therefore increases buspirone levels and effects.

Importance and management
Direct information appears to be limited to this study but the interaction would seem to be established. The dosage of buspirone should be greatly reduced if itraconazole is given concurrently. The manufacturers recommend 2.5 mg daily or twice daily. Ketoconazole is predicted to interact similarly because it is also a potent CYP3A4 inhibitor.

Buspirone + Calcium-channel blockers
Diltiazem and verapamil can markedly raise the plasma levels of buspirone, increasing the likelihood of adverse effects.

Clinical evidence, mechanism, importance and management
In a randomised study in 9 healthy subjects, diltiazem 60 mg three times daily for 5 doses increased the AUC of a single 10-mg dose of buspirone by 5.5-fold and increased its maximum plasma levels by 4.1-fold.

When verapamil 80 mg three times daily was similarly given with buspirone, the buspirone AUC and maximum plasma levels were both increased by 3.4-fold.

The increased buspirone levels are thought to occur because both diltiazem and verapamil inhibit the cytochrome P450 3A4 isozyme, which is concerned with the metabolism of the buspirone. The practical consequences of this interaction are that the effects of buspirone are likely to be increased by diltiazem and verapamil. Concurrent use need not be avoided but may be advisable.

Buspirone + Grapefruit juice
Grapefruit juice can significantly increase plasma levels of buspirone.

Clinical evidence, mechanism, importance and management
In a randomised, crossover study, 10 healthy subjects were given either double-strength grapefruit juice 200 mL or water 200 mL three times daily for 2 days, with a single 10-mg dose of buspirone, given at the same time as the grapefruit juice or water, on the third day, with additional grapefruit juice or water 30 and 90 minutes later. Grapefruit juice increased the peak plasma level and AUC of buspirone by 4.3-fold and 9.2-fold, respectively. The time to peak buspirone level was increased from 0.75 to 3 hours. An increase in the effects of buspirone was seen only in the subjective overall drug effect. Grapefruit juice probably delayed gastric emptying and inhibited the metabolism of buspirone by the cytochrome P450 3A4 isozyme. The authors of this study recommended that the concurrent use of buspirone and grapefruit juice should be avoided. However the UK manufacturer recommends that a lower dose of buspirone 2.5 mg twice daily should be used with potent inhibitors of CYP3A4 such as grapefruit juice. The US manufacturer suggests that patients should avoid drinking large quantities of grapefruit juice.

Buspirone + Herbal medicines
Two patients taking buspirone developed marked CNS effects after starting to take herbal medicines including St John’s wort and ginkgo biloba.
Clinical evidence, mechanism, importance and management

A 27-year-old woman who had been taking buspirone 30 mg daily for over one month started to take St John’s wort (Hypericum 2000 Plus, Herb Valley, Australia) three tablets daily. After 2 months she complained of nervousness, aggression, hyperactivity, insomnia, confusion and disorientation, which was attributed to the serotonin syndrome. The St John’s wort was stopped, the buspirone was increased to 50 mg daily and her symptoms resolved over a week. A 42-year-old woman who was taking fluoxetine 20 mg twice daily and buspirone 15 mg twice daily started to develop symptoms of anxiety, with episodes of over-sleeping and memory deficits. It was discovered that she had been self-medicating with St John’s wort, ginkgo biloba and melatonin. She was asked to stop the non-prescribed medication and her symptoms resolved.2

The exact mechanism of these interactions are not clear, but it seems most likely they were due to the additive effects of the buspirone and the herbal medicines, either through their effects on elevating mood or through excess effects on serotonin. Fluoxetine may have had a part to play in one of the cases, see ‘SSRIs + St John’s wort (Hypericum perforatum)’, p.1224. The clinical significance of these cases is unclear, but they highlight the importance of considering adverse effects from herbal medicines when they are used with conventional medicines.

Buspirone + Macrolides

The plasma levels of buspirone are markedly increased by erythromycin.

Clinical evidence

In a placebo-controlled study buspirone 10 mg was given to 8 healthy subjects before and after they took erythromycin 500 mg three times daily for 4 days. It was found that the buspirone maximum plasma levels and its AUC were increased fivefold and sixfold, respectively, by the erythromycin. These increased buspirone levels caused a moderate impairment of psychomotor performance (digital symbol substitution, body sway, drowsiness, etc.) and an increase in adverse effects.1

Mechanism

Erythromycin is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which buspirone is metabolised. Erythromycin therefore increases buspirone levels and hence its effects.

Importance and management

Direct information appears to be limited to this study but the interactions would seem to be established. The dosage of buspirone should be reduced if erythromycin is given concurrently. The manufacturers suggest using buspirone 2.5 mg twice daily,2,3 adjusted according to response.3 Other macrolides (such as clarithromycin) are also inhibitors of CYP3A4 and may therefore interact similarly.4

Buspirone + Miscellaneous

Buspirone does not appear to interact with amitriptyline, cimetidine or terfenadine. An isolated report describes mania when an alcoholic patient taking buspirone was given disulfiram. Nefazodone greatly increases buspirone levels.

Clinical evidence, mechanism, importance and management

(a) Amitriptyline

Buspirone 15 mg every 8 hours given with amitriptyline 25 mg every 8 hours for 10 days had no significant effect on the steady-state serum levels of amitriptyline or its metabolite, nortriptyline, in healthy subjects. No evidence of a pharmacodynamic interaction was seen.1 There would seem to be no reason for avoiding concurrent use.

(b) Cimetidine

In 10 healthy subjects, cimetidine 1 g daily for 7 days had no effect on the plasma levels of buspirone 15 mg three times daily. Some small pharmacokinetic changes were seen, but the performance of three psychomotor function tests remained unaltered.5 There would seem to be no reason for avoiding concurrent use.

(c) Disulfiram

An isolated report describes mania in an alcoholic patient taking buspirone 20 mg daily, possibly due to an interaction with disulfiram 400 mg daily,3 but buspirone on its own has also apparently caused mania.4,5 The reasons for this reaction are not understood, and the general significance of this isolated case is unknown.

(d) Nefazodone

Nefazodone 250 mg twice daily caused a 20-fold increase in the maximum plasma levels of buspirone 2.5 mg or 5 mg twice daily and a 50-fold increase in its AUC. Buspirone 5 mg twice daily raised the AUC of nefazodone by 23%, which is unlikely to be clinically significant. The manufacturer recommended that buspirone 2.5 mg daily should be used if nefazodone is given.6

(e) Terfenadine

A single 10-mg dose of buspirone was given to 10 healthy subjects after they had taken terfenadine 120 mg daily for 3 days. There were no significant effects on the pharmacokinetics or pharmacodynamics of buspirone.7

Buspirone + Rifampin (Rifampin)

Rifampin can cause a marked reduction in the plasma levels and effects of buspirone.

Clinical evidence

In a randomised study, buspirone 30 mg daily was given to 10 healthy subjects, before and after they took rifampin 600 mg daily for 5 days. It was found that rifampin reduced the total AUC of buspirone by almost 90% and reduced its peak plasma levels by 87%. The pharmacodynamic effects of buspirone were reduced accordingly (as measured by digit symbol substitution, critical flicker fusion, body sway and visual analogue scales for subjective drowsiness).1

Mechanism

Not fully established, but it is almost certain that rifampin induces the cytochrome P450 isoenzyme CYP3A4 in the gut and liver, which metabolises buspirone. Therefore the metabolism and clearance of buspirone are increased.

Importance and management

Direct information appears to be limited to this study but it is consistent with the way rifampin interacts with many other drugs. This interaction would appear to be clinically important. If both drugs are used be alert for the need to use an increased buspirone dosage.

Buspirone + SSRIs

An isolated report describes the development of the serotonin syndrome when buspirone was given with citalopram. The combination of buspirone and fluoxetine can be effective, but seizures and worsening of symptoms have been reported. Fluvoxamine may possibly reduce the effects of buspirone.

Clinical evidence, mechanism, importance and management

(a) Citalopram

An isolated report describes the development of the serotonin syndrome and hyponatraemia, thought to be caused by an interaction between citalopram and buspirone.1 The general importance of this interaction is unknown.

(b) Fluoxetine

A 35-year-old man with a long history of depression, anxiety and panic started taking buspirone 60 mg daily. His anxiety abated, but, because of worsening depression he was also given trazodone 200 mg daily for 3 weeks. This had little effect, so fluoxetine 20 mg daily was added. Within 48 hours his usual symptoms of anxiety had returned and persisted even when the dose of buspirone was raised to 80 mg daily. Stopping the buspirone did not increase his anxiety.2 Another patient with obsessive-compulsive disorder taking fluoxetine experienced a marked worsening of his symptoms when buspirone 5 mg twice daily was added.3 A patient taking fluoxetine 80 mg daily had a grand mal seizure 3 weeks after buspirone 30 mg daily was added. The drugs were stopped and an EEG showed no signs of epilepsy, so the seizure was attributed to a drug interaction. Other reports describe the effective concurrent use of fluoxetine and buspirone in patients with treatment-resistant depression2 and with obsessive-compulsive disorders.2,7

The reasons for these adverse reactions are not understood, but there would seem to be little reason for avoiding concurrent use, however bear these case reports of interactions in mind when both drugs are used.

(c) Fluvoxamine

A double-blind study in 9 healthy subjects found that after taking fluvoxamine (mean dose 127 mg daily, range 100 to 150 mg daily) for 3 weeks, the plasma levels of a single 30-mg dose of buspirone were increased almost threefold. Even so, the psychological responses to the buspirone were reduced.8 However, a study in 10 healthy subjects given a single 10-mg dose of buspirone after taking fluvoxamine 100 mg daily for 5 days, found that although the pharmacokinetics of buspirone were altered (AUC increased 2.4-fold) the pharmacodynamic tests remained unchanged.9

It has been suggested that fluvoxamine inhibits the liver enzymes concerned with the metabolism of buspirone. Concurrent use need not be avoided but it would be wise to remain alert to the possibility of reduced buspirone effects until more is known.

Chlorpromazine + Cimetidine

One study found that chlorpromazine serum levels are reduced by cimetidine, while another study suggested that cimetidine can increase chlorpromazine levels.

Clinical evidence, mechanism, importance and management

A study in 8 patients taking chlorpromazine 75 to 450 mg daily found that cimetidine 1 g daily in divided doses for one week decreased their steady-state chlorpromazine levels by one-third, from 37 to 24 micrograms/mL. A two-thirds reduction was noted in one patient.1 The reasons for this effect are not understood but a decrease in absorption from the gut has been suggested.1

In contrast, another report describes 2 schizophrenic patients taking chlorpromazine 100 mg four times daily who became excessively sedated when they were given cimetidine 400 mg twice daily. The sedation disappeared when the chlorpromazine dosage was halved. When the cimetidine was later withdrawn it was found necessary to give the original chlorpromazine dosage.2 Chlorpromazine serum levels were not measured. There is no simple explanation for these discordant reports, but they emphasise the need to monitor the concurrent use of chlorpromazine and cimetidine. More study is needed. There seems to be no information about other phenothiazines.

Chlorpromazine + Tetrabenazine

An isolated report describes severe Parkinson-like symptoms when a woman with Huntington’s chorea was given tetrabenazine and chlorpromazine.

Clinical evidence, mechanism, importance and management

A woman with Huntington’s chorea, successfully treated with tetrabenazine 100 mg daily for 9 years, became motionless, rigid, mute and only able to respond by blinking her eyes within one day of being given two intramuscular injections of chlorpromazine 25 mg. This was diagnosed as severe drug-induced parkinsonism, which rapidly responded to the withdrawal of both drugs and treatment with benzatropine mesilate given intramuscularly and orally. She had previously tolerated chlorpromazine well.1 The reason for this reaction is not understood, and, as tetrabenazine is used to treat movement disorders its clinical significance is unclear.

**Clomethiazole + Diazoxide**

Clomethiazole and diazoxide, given to pregnant women in labour, can cause marked respiratory depression in their infants for up to 36 hours after birth.

**Clinical evidence**

An infusion of 0.8% clomethiazole, in a dose of 4 to 24 g, was given during labour to 21 pregnant women of 28 to 40 weeks gestation for eclampsia or pre-eclamptic toxemia. Diazoxide 75 to 150 mg was also given intravenously to 14 of the women for hypertension. All 21 babies were born alive but 13 suffered hypotonia, hypventilation or apnoea for 24 to 36 hours after birth. All of the neonates affected, apart from one, came from the group of mothers who had been given diazoxide. Three of them died of respiratory distress syndrome; one was only 28 weeks’ gestation.

**Mechanism**

Clomethiazole has some respiratory depressant effects, and is contraindicated in patients with respiratory deficiency, but it is not clear why, having passed across the placenta into the foetus, its effects should apparently be so markedly increased by diazoxide.

**Importance and management**

Although use of this drug combination in eclampsia is historical, the interaction is included on account of its severity. The author of the report says that the respiratory depression was managed successfully with intermittent positive pressure ventilation, provided that respiratory distress syndrome was not also present.

1. Johnson RA. Adverse neonatal reaction to maternal administration of intravenous chlormethiazole and diazoxide. BMJ (1976) 1, 943.

---

**Clomethiazole + Furosemide**

Ten female patients aged 66 to 90 years were given clomethiazole edisilate syrup 500 mg each evening and 250 mg each morning as a sedative, with furosemide 20 to 80 mg. No significant changes in the serum levels or effects of clomethiazole or furosemide were detected, and no other significant adverse reactions were seen.

---

**Clozapine + Antiepileptics**

Clozapine serum levels are approximately halved by carbamazepine and possibly by phenobarbital and phenytoin. An isolated case of fatal pancytopenia has been seen in one patient taking clozapine and carbamazepine, and neuroleptic malignant syndrome occurred in another. Sodium valproate can apparently lower serum clozapine levels, and an isolated case report suggests that lamotrigine may raise them.

**Clinical evidence**

(a) Carbamazepine

A study by a therapeutic drug monitoring service for clozapine found that the concentration/dose ratio of 17 patients taking carbamazepine was 50% of that found in 124 other patients taking clozapine alone. A 47% decrease in the serum levels of clozapine were seen in another 12 patients when they were given carbamazepine. **Oxcarbazepine** did not interact.

The plasma clozapine levels of 2 patients who had been taking clozapine 600 or 800 mg daily and carbamazepine 600 or 800 mg daily for several months were increased from 1.4 to 2.4 micromol/L and from 1.5 to 3 micromol/L, respectively, within 2 weeks of stopping the carbamazepine. A man with mania taking carbamazepine 1.2 g daily and lithium developed muscle rigidity, mild hyperpyrexia, tachycardia, sweating and somnolence (diagnosed as neuroleptic malignant syndrome) 3 days after his lithium was stopped and clozapine 25 mg daily started. The symptoms immediately improved when the clozapine was stopped.

A patient taking carbamazepine, lithium, benzatropine and clonazepam developed fatal pancytopenia about 10 weeks after starting clozapine 400 mg daily. A retrospective study of the records of other patients given clonazepam and carbamazepine found a significant increase in granulopenia. A previous report had not found this, due to a statistical error.

A case report describes 2 schizophrenic patients taking clozapine whose treatment was changed from carbamazepine to oxcarbazepine. After 3 weeks their plasma clozapine levels had risen from 1.4 to 1.7 micromol/L and from 1.5 to 2.5 micromol/L, respectively.

(b) Lamotrigine

A 35-year-old man, who had been taking clozapine for 3 years, became dizzy and sedated about one month after starting to take lamotrigine. His plasma clozapine levels were found to have increased to 1020 micrograms/L. When the lamotrigine was stopped his levels fell to 450 micrograms/L.

A study in 11 patients taking clozapine in doses of 200 mg to 500 mg daily, and who were also given lamotrigine in increasing doses over 8 weeks to 200 mg daily found no significant changes in the pharmacokinetics of clozapine.

(c) Phenobarbital

Mean clozapine plasma levels in 7 patients taking clozapine and phenobarbital were 35% lower than those of 15 patients taking clozapine alone.

(d) Phenytoin

Two patients developed reduced clozapine levels (falls of 65 to 85%) and worsening psychoses when phenytoin was added to their treatment. Another patient developed neutropenia, which was attributed to concurrent use of phenytoin and clozapine. When the phenytoin was stopped clozapine levels rose from 114 to 137 nanograms/mL, suggesting a pharmacokinetic interaction, rather than just additive adverse effects.

(e) Valproate

A controlled study in 11 patients found that when sodium valproate (at an average dose of 1.06 g daily) was added to clozapine, the steady-state serum clozapine levels were increased by 39% and the levels of the demethylated metabolite increased by 23%. However, correction of these levels for dose and weight reduced the total clozapine metabolite values to only 6% above those of the controls. No increase in clozapine adverse effects was seen.

Another study found that sodium valproate and clozapine had no significant effect on the pharmacokinetics of each other. In contrast, a study in 4 schizophrenics treated with clozapine 550 to 650 mg daily found that when valproate sodium 750 mg to 1 g daily was added, the serum clozapine levels began to fall, and by 3 weeks had dropped by an average of 41%. No deterioration in clinical condition occurred. A 15% decrease in clozapine levels was seen in another study in 7 patients given clozapine and sodium valproate. Clozapine levels were doubled in a patient after valproic acid treatment was stopped, suggesting that the valproate had increased the metabolism of clozapine. An alternative explanation suggested was that the valproate may have reduced the absorption of clozapine.

An isolated report describes sedation, confusion, slurred speech and impaired functioning on two occasions when semisodium valproate was added to clozapine treatment in a 37-year-old man.

**Mechanism**

Not established, but it seems likely that carbamazepine, phenobarbital and phenytoin (recognised potent enzyme inducers) increase the metabolism of clozapine by the liver, thereby reducing its effects. It has been suggested that this is because these drugs induce the activity of the cytochrome P450 isoenzyme CYP1A2. Carbamazepine and phenobarbital may also have an effect via CYP3A4. The case of pancytopenia may possibly have been due to the additive bone marrow depressant effects of the clozapine and carbamazepine.

**Importance and management**

The interaction between clozapine and carbamazepine is much more firmly established than that between clozapine and phenobarbital or phenytoin, but they appear to be clinically important. Monitor symptoms and be alert for the need to increase the clozapine dosage if any of these drugs are giv-
en concurrently, and reduce the dosage if they are withdrawn. However, because of the substantial risk of bone marrow suppression the manufacturers of clozapine advise that carbamazepine should not be given concurrently.2,21

As yet there only appears to be one case report with lamotrigine, so the situation is unclear. There appears to be no pharmacokinetic mechanism for this interaction, so it awa des as a confirmed interaction.2,21

The situation with sodium valproate is not entirely clear. There are cases of successful concurrent use,1,9 but in the light of the reports cited here it would clearly be prudent to monitor concurrent use closely. A subgroup analysis of 20 patients who received clozapine and carbamazepine, clonazepam, phenobarbital, phenytoin, or valproate suggested that this group of patients showed less clinical improvement than patients who were not also taking an antiepileptic drug. However, the indication for the antiepileptic drug was not always clear and combined treatment may have been used in patients who were more severely ill, or less responsive to clozapine alone.22

### Clozapine + Antimuscarinics

**The antimuscarinic effects of clozapine are additive with those of other antimuscarinic drugs, which has led to urinary retention and delirium.**

**Clinical evidence, mechanism, importance and management**

The manufacturers of clozapine warn that the antimuscarinic effects of some drugs may be additive with those of clozapine, which may lead to adverse effects such as dry mouth and constipation.2,3 Confirmation of the clinical relevance of this proposed interaction was seen in a patient who developed severe urinary retention while taking clozapine and meclozine.3 A man with a schizoaffective disorder taking nortriptyline, perphenazine and propranolol was also given clozapine 150 mg daily. Some improvement was seen after 8 days, and over the next week the propranolol was gradually discontinued while the clozapine dosage was raised to 225 mg daily. The patient then began to complain of extreme fatigue and slurred speech, and day 17 was delirious and confused. His serum nortriptyline levels were found to have doubled (from 93 to 185 nanograms/mL) from the time the clozapine was started. He recovered within 5 days of stopping all of the drugs, after which the clozapine was restarted.4 The authors of the report interpreted the symptoms as an antimuscarinic delirium arising from the additive antimuscarinic effects of the clozapine, nortriptyline and perphenazine, made worse by the increased levels of nortriptyline.5 Just why the nortriptyline levels rose is not clear, but one possible explanation is that the nortriptyline and clozapine compete for metabolism by the same liver enzymes, resulting in a reduction in the clearance of the nortriptyline.6

### Clozapine + Azoles

*Itraconazole and ketoconazole do not interact with clozapine.*

**Clinical evidence, mechanism, importance and management**

A double-blind study in 7 schizophrenic patients taking clozapine found that when *itraconazole* 200 mg daily was given for a week, no changes in the levels of clozapine or its desmethylclozapine metabolite were seen.1 A single 50-mg dose of clozapine was given to 5 schizophrenic patients

---

6. Itraconazole and ketoconazole do not interact with clozapine.
before and after a 7-day course of ketoconazole 400 mg daily. The ketoconazole had no significant effect on the pharmacokinetics of the clozapine.²

The conclusion is that the cytochrome P450 isoenzyme CYP3A4 is of only minor importance in clozapine metabolism, and that because no interaction takes place between clozapine and iraconazole or ketoconazole, both it and other inhibitors of CYP3A4 can be used with clozapine.¹² However, note that raised clozapine levels have been attributed to treatment with the CYP3A4 inhibitor, erythromycin, see ‘Clozapine + Erythromycin’, p.747.

### Clozapine + Benzodiazepines

A handful of reports describe severe hypotension, respiratory depression, unconsciousness and potentially fatal respiratory arrest in patients taking benzodiazepines and clozapine. One case of fatal respiratory arrest has been reported with lorazepam and clozapine. Dizziness and sedation are also increased.

### Clinical evidence

A schizophrenic patient failed to respond to fluphenazine, diazepam, clozapam and lormetazepam having taken the combination for several weeks. The fluphenazine was stopped and clozapine started at a dose of 25 mg at noon and 100 mg at night. Toxic delirium and severe hypersalivation developed 3 hours later. The patient collapsed (systolic blood pressure 50 mmHg, diastolic blood pressure unrecordable) and stopped breathing. Resuscitation was started, and the patient remained unconscious for 30 minutes. After a few drug-free days clozapine 12.5 mg was successfully re-introduced, and very slowly titrated upwards; a low benzo diazepine level was maintained throughout. After a further 3 days clozapine 25 mg at noon and 100 mg at night. Toxic delirium and severe hypersalivation, unconsciousness and potentially fatal respiratory arrest have been seen in patients taking clozapine and chloroquine, co-trimoxazole, methazolamide, nitrofurantoin, olanzapine, or thiamazole.

### Mechanism

Caffeine increases serum clozapine levels, which may increase the incidence of its adverse effects.

### Clinical evidence

In a crossover study, 6 coffee-drinking patients taking clozapine were given decaffeinated or caffeine-containing instant coffee for 7 days. The plasma levels of clozapine were 26% higher while the patients were taking caffeine.³ A study in 12 healthy subjects found that caffeine 400 mg to 1 g daily, raised the AUC and decreased the clearance of a single 12.5-mg dose of clozapine by 19% and 14%, respectively. A previous study in 7 patients had found that clozapine levels decreased by 47% when the subjects avoided caffeine for 5 days, and increased again when caffeine consumption was resumed.³

A 66-year-old woman taking clozapine 300 mg daily developed supraventricular tachycardia (180 bpm) when she was given 500 mg of intravenous caffeine sodium benzoate to increase seizure length during an ECT session. Verapamil was needed to revert the arrhythmia. Before taking clozapine she had received caffeine sodium benzoate in doses of up to 1 g during ECT sessions without problems.² Another patient taking clozapine for schizophrenia had an exacerbation of his psychotic symptoms, which was attributed to caffeine-containing coffee (5 to 10 cups daily). The problem resolved when the patient stopped drinking coffee. He had previously not had any problems with caffeine while taking haloperidol 30 mg and procyclidine 30 mg daily.³ A 31-year-old woman taking clozapine 550 mg daily developed increased daytime sleepiness, sialorrhoea and withdrawn behaviour after taking about 1.2 g of caffeine daily (as drinks and tablets). Her plasma clozapine levels fell from 1500 to 630 nanograms/mL when her caffeine intake was stopped.⁶

### Importance and management

This would appear to be an established and clinically important interaction, but unlikely to be a problem if clozapine serum levels are established and well monitored, and caffeine intake remains fairly stable and moderate. Possible exceptions are if large doses of caffeine are given during ECT treatment or if for some other reason the caffeine intake suddenly increases or decreases markedly.

### Clozapine + Drugs that suppress bone marrow

The manufacturers caution the use of clozapine with other drugs that can cause bone marrow suppression. Low white cells counts have been seen in patients taking clozapine and chloroquine, co-trimoxazole, methazolamide, nitrofurantoin, olanzapine, or thiamazole.

### Clinical evidence, mechanism, importance and management

Clozapine can cause blood dyscrasias and potentially fatal agranulocytosis, therefore the manufacturers say that it should not be given with other drugs that have a well-known potential to cause agranulocytosis.¹² The
UK manufacturer lists erbamazine (see also ‘Clozapine + Antiepileptics’, p.744), chloramphenicol, cytotoxics, penicillamine, pyrazolone analogues (e.g. phenylbutazone), sulphonamides (e.g. co-trimoxazole) and because they cannot be stopped if an adverse reaction occurs, they advise against the use of depot antipsychotics.1 There are several cases that confirm the clinical significance of these predicted interactions.2

A woman was taking thiamazole for Graves’ disease, at times with various different antipsychotics including haloperidol, flupentixol, zuclopenthixol and perphenazine for schizophrenia. Because of the severe extrapyramidal reactions and failure to control the schizophrenia, clozapine, increased over 5 days to 250 mg daily, was started instead. Within 5 days her white cell count had fallen to 2200/mm³, which rose to 4000/mm³, one month after both drugs were stopped. Later, after the thiamazole was stopped she was given the same dose of clozapine without these adverse effects.3

A patient who had been taking clozapine 500 mg daily for 8 months developed granulocytopenia within 8 days of starting nitrofurantoin 200 mg daily.4 An 86-year old woman taking clozapine developed neutropenia 2 weeks after methazolamide for glaucoma was added. Both drugs were stopped and her white cell count recovered. She later restarted clozapine without problem and so the toxic effect was attributed to the combined use of two drugs.5

Neutropenia developed 4 days after co-trimoxazole was started in a 47-year-old woman who had been uneventfully taking clozapine for 5 years. Co-trimoxazole was stopped and the white cell counts returned to normal over the next 2 weeks.6

Three patients have been described who showed a delay in recovery from clozapine-induced agranulocytosis when given olanzapine, and it has been suggested that olanzapine should therefore be avoided until the patient’s haematological status has normalised.7

However, in contrast, a patient taking clozapine 25 mg daily had no significant changes in his white cell count after taking chloroquine for malaria prophylaxis, over the course of one month.8

ed drowsiness, weakness and dizziness. The patient was also taking a combi-
combined oral contraceptive containing northisterone 500 micrograms and
ethinylestradiol 35 micrograms. Clozapine plasma levels ranged from
736 to 792 nanograms/mL (therapeutic range 300 to 700 nanograms/mL). After 2 months she stopped taking her combined oral contraceptive and
noted that the adverse effects of clozapine resolved, and clozapine levels
were found to be 378 to 401 nanograms/mL. The patient did not stop
smoking during this time. It was suggested that the oral contraceptive in-
hhibited the cytochrome P450 isoenzymes CYP1A2, CYP2C19 and
CYP3A4 resulting in raised clozapine plasma levels. The authors note that
slower titration and smaller doses of clozapine may be needed in patients
taking hormonal contraceptives. Further study is needed as this appears
to be the only published case report of this interaction.

Clozapine + Lithium

A few patients given lithium carbonate and clozapine have expe-
perienced adverse reactions including myoclonus, neuroleptic ma-
lignant syndrome, seizures, delirium and psychoses.

Clinical evidence

A man with poorly controlled schizophrenia, taking clozapine 750 mg dai-
aily for 6 weeks, was given lithium, initially 900 mg and then subse-
sequently 1.2 g daily. His serum lithium level was 0.86 mmol/L. Within one week he be-
egan to experience paroxysmal jerky movements of his upper and lower extremities lasting about 30 minutes. This myoclonus resolved when both drugs were stopped, and did not recur when clozapine was re-
started alone. Another patient developed neuroleptic malignant syndrome (stiffness, rigidity, tachycardia, diaphoresis, hypertension) 3 to 4 weeks after clozapine was added to his lithium treatment. The symptoms disap-
peared within 2 to 3 days of stopping the clozapine. An elderly man also developed neuroleptic malignant syndrome 3 days after starting to take
clozapine 25 mg daily. He was also taking carbamazepine, and had stopped taking lithium 3 days earlier.

Four out of 10 patients taking lithium carbonate (mean dose of 1.4 g dai-
ily) and clozapine (mean maximum dose 900 mg daily) developed revers-
ible neurological symptoms including involuntary jerking of the limbs and tongue, facial spasm, tremor, confusion, generalised weakness, stumbling gait, leaning and falling to the right. One of them also became delirious. Serum lithium levels remained unchanged, and the problems resolved when the lithium was stopped. Three of the four had a recurrence of the symptoms when rechallenged with the drug combination. A man taking clozapine and lithium carbonate developed psychosis with delusions and visual hallucinations over a 5-day period when clozapine was tapered off and stopped. This was accompanied by a doubling in his serum lithium levels. He recovered completely when the drugs were stopped. Two pa-
tients taking clozapine developed seizures: one developed a tonic clonic seizure within 4 days of adding lithium carbonate 900 mg to clozapine 600 mg daily, and the other a grand mal seizure within 6 days of adding lithium carbonate 900 mg to clozapine 900 mg daily.

A review of the medical records of 44 patients taking clozapine and lith-
ium identified 28 patients who had experienced an adverse effect, three of
which were possibly associated with the drug combination. There were
two reports of myoclonus and one of a grand mal seizure.

Lithium is thought to have masked a clozapine-induced agranulocytosis in a 59-year-old woman who developed leucopenia and subsequently agranulocytosis after 40 days of treatment with lithium and clozapine. It has been suggested that lithium may help to protect patients from adverse effects of clozapine, in particular agranulocytosis, although a clozapine re-
challenge in a patient who has previously experienced a blood dyscrasia with clozapine should only be undertaken with great caution.

Mechanism

Not understood.

Importance and management

Some patients develop a toxic reaction when given both drugs, and others
do not, for reasons that are not understood. Concurrent use should there-
fore be extremely well monitored including close monitoring of full blood
counts as well as lithium levels. One group of workers suggest that lithium
levels of no more than 0.5 mmol/L may give therapeutic benefits while
minimising adverse effects. 4

Clozapine + Miscellaneous

There are isolated cases of apparent interactions between cloza-
pine, and ampicillin, buspirone, caffeine, haloperidol, loperamide,=
modafinil, nefazodone, nicotine acid, tryptophan, or vitamin C. Gra-
pfruit juice, influenza vaccine mirtazapine, reboxetine, or venlafaxine do not appear to interact. Cocaine levels may increase when taken with clozapine.

Clinical evidence, mechanism, importance and management

(a) Ampicillin

An isolated report describes a 17-year-old taking clozapine (12.5 mg in-
creased to 50 mg three times daily) who was given ampicillin 500 mg four
times daily, starting on day 15 of clozapine treatment. On the next day the
patient became easily distracted, very drowsy and salivated excessively. These adverse reactions stopped when the ampicillin was replaced by dox-
cycline.

(b) Buspirone

A man who had been taking clozapine for a year developed acute and po-
tentially lethal gastrointestinal bleeding and marked hyperglycaemia about 5 weeks after starting buspirone, and one week after the buspirone
dosage was raised to 20 mg daily. No gut pathology (e.g. ulceration) was
detected and there were no problems when he was subsequently given
clozapine alone, so the reaction was attributed to the drug combination.

(c) Cocaine

A single-dose study in 8 cocaine addicts found that there was a dose-de-
pendent rise in cocaine levels of 6%, 49% and 67% after clozapine was
given in doses of 12.5, 25 or 50 mg, respectively, with intranasal cocaine
and stopped taking lithium 3 days earlier.

8. Valevski A, Modai I, Lahav M, Weizman A. Clozapine-lithium combined treatment and agran-

(e) Haloperidol

A 68-year-old man taking clozapine 600 mg daily and venlafaxine, lo-
razepam, aspirin, vitamin E and multivitamins, was given haloperidol 4 mg daily to control persistent paranoid delusions and hallucinations. Af-
er 27 days he was found collapsed and was lethargic, tachycardic, fever-
ish and delirious. Neuroleptic malignant syndrome was suspected so the
antipsychotics were withheld, and the patient recovered over the following
7 days. Clozapine was later re-started without a recurrence of symptoms. A case of elevated haloperidol levels has been reported in a 40-year-old
man who was given haloperidol intramuscular injections 50 mg ever-
4 weeks. He was also given clozapine in increasing doses from 50 to
250 mg daily. Over this time his haloperidol levels increased from
12 nanogram/mL to 166 nanogram/mL, although it is not clear whether he
had attained steady-state levels when the first measurement was reported.
(f) **Influenza vaccine**

In an open-label study in 14 patients the metabolism of clozapine was not altered following a single intramuscular dose of influenza vaccine (Influvac 2001 to 2002 formula, Solvay).8

(g) **Loperamide**

A patient taking clozapine 500 mg daily died after taking loperamide 6 mg daily during an episode of food poisoning. The authors of the report attribute the death to toxic megacolon brought on by the additive effects of clozapine and loperamide on gut transit.9 Toxic megacolon can sometimes occur with loperamide alone, especially in the presence of an infection. Also, the manufacturers of clozapine say that care is necessary in patients given clozapine with drugs known to cause constipation (see also ‘Clozapine + Antimuscarinics’, p.745) because on rare occasions clozapine alone has been shown to cause significant impairment of intestinal function (such as paralytic ileus).10,11

(h) **Mirtazapine**

A study in 9 patients taking clozapine in doses ranging from 100 to 650 mg daily found no significant change in the pharmacokinetics of clozapine after the addition of mirtazapine 30 mg daily.12

(i) **Modafinil**

A 42-year-old man taking clozapine 450 mg daily was given modafinil, titrated up to 300 mg daily, to combat sedation. After about one month of concurrent use he developed dizziness and an unsteady gait, and his clozapine level was found to be 1400 nanograms/mL. His clozapine level had been 761 nanograms/mL while taking clozapine 400 mg daily, and beat an interaction with modafinil was suspected.13

(j) **Nefazodone**

A 40-year-old man who had been successfully treated with risperidone and clozapine 425 to 475 mg daily started taking nefazodone 200 mg daily, increasing to 300 mg daily, for the treatment of persistent depression. After one week on the higher dose he became dizzy and hypotensive and it was noted that his clozapine level had risen from 133 to 233 nanograms/mL. This was thought to be due to an inhibitory effect of nefazodone on the cytochrome P450 isoenzyme CYP3A4,14 although note that other potent inhibitors of CYP3A4 (such as ‘erythromycin’, (p.747) or the ‘azoles’, (p.745)) rarely appear to increase clozapine levels. In contrast, a small study in 6 patients taking clozapine and who were then additionally prescribed nefazodone found no significant effects on the pharmacokinetics of clozapine.15

A possible case of neutropenia caused by the addition of nefazodone to treatment with sodium valproate and clozapine has been reported. The patient had been receiving treatment with sodium valproate and clozapine for many months when nefazodone was started in increasing doses up to 200 mg twice daily. Within one week her neutrophil count had dropped to 1.8x10^9/L, and remained low until the nefazodone was discontinued. The patient’s serum level of clozapine was reported to remain stable during this time and the patient had not had any previous episodes of leucopenia during treatment with clozapine.16

(k) **Nicotinic acid/Trifluperazine/Vitamin C**

A man with schizophrenia taking trifluperazine, lorazepam, vitamin C, benzatropine and nicotinic acid, developed a severe urticarial rash covering most of his body. In whom the proton pump inhibitor was subsequently changed to pantoprazole. This resulted in an increase in the mean clozapine serum level from 445 to 579 nanograms/mL in 3 non-smokers, but in the 10 smokers there was a slight reduction in levels, from 364 to 323 nanograms/mL. Both omeprazole and smoking are known to induce the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in the metabolism of clozapine. The authors suggest that when omeprazole was stopped in the non-smokers there was no CYP1A2 induction, hence clozapine levels rose, whereas CYP1A2 induction continued in the smokers, so their levels were only slightly affected.1

A case report describes two patients (both smokers) whose clozapine levels were reduced, from 762 to 443 nanograms/mL and from 369 to 204 nanograms/mL, respectively, after omeprazole was started. However, no changes in clinical condition were noted.2

Other proton pump inhibitors do not appear to have been studied.

---

**Clozapine + Proton pump inhibitors**

Omeprazole appears to reduce the serum levels of clozapine.

Clinical evidence, mechanism, importance and management

A retrospective study identified 13 patients taking clozapine and omeprazole in patients with chronic schizophrenia.1,2 This resulted in an increase in the mean clozapine serum level from 445 to 579 nanograms/mL in 3 non-smokers, but in the 10 smokers there was a slight reduction in levels, from 364 to 323 nanograms/mL.

---

An isolated report describes the development of agitation in an elderly man taking clozapine, which was tentatively attributed to an interaction with ciprofloxacin. A study supports this observation.
Clinical evidence, mechanism, importance and management

An elderly man with multi-infarct dementia and behavioural disturbances, taking clozapine, glibenclamide (glyburide), trazodone and melatonin, was hospitalised for agitation on the last day of a 10-day course of ciprofloxacin 500 mg twice daily. When the ciprofloxacin course was completed, his plasma clozapine serum levels fell from 90 nanograms/mL to undetectable levels (lower limit of detection being 50 nanograms/mL).\(^1\)

Ciprofloxacin 250 mg twice daily for 7 days was given to 7 schizophrenic patients taking clozapine. The mean serum clozapine and N-desmethylclozapine levels were increased by 29% and 31%, respectively, but no additional adverse effects were reported. Interindividual variation in serum levels was high, so it seems likely that some patients may demonstrate a clinically significant interaction.\(^2\) This interaction probably occurs because ciprofloxacin inhibits the cytochrome P450 isoenzyme CYP1A2, the major isoenzyme involved in the metabolism of clozapine, resulting in elevated clozapine levels. Monitor the outcome carefully if ciprofloxacin is added to clozapine treatment. There seem to be no other reports of an interaction between clozapine and other quinolones, but as they all inhibit CYP1A2 to a varying extent (see ‘Theophylline + Quinolones’, p.1192) some interaction seems possible.

### Clozapine + Rifampicin (Rifampin)

The serum clozapine levels of a patient were greatly reduced when rifampicin was also given.

Clinical evidence, mechanism, importance and management

A schizophrenic patient taking clozapine developed tuberculosis and was given rifampicin, isoniazid and pyrazinamide. Within 2 to 3 weeks his trough serum clozapine levels had fallen dramatically from about 250 nanograms/mL to 40 nanograms/mL, but rose again rapidly when the rifampicin was replaced by ciprofloxacin. It was suggested that rifampicin (a potent non-specific enzyme inducer) increased the metabolism of clozapine, probably by the cytochrome P450 isoenzymes CYP1A2 and CYP3A, thereby reducing its levels.\(^1\)

This appears to be an isolated case but it is consistent with the way rifampicin interacts with other drugs. Clozapine serum levels should be well monitored if rifampicin is added, being alert for the need to increase its dosage. An alternative (as in this case) is to use another antibiotic. However, note that there are reports of an interaction between ‘clozapine and ciprofloxacin’, (p.749).

---

### Clozapine + Risperidone

The concurrent use of clozapine and risperidone can be effective and well tolerated but two isolated reports describe a rise in serum clozapine levels when risperidone was added and the development of atrial ectopies. Dystonia has been seen when clozapine was replaced by risperidone.

Clinical evidence

A man with a schizoaffective disorder taking clozapine started to take risperidone, firstly 500 micrograms twice daily, and then after a week 1 mg twice daily. Clinical improvement was seen and it was found that after 2 weeks his serum clozapine levels had risen by 74%, from 344 to 598 nanograms/mL, without any adverse effects.\(^1\) The serum clozapine levels of another patient more than doubled when risperidone was given. No signs of clozapine toxicity were seen, but mild oculogyric crises were reported.\(^2\) A schizophrenic patient taking clozapine and trihexyphenidyl who developed tachycardia of 120 bpm, which was controlled with propanolol, developed atrial ectopies when risperidone 1.5 mg daily was added. The ectopies stopped when the risperidone was withdrawn and started again when it was re-introduced. Clozapine plasma levels were normal throughout the duration of risperidone treatment.\(^3\) Four patients have been described who developed dystonia after their treatment was changed from clozapine to risperidone.\(^4\) A single case of agranulocytosis has been seen 6 weeks after risperidone was added to stable clozapine treatment. The patient needed 3 doses of G-CSF before the white cell count returned to normal.\(^5\) Another case report describes neuroleptic malignant syndrome in a 20-year-old man within 2 days of clozapine being added to risperidone treatment. The drugs were stopped and he recovered over the following 10 days. He subsequently received clozapine alone without problem.\(^6\)

Contrasting with these reports is a study in 12 schizophrenic patients, which found that the addition of risperidone to clozapine was both effective and well tolerated, although 4 patients complained of mild akathisia. Serum clozapine levels were not significantly changed.\(^7\) A retrospective study in 18 patients also found that risperidone did not alter clozapine serum levels.\(^8\)

#### Mechanism, importance and management

The suggested reason for the raised clozapine levels is that both drugs compete for metabolism by the cytochrome P450 isoenzyme CYP2D6 resulting in a reduction in the metabolism of the clozapine.\(^1\) The dystonias are attributed to cholinergic rebound and ongoing dopamine blockade caused by a rapid switch of medication. The recommendation is that withdrawal of clozapine should be tapered and possibly that an antimuscarinic drug should be given.\(^4\) The raised clozapine levels seem to be isolated cases and therefore of doubtful general significance.

### Clozapine + SSRIs

Fluoxetine, paroxetine, sertraline and possibly citalopram can raise serum clozapine levels. Escitalopram is predicted to interact similarly. Particularly large increases in clozapine levels can occur with fluvoxamine. Clozapine toxicity has been seen in some patients.

#### Clinical evidence

(a) Citalopram

Preliminary studies in 5 patients found that their mean plasma clozapine levels were unchanged by citalopram.\(^1\) Another study in 8 patients found similar results.\(^2\) However, a patient who was stable taking clozapine developed hyperactivation and confusion shortly after he started to take citalopram 40 mg daily. When total clozapine serum levels were measured they were found to be 1097 nanograms/mL. The citalopram dose was reduced to 20 mg daily, the symptoms resolved over the following 2 weeks, and the total clozapine level dropped to 792 nanograms/mL.\(^3\)

(b) Fluoxetine

Several studies and case reports have found increased clozapine levels of 30 to 75%, and increased levels of the metabolite norclozapine of 34 to 52% after fluoxetine was added to established clozapine treatment.\(^4\) In one case the levels of clozapine and norclozapine were raised over fivefold, accompanied by hypertension. Clozapine levels became subtherapeutic 2 weeks after fluoxetine was withdrawn, necessitating an increase in dosage.\(^5\)

A patient who had been taking clozapine 500 mg and lorazepam 3 mg daily, developed myoclonic jerks of his whole body 79 days after fluoxetine 20 mg was added. These decreased over the next 2 days when the fluoxetine and lorazepam were stopped.\(^6\) A case report describes a patient taking clozapine, who developed severe SSRI withdrawal within a day of...
stopping treatment with fluoxetine 40 mg daily, which had been taken for 4 months. The symptoms resolved when treatment with fluvoxamine was started. Although it was suggested that clozapine may have been involved in this effect its role is unclear.

The death of a 44-year-old patient who was taking clozapine and fluoxetine was felt to be due to an increase in clozapine levels caused by fluoxetine.10 In contrast, there are reports of successful use,11,12 and no pharmacokinetic changes12 when clozapine and fluoxetine were used together. A case has also been reported of a patient with schizophrenia and depression, whose cognitive symptoms improved when he took clozapine and fluoxetine, but when treatment was changed to sertraline, this improvement was not sustained. The authors tentatively suggested that the fluoxetine elevated plasma clozapine levels by inhibition of CYP2D6, whereas this effect was not seen with sertraline as it is a much weaker inhibitor of this enzyme.13 However, this explanation has been questioned, since the role of other drug metabolising enzymes was not considered.14

(c) Fluvoxamine

Up to tenfold elevations in plasma clozapine levels have been seen in several studies and case reports when clozapine was given with fluvoxamine.15-25 These elevations occurred as early as 14 days after combined treatment was started,25 but were often not associated with any significant adverse effects, even after treatment had continued for a year in one patient.18 Another study, which compared 12 patients taking clozapine with 11 patients taking clozapine and fluvoxamine, found that in the combined treatment group, clozapine doses were about half those used when clozapine was given alone. A trend towards decreased granulocyte levels was also seen in the clozapine/fluvoxamine group, but not when clozapine was used alone.36

Another patient had extremely high plasma clozapine levels of up to 4160 micrograms/L as a result of taking fluvoxamine.27 Other cases have also demonstrated worsening psychosis28 or extrapyramidal adverse effects29 (including, rigidity, tremors and akathisia) and sedation within days of giving fluvoxamine with clozapine. A study in 68 patients taking either clozapine alone or clozapine and fluvoxamine found a trend towards less weight increase after 12 weeks of treatment in the group of patients also taking fluvoxamine. Those patients taking clozapine alone were found to have significantly higher glucose and triglyceride levels.30 Note that fluvoxamine treatment alone can result in weight loss.

(d) Paroxetine

The serum levels of clozapine and norclozapine rose by 57% and 50%, respectively, in 16 schizophrenic patients after they took an average of 31.2 mg of paroxetine daily. One patient taking clozapine 300 mg daily developed reversible cerebral intoxication when given paroxetine 40 mg daily.3 Another patient with a delusional disorder developed an antimuscarinic syndrome with doubled serum clozapine levels within 3 weeks of the addition of paroxetine.31 A further study in 9 patients found that the serum levels of clozapine and norclozapine rose by 31% and 20%, respectively, when paroxetine 20 to 40 mg daily was given for 3 weeks. Two patients experienced mild and transient sedation 2 to 3 days after starting paroxetine. The rise in clozapine levels was not associated with an increase in efficacy and was well tolerated.32 In contrast, a study in 14 patients taking clozapine 2.5 to 3 mg/kg daily found that the addition of paroxetine 20 mg daily had no effect on the serum levels of clozapine.23 This, or similar work, has been published elsewhere.33 An increase in the plasma levels of clozapine, thought to be due to concurrent treatment with paroxetine, has been suggested as the causative factor in the development of a fatal venous thromboembolism in a 47-year-old woman.34 A fatal case of neuroleptic malignant syndrome which started to develop 2 days after the introduction of clozapine 25 mg daily to established treatment with paroxetine 20 mg daily has been reported. The patient had previously taken clozapine alone with no problem.35

(e) Sertraline

In 10 schizophrenic patients the serum levels of clozapine and norclozapine increased by 30% and 52%, respectively, when they started to take an average of 92.5 mg of sertraline daily.3 Another patient taking clozapine 600 mg daily had a 40% reduction in total clozapine serum levels within one month of stopping sertraline 300 mg daily.36

The serum clozapine levels of a schizophrenic patient doubled within a month of adding sertraline 50 mg daily and her psychosis worsened. When the sertraline was stopped she improved and her serum clozapine levels fell once again.23 In contrast, a study in 8 patients who were taking clozapine 200 to 400 mg daily and were also given sertraline 50 to 100 mg per day for 3 weeks, found no significant changes in the levels of clozapine and its major metabolites.26

A case report describes sudden cardiac death in a 26-year-old man, which the authors attributed to an interaction between clozapine and sertraline.37 However, this interaction has been questioned as it is said that the patient had other risk factors that were more likely to have caused the fatality.38

Mechanism

The SSRIs (including escitalopram) are known to inhibit the cytochrome P450 isoenzyme CYP2D6 to a varying extent. Fluvoxamine is also a potent inhibitor of CYP1A2. Both of these isoenzymes are involved in the metabolism of clozapine, the most significant being CYP1A2, so their inhibition causes clozapine levels to rise. The levels of clozapine and norclozapine rise together, and so it has been suggested that the metabolic step inhibited is after the N-dealkylation step.3

Importance and management

These interactions are established. Concurrent use need not be avoided, but it would be prudent to monitor the outcome closely when any is used with clozapine because of the rises in serum clozapine and norclozapine levels that can occur, and because of the rare potential for deterioration in clinical status. Adjust the clozapine dosage as necessary. The authors of one study suggest particularly close monitoring if the daily clozapine dosage exceeds 300 mg or 3.5 mg/kg.3 The interaction is greatest with fluvoxamine, so other SSRIs may be a more prudent choice, although close monitoring is still required.

Clozapine + Tobacco

Smoking tobacco appears to decrease clozapine levels, although not all studies have found an effect.

Clinical evidence, mechanism, importance and management

Tobacco smoking might be expected to lower serum clozapine levels because the smoke contains aromatic hydrocarbons that are potent inducers of the cytochrome P450 isozyme CYP1A2, but studies of this likely interaction have been equivocal. One group of workers found no differences in clozapine levels with smoking, while another group found that smokers had lower clozapine levels. In addition, a case report describes clozapine-induced seizures in a man when he gave up smoking, although no smoking cessation was the cause. Two further case reports describe elevated plasma levels within 2 to 4 weeks of stopping smoking. In all cases, a 1.5-fold increase in clozapine dose should be anticipated. Likewise, a patient-dependent pharmacokinetic interaction of clozapine and paroxetine in an extensive metabolizer.

Fluphenazine + Ascorbic Acid (Vitamin C)

A single case report describes a reduction in serum fluphenazine levels and signs of a reduction in its effects when a patient was also given ascorbic acid.

Clinical evidence, mechanism, importance and management

A man with a history of manic behaviour, taking fluphenazine 15 mg daily, had a 25% reduction in his plasma fluphenazine levels, from 0.93 to 0.705 nanograms/mL, over a 13-day period while taking ascorbic acid 500 mg twice daily. This was accompanied by a deterioration in his behaviour. The reason for this effect is not understood. There seem to be no other reports of this interaction with fluphenazine or any other phenothiazine so that this interaction would not appear to be of general importance.

Fluphenazine + Spiramycin

Acute dystonia occurred when a man taking fluphenazine was also given spiramycin.

Clinical evidence, mechanism, importance and management

A man with a schizoaffective disorder taking lorazepam, paroxetine, fluvoxamine and fluphenazine decanoate 12.5 mg every 2 weeks, developed acute and painful dystonia of the trunk, neck, right arm and leg about one week after his last fluphenazine injection and on the fourth day of taking spiramycin 6 million units daily for gymgivitis. The problem resolved when he was given biperiden. The reasons for this adverse reaction are not understood, nor is it entirely clear whether this was an interaction between fluphenazine and spiramycin, although the author suggested that a causal link existed. This seems to be the only report of an alleged interaction between fluphenazine and a macrolide antibacterial and it is therefore of little or no general importance.

Glutethimide + Tobacco

A study in 7 subjects found that glutethimide worsened psychomotor performance in smokers more than in non-smokers, possibly due to an increase in glutethimide absorption.

27. Pinnimini NR, De Leon J. Interaction of steady-state fluvoxamine on the pharmacokinetics of olanzapine levels and signs of a reduction in its effects when a patient was also given ascorbic acid.
33. A study in 7 subjects found that glutethimide worsened psychomotor performance in smokers more than in non-smokers, possibly due to an increase in glutethimide absorption. However there
would seem to be no need for particular caution if smokers take glutethimide.

### Haloperidol + Alopsetron

A placebo-controlled study in 10 patients taking haloperidol found that alopsetron 1 mg daily given during weeks 2 and 3 of the 8-week study period caused no change in haloperidol pharmacokinetics.

### Haloperidol + Antimyocobacterials

The serum levels of haloperidol can be reduced by rifampicin (rifampin), and possibly raised by isoniazid.

#### Clinical evidence

A study in schizophrenic patients taking haloperidol, 7 of whom were also taking a range of antimycobacterial drugs (ethambutol, isoniazid, rifampicin), and 18 of whom were taking isoniazid only, showed that these receiving multiple drugs, which included rifampicin had significantly lower haloperidol serum levels. The half-life of haloperidol in 2 patients taking rifampicin was 4.9 hours compared with 9.4 hours in 3 other patients not taking rifampicin. Three of the patients taking isoniazid (without rifampicin or ethambutol) had increased serum haloperidol levels.

The trough serum haloperidol levels of 15 schizophrenics fell to 37.4% of the expected level after they took rifampicin 600 mg daily for 7 days. After 28 days the serum level had dropped further to 30% of the expected level.

#### Mechanism

The likeliest explanation is that the rifampicin, a recognised enzyme inducer, increases the metabolism and loss of the haloperidol from the body.

#### Importance and management

The interaction between haloperidol and rifampicin would appear to be established and clinically important. Be alert for any evidence of reduced haloperidol effects if rifampicin alone is used, and possibly increased effects if isoniazid alone is used. Adjust the haloperidol dosage if necessary.

### Haloperidol + Buspirone

Two studies found that buspirone can cause a rise in plasma haloperidol levels, while another study found that no interaction occurred.

#### Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 27 schizophrenic patients taking haloperidol 10 to 40 mg daily found that buspirone 5 mg three times daily for 4 weeks, followed by 10 mg three times daily for 4 weeks, did not significantly affect the steady-state plasma haloperidol levels.

These findings contrast with those of a 6-week study, in which 6 out of 7 schizophrenics had 15 to 122% rises in their plasma haloperidol levels when they were given buspirone. The authors also mention a single-dose study in healthy subjects, which found a 30% rise in haloperidol levels when subjects were given buspirone.

It is not known why these findings differ, but since no adverse reactions have been reported, there would seem to be no reason for avoiding concurrent use. However, be aware that some patients seem to experience large rises in haloperidol levels, so consider this potential interaction if the effects of haloperidol seem excessive.

### Haloperidol + Chlorpromazine

Some patients may show a large increase in haloperidol levels when they are given chlorpromazine.

#### Clinical evidence, mechanism, importance and management

Haloperidol was given to 43 patients in doses of 2 to 21 mg daily for 2 months, and then chlorpromazine 50 mg to 300 mg daily was added for a further 2 months. Haloperidol plasma levels were found to increase by an average of 28.5%, and levels of the metabolite, reduced haloperidol, were increased by 161%. However, the variation in effect was large. Chlorpromazine was thought to raise haloperidol levels by inhibiting haloperidol metabolism by the cytochrome P450 isoenzyme CYP2D6. The large inter-individual variation suggested that differences in cytochrome P450 genotypes may affect haloperidol metabolism, and therefore some patients may be at risk of developing adverse effects related to high haloperidol levels.

### Haloperidol + Dexamfetamine

Acute dystonia occurred in two healthy subjects when they were given haloperidol with dexamfetamine.

#### Clinical evidence, mechanism, importance and management

Two healthy young women were given haloperidol 5 mg and dexamfetamine 5 mg as part of a neuropharmacological study. After 29 hours one of them developed stiffness of neck and limbs, parkinsonian facies, her tongue protruded, and she had oropharyngeal spasm. After 34 hours the other woman developed an oculogyric crisis and acute dystonia of the neck with her back slightly arched. Both recovered rapidly after being given 10 mg of intramuscular procyclidine.

The reasons for this interaction are not fully understood, but the authors of the study suggest that the acute dystonia was due to a potentiation of dopamine release. The clinical significance of this interaction is unclear.

### Haloperidol + Granisetron

Granisetron appears not to increase the adverse effects of haloperidol.

#### Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that while haloperidol 3 mg alone caused some impaired psychometric performance (increased drowsiness, muzziness, lethargy, mental slowness, etc.), the addition of granisetron 160 micrograms/kg did not seem to make performance significantly
Ingestion of 200 mL of regular-strength grapefruit juice three times a day for 7 days was found not to affect the pharmacokinetics of haloperidol in 12 schizophrenic patients receiving haloperidol 6 mg twice daily.\(^1\)

**Haloperidol + Grapefruit juice**

Marked but transient hypotension was seen when three patients receiving intravenous imipenem were given low dose intravenous haloperidol.

### Clinical evidence, mechanism, importance and management

Three patients in intensive care who were being treated with intravenous imipenem 500 mg (with cilastatin) every 6 hours for 2, 3, and 7 days, respectively, developed a rapid and short-lived episode of hypotension when they were given a 2.5-mg dose of intravenous haloperidol. For example, the blood pressure of one of the patients fell from 117/75 mmHg to 91/49 mmHg. After 30 minutes her blood pressure had risen to 100/57 mmHg. No treatment for hypotension was given to any of the patients and the reaction was brief and self-limiting. Two of them were also taking famotidine and erythromycin. No acute ECG changes were seen.\(^1\)

The reason for this fall in blood pressure is not understood, but the authors attribute what happened to the concurrent use of haloperidol and imipenem, although they point out that intravenous haloperidol alone can cause orthostatic hypotension. One suggestion is that competitive protein binding displacement might have transiently increased the levels of free haloperidol,\(^1\) although this has been questioned, and a suggestion made that this interaction is mediated by the CYP2D6 enzyme, which metabolises haloperidol.\(^2\)

The authors advise that if haloperidol is used, low doses should be given, and the outcome well monitored. They say that no pressor agent was needed in these cases, but they suggest the possible use of metaraminol, phenylephrine or noradrenaline (norepinephrine) rather than dopamine, the vasopressor effects of which might be blocked or reversed by haloperidol.\(^3\)

### Haloperidol + Imipenem

### Haloperidol + Indometacin

Profound drowsiness and confusion have been described in patients given haloperidol with indometacin.

### Clinical evidence, mechanism, importance and management

A crossover study in 20 patients, designed to find out the possible advantages of combining haloperidol 5 mg daily with indometacin 25 mg three times daily, was eventually abandoned because 13 patients (11 taking haloperidol and 2 taking placebo) failed to complete the study. Profound drowsiness or tiredness caused 6 of the haloperidol-treated patients to withdraw. The authors of this paper said that the combined treatment produced drowsiness and confusion greater than anything expected with haloperidol alone, and sufficiently severe that in some cases independent functioning was affected.\(^1\)

Evidence of this interaction appears to be very limited. If concurrent use is thought appropriate, warn patients about this potentially severe effect. It might be wiser to avoid concurrent use because many patients requiring this type of treatment may not be hospitalised and under the day-to-day scrutiny of the prescriber.\(^1\)

### Haloperidol and related drugs + Itraconazole

Itraconazole increases the plasma levels of haloperidol, and its metabolite, reduced haloperidol. Bromperidol may be similarly affected.

### Clinical evidence

#### (a) Bromperidol

A study in 8 patients found that plasma levels of bromperidol 12 or 24 mg daily, were increased by itrarconazole 200 mg daily for 7 days. The average increase was approximately 8%, but there was wide variation between patients, with some being unaffected and others having increases of up to 302%. Levels of the metabolite of bromperidol, reduced bromperidol, were similarly increased, by up to 415%.\(^1\)

#### (b) Haloperidol

A study in 13 schizophrenic patients taking haloperidol 6 mg or 12 mg twice daily found an increase in the levels of haloperidol and its metabolite, reduced haloperidol, when itraconazole 200 mg daily was given for 7 days. Haloperidol levels increased by 30%, and levels of the metabolite, reduced haloperidol, were increased by 24%. There was also an increase in neurological adverse effects during itraconazole treatment.\(^2\) In a randomised study 15 healthy subjects were given itracanazole 200 mg twice daily for 10 days with a single 5-mg dose of haloperidol on day 7. Itraconazole increased the AUC of haloperidol by 55% in the 8 subjects with normal CYP2D6 and by 81% in those with unstable CYP2D6. No significant changes in QT prolongation were seen.\(^3\)

### Mechanism, importance and management

It is likely that itraconazole inhibited the metabolism of bromperidol and haloperidol by CYP3A4. The wide variation in results may be attributed to interindividual variation in CYP3A4 activity.

The clinical significance of the raised levels is unclear, although one study found an increase in neurological adverse effects with haloperidol. It may be prudent to monitor concurrent use, decreasing the haloperidol or bromperidol dose if adverse effects become troublesome. This interaction may be of more importance in those patients have less active CYP2D6, the predominant isoenzyme involved in the metabolism of haloperidol, as CYP3A4, which is inhibited by itraconazole, will then become more important. It is likely that other azoles that are potent inhibitors of CYP3A4, such as ketoconazole, would interact similarly, but this needs confirmation.

### Haloperidol + Nefazodone

Nefazodone does not appear to significantly affect the pharmacokinetics of haloperidol.

### Clinical evidence, mechanism, importance and management

After taking nefazodone 200 mg twice daily for about 7 days to achieve steady-state pharmacokinetics, the AUC of haloperidol 5 mg in 12 healthy subjects was found to be increased by 36% but the maximum plasma lev-
els of haloperidol were unaltered. The pharmacokinetics of the nefazodone were unaltered.1 It seems fairly unlikely that this change is enough to be of clinical relevance.

**Haloperidol + Quinidine**

**Clinical evidence, mechanism, importance and management**

An experimental study in 13 healthy subjects found quinidine bisulfate 250 mg, taken about 1 hour before a single 5-mg dose of haloperidol approximately doubled the maximum plasma levels and the AUC of haloperidol. The reasons for this effect are not understood.1 The clinical importance of this interaction has not been assessed, but it seems likely that the effects and adverse effects of haloperidol will be increased if quinidine is added. Be alert for this interaction if both drugs are given.

See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

**Haloperidol + Risperidone**

A case report describes neuroleptic malignant syndrome in a patient taking risperidone and haloperidol.

**Clinical evidence, mechanism, importance and management**

A case report describes a 57-year-old man who had been taking haloperidol 4 mg three times daily unintentionally for several years. At a review, his treatment was changed to risperidone, in increasing doses to 3 g twice daily, and mirtazapine 15 mg at night. Despite being advised to stop haloperidol when he started risperidone, the patient continued to take haloperidol, and by the third day of concurrent use he had become pyrexial, and exhibited rigidity of his trunk and extremities. He was diagnosed as having the neuroleptic malignant syndrome, was given dantrolene, bromocriptine and lorazepam, and recovered over the next 2 months. The effects seen in this patient were thought to be due to the additive dopamine antagonism from both the haloperidol and risperidone. Mirtazapine may have also contributed, although the patient only took two doses before he was admitted. The authors suggest that if antipsychotic treatment is to be changed, it is advisable to slowly reduce the dose of the old antipsychotic and, simultaneously, slowly increase the dose of the new drug to avoid the risk of a psychotic relapse, and the patient should be closely monitored during this time for signs of neuroleptic malignant syndrome.1

**Haloperidol + Venlafaxine**

Venlafaxine can increase the serum levels of haloperidol. This is consistent with an isolated report, which describes a man who developed urinary retention when venlafaxine was added to a previously well-tolerated regimen of haloperidol and alprazolam.

**Clinical evidence, mechanism, importance and management**

A study in 24 healthy subjects found that steady-state venlafaxine 75 mg every 12 hours reduced the renal clearance of a single 2-mg dose of haloperidol by 42%, resulting in a 70% rise in the AUC and an 88% rise in its maximum serum levels.1,2,3 This rise in haloperidol levels would seem to be consistent with an isolated report of a 75-year-old man taking haloperidol 1 mg and alprazolam 500 micrograms daily, who suddenly developed urinary retention when venlafaxine 37.5 mg daily was added. Urinary retention resolved spontaneously when all the drugs were stopped.4

It was suggested that venlafaxine inhibits the cytochrome P450 isoenzyme CYP2D6, which is concerned with the metabolism of haloperidol. As a result the serum levels of the haloperidol rise, thereby increasing its antimuscarinic effects,5 which in this case resulted in urinary retention. The evidence is very limited but be aware that increased haloperidol adverse effects may occur if venlafaxine is also given. It may be necessary to reduce the haloperidol dosage.

**Olanzapine + Antiepileptics**

Carbamazepine and valproate appear to lower olanzapine levels. The combination of olanzapine and valproate appears to increase the risk of hepatic injury in children. Olanzapine reduces lamotrigine levels and lamotrigine may increase olanzapine levels, although these changes are not expected to be clinically significant in the majority of patients. Oxcarbazepine dose not appear to affect the pharmacokinetics of olanzapine.

**Clinical evidence, mechanism, importance and management**

(a) Carbamazepine

Multiple-dose studies in healthy subjects have shown that carbamazepine increases the metabolism of olanzapine (by induction of the cytochrome P450 isoform CYP1A2). The clearance of olanzapine was increased by 44% and its elimination half-life was reduced 20%, but these changes were not considered significant enough to necessitate dosage adjustments of either drug.1 Another study found that 5 patients taking olanzapine and carbamazepine had a concentration/dose ratio 36% lower than 22 patients taking olanzapine alone.2 A later study by the same authors found similar results, and also found that this increased olanzapine metabolism was probably due to an increase in glucuronidation, which was induced by the carbamazepine.3

A retrospective study identified 10 patients taking olanzapine and carbamazepine. The patients taking carbamazepine were taking olanzapine doses that were double those of subjects taking olanzapine alone. When corrected for dose it was found that the concentration/dose ratio of olanzapine was 71% lower in those also taking carbamazepine.4 A 23-year-old woman required an olanzapine dose reduction from 15 mg daily to 10 mg daily to maintain similar serum olanzapine concentrations after discontinuing treatment with carbamazepine 600 mg per day.

It would seem prudent to closely monitor the outcome of concurrent use and adjust the olanzapine dose as necessary.

(b) Lamotrigine

A study in 43 healthy subjects found that steady-state olanzapine pharmacokinetics were not affected by lamotrigine 200 mg daily. However, the AUC and maximum plasma concentrations of lamotrigine were reduced by 24% and 20%, respectively. Although this reduction was not considered to be clinically significant, interpatient variation indicated that some patients may require adjustment of their lamotrigine dose if olanzapine is started or discontinued.5

A further study in 14 healthy subjects given lamotrigine 50 mg daily, and a single 5-mg dose of olanzapine found no significant changes in the AUC and maximum plasma concentrations of lamotrigine when given with olanzapine, although the time to maximum plasma levels of lamotrigine was increased from 1.8 hours to 4.2 hours. This may be due to antimuscarinic effects of olanzapine slowing the gastrointestinal absorption of lamotrigine.6 As only a single dose of olanzapine, and low doses of both drugs were used, the clinical significance of this finding is unclear.

A study in 14 patients taking olanzapine in doses of 10 mg to 20 mg daily, and who were also given lamotrigine in increasing doses over 8 weeks to 200 mg daily found no changes in the pharmacokinetics of olanzapine with a lamotrigine dose of 100 mg daily, but when the dose was increased
to 200 mg daily, an increase of 16% in olanzapine plasma levels occurred. This increase would not be expected to have clinical significance.8

(c) Oxcarbazepine

A study in 13 patients taking olanzapine 5 to 20 mg daily found that the addition of oxcarbazepine for 5 weeks, at an initial dose of 300 mg daily increased to 900 mg to 1.2 g after one week, had no significant effects on the pharmacokinetics of olanzapine. Concurrent use was generally well tolerated.9 No special consideration or monitoring therefore appears necessary with oxcarbazepine and olanzapine treatment.

(d) Valproate

A retrospective study identified 52 children (under 18 years old) who were treated with olanzapine alone (17), semisodium valproate alone (23) or both drugs together (12). At least one peak liver enzyme level (ALT, AST or lactate dehydrogenase) was found to be above the normal range in 59% of those taking olanzapine alone, 26% of those taking valproate alone, and 100% of patients receiving the combination. Liver enzymes were persistently elevated in 42% of the patients receiving combination treatment, and 2 of these patients had levels that were three times the upper limit of normal. Treatment was discontinued due to pancreatitis in one and steatohepatitis in the other. The authors recommend measuring liver enzymes every 3 to 4 months for the first year of treatment, thereafter monitoring every 6 months if no adverse effects are detected.10

A significant reduction in olanzapine plasma levels of between 32.3% and 78.8% was found in 4 patients who were additionally given valproate, thought to be due to the valproate inducing the enzymes involved in the metabolism of olanzapine.11

Olanzapine + Lithium

Several case reports suggest that some patients taking olanzapine and lithium may develop adverse reactions (neuroleptic malignant syndrome or serotonin syndrome, encephalopathy, priapism) without raised serum lithium levels. One study found no pharmacokinetic interaction between the drugs, but another analysis suggested that lithium may reduce olanzapine plasma levels.

Clinical evidence, mechanism, importance and management

A 16-year-old boy taking lithium 1.2 g daily with a therapeutic serum lithium level, developed neuroleptic malignant syndrome (generalised rigidity, urinary retention, fever, tachycardia) about 2 weeks after his olanzapine dose was increased from 10 to 20 mg daily. Both drugs were stopped, and the symptoms resolved over 8 days. He had previously taken olanzapine and lithium separately without problem.1

A 59-year-old man who had been diagnosed with encephalopathy and confusion while taking a combination of carbamazepine, haloperidol and lithium (therapeutic lithium level), developed similar symptoms when he was later given lithium with olanzapine.2 Another elderly patient who had taken lithium for 7 years, developed severe delirium and extrapyramidal symptoms after the addition of olanzapine. Serum lithium levels were found to be 3 mmol/L.3 The serotonin syndrome developed in a patient with bipolar affective disorder taking lithium and citalopram after olanzapine was also given. She became increasingly irritable 3 months after starting the combination and one month later (4 days after increasing the dose of olanzapine from 15 to 20 mg and stopping the citalopram) she became severely agitated, confused and was sweating profusely with hyperreflexia, tremor and a low-grade fever. The symptoms resolved on cessation of her medication.4 Citalopram may have contributed to this reaction, as the serotonin syndrome has been reported with lithium and SSRIs,5 (p.1115).

A case of non-ketotic hyperosmolar syndrome has been reported in a non-diabetic patient taking olanzapine, lithium and valproic acid. Symptoms began only 5 days after the olanzapine was started.6 Priapism, which was reversed by surgical detumescence, occurred when a 30-year-old man took olanzapine with lithium.7

In an open-label study, 12 healthy subjects took a single 32.4-mmol dose of lithium with 10 mg, and after a washout period, olanzapine 10 mg daily for 8 days, with a single 32.4-mmol dose of lithium on the last day. No pharmacokinetic interactions were detected.8 However, an analysis of olanzapine levels in schizophrenic patients found that concurrent lithium was associated with lower olanzapine plasma levels.9

The case reports detailed above suggest that some patients may develop a pharmacodynamic interaction. Concurrent use of lithium and olanzapine need not be avoided but be aware that there is some risk of developing adverse reactions to the combination. The presence of other serotonergic drugs (e.g. antidepressants such as SSRIs) or dopamine antagonists (e.g. antipsychotics such as haloperidol) is likely to increase the risk of an interaction.

Olanzapine + Miscellaneous

Activated charcoal causes a fall in olanzapine levels and venlafaxine moderately raise olanzapine levels. Additive dopaminergic effects have been seen in one patient taking olanzapine and haloperidol. Olanzapine appears not to interact to a clinically relevant extent with aluminium/magnesium hydroxide antacids, cimetidine or diazepam. However, excessive sedation and hypotension may occur with parenteral benzodiazepines and intramuscular olanzapine.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturers of olanzapine say that single doses of an aluminium/magnesium-containing antacid had no effect on the pharmacokinetics of olanzapine.10 No special precautions would seem to be needed during concurrent use.

(b) Benzodiazepines

In vivo studies have found that no pharmacokinetic interaction occurs between olanzapine and diazepam.1 This confirms in vitro studies using human liver microsomes,1 which demonstrated that olanzapine did not inhibit the cytochrome P450 isoenzymes CYP3A4 or CYP2C19, which are concerned with the metabolism of diazepam. It was noted that mild increases in heart rate, sedation and dry mouth were seen in patients taking both drugs, but no dosage adjustments were thought to be necessary.2 There would therefore appear to be no reason for avoiding concurrent use. Intramuscular lorazepam 2 mg, given 1 hour after intramuscular olanzapine 5 mg increased the drowsiness seen with either drug alone. The pharmacokinetics of both drugs were not affected.3,4 One case report de-
scribes hypotension occurring following the intramuscular use of a single 2-mg dose of lorazepam to a patient receiving treatment with intramuscular olanzapine 10 mg, the most recent dose being given 30 minutes before the lorazepam. His blood pressure dropped from 124/74 to 66/30 mm Hg; 12 hours later his blood pressure had returned to normal. Intramuscular olanzapine has been associated with hypotension, bradycardia, respiratory depression, and rarely death, particularly in patients who have also received benzodiazepines. The manufacturers therefore say that concurrent use is not recommended. If both drugs are needed, parenteral benzodiazepines should not be given for 1 hour after intramuscular olanzapine. If a parenteral benzodiazepine has already been given, intramuscular olanzapine should only be given with careful consideration and monitoring of sedation and respiration.4

(c) Charcoal, activated

The manufacturers report that activated charcoal reduces the bioavailability of oral olanzapine by 50 to 60%,1,3 and recommend that administration be separated by 2 hours.1

(d) Cimetidine

The manufacturers say that cimetidine has no effect on the bioavailability of olanzapine.3 No special precautions would seem to be needed during concurrent use.

(e) Haloperidol

A 67-year-old man with a long history of bipolar disorder was taking haloperidol 10 mg daily, with valproate and benzatropine. Because he had previously had parkinsonian symptoms, olanzapine was started, to be increased as the haloperidol was decreased. On day 6 his parkinsonian symptoms became particularly marked. The haloperidol was stopped and 2 days later the symptoms had resolved. It is thought that either the small amount of dopaminergic activity of olanzapine combined with that of the haloperidol brought on these symptoms, or that olanzapine affected the metabolism of haloperidol, caused increased levels and therefore greater dopaminergic activity.6 The significance of this interaction is not clear, but it would be wise to be aware of this interaction if both drugs are used.

(f) Venlafaxine

A retrospective study found that venlafaxine caused a 27% increase in olanzapine plasma levels. The clinical significance of this finding is unclear.7

Olanzapine + Quinolones

The olanzapine levels of a patient were reduced when ciprofloxacin was stopped.

Clinical evidence, mechanism, importance and management

The olanzapine levels of a patient were rapidly reduced, by more than 50%, when ciprofloxacin 250 mg twice daily was stopped. On the day of the last dose of a 7 day course of ciprofloxacin her olanzapine plasma level was 32.6 nanograms/mL, but within 3 days it had fallen to 14.6 nanograms/mL. It is thought that elevated levels occurred because ciprofloxacin inhibits the cytochrome P450 isozyme CYP1A2, which is involved in the metabolism of olanzapine.1 The UK manufacturers of olanzapine recommend that a lower dose of olanzapine should be given to patients taking ciprofloxacin.2 Note that other quinolones can inhibit CYP1A2 to varying degrees (for an example see ‘Theophylline + Quinolones’, p.1192) and may therefore be expected to interact similarly.

Olanzapine + Ritonavir

Ritonavir almost halves olanzapine levels.

Clinical evidence, mechanism, importance and management

A single 10-mg dose of olanzapine was given to 14 healthy, non-smoking subjects after they had taken ritonavir for 11 days (initially 300 mg twice daily, escalating to 500 mg twice daily). Ritonavir decreased the AUC and maximum plasma levels of olanzapine by 53% and 40%, respectively, and reduced the half-life from 32 to 16 hours.1

The authors suggest that ritonavir increased the metabolism of olanzapine by inducing the cytochrome P450 isozyme CYP1A2, which is the main metabolic route of olanzapine. They also suggest that increased glucuronidation, mediated by glucuronyltransferases induced by ritonavir, may have contributed. It seems likely that increased olanzapine doses may be needed in the presence of ritonavir. If concurrent use is necessary monitor for olanzapine efficacy and increase the dose if necessary.

Olanzapine + SSRIs

Fluvoxamine causes a rise in serum olanzapine levels, which is associated with increased adverse effects. Fluoxetine, paroxetine and sertraline appear to moderately raise olanzapine levels while citalopram appears to have no effect. A case of retarded ejaculation has been seen in one patient taking olanzapine and paroxetine, and the serotonin syndrome has been reported in patients taking citalopram or fluoxetine with olanzapine.

Clinical evidence, mechanism, importance and management

(a) Fluvoxamine

In a placebo-controlled study, fluvoxamine 50 to 100 mg daily was given to 10 male smokers daily for 11 days, with olanzapine 2.5 to 7.5 mg daily on days 4 to 11. During the initial 4 days of concurrent use somnolence was increased by 19 to 115%, when compared to the group taking olanzapine and placebo, but the subjects accommodated to this over the next 4 days. Fluvoxamine increased the olanzapine maximum plasma levels and AUC by 84% and 119%, respectively, and the olanzapine clearance fell by 50%.2 A retrospective study found that in patients taking fluvoxamine and olanzapine the concentration/dose ratio was 2.3-fold higher than the taking olanzapine alone.3 In another study 10 schizophrenic patients were given fluvoxamine 50 mg daily from days 1 to 14 followed by fluvoxamine 100 mg daily from days 15 to 28. A single 10-mg dose of

Olanzapine + Probenecid

Probenecid may increase the AUC and maximum plasma levels of olanzapine, but the clinical significance of this finding is unclear.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects were given a single 5-mg dose of olanzapine alone, or on day 2 of a 4 day course of probenecid 500 mg twice daily. The AUC and maximum plasma levels of olanzapine were significantly increased by about 20%, but overall bioavailability was not affected. The probenecid is thought to have caused these small effects by reducing the glucuronidation of olanzapine.1 As this was a single dose study, the clinical implications of this interaction when olanzapine is taken regularly, are unclear, but probably small

Olanzapine + Ritonavir

Ritonavir almost halves olanzapine levels.

Clinical evidence, mechanism, importance and management

A single 10-mg dose of olanzapine was given to 14 healthy, non-smoking subjects after they had taken ritonavir for 11 days (initially 300 mg twice daily, escalating to 500 mg twice daily). Ritonavir decreased the AUC and maximum plasma levels of olanzapine by 53% and 40%, respectively, and reduced the half-life from 32 to 16 hours.1

The authors suggest that ritonavir increased the metabolism of olanzapine by inducing the cytochrome P450 isozyme CYP1A2, which is the main metabolic route of olanzapine. They also suggest that increased glucuronidation, mediated by glucuronyltransferases induced by ritonavir, may have contributed. It seems likely that increased olanzapine doses may be needed in the presence of ritonavir. If concurrent use is necessary monitor for olanzapine efficacy and increase the dose if necessary.

Olanzapine + SSRIs

Fluvoxamine causes a rise in serum olanzapine levels, which is associated with increased adverse effects. Fluoxetine, paroxetine and sertraline appear to moderately raise olanzapine levels while citalopram appears to have no effect. A case of retarded ejaculation has been seen in one patient taking olanzapine and paroxetine, and the serotonin syndrome has been reported in patients taking citalopram or fluoxetine with olanzapine.

Clinical evidence, mechanism, importance and management

(a) Fluvoxamine

In a placebo-controlled study, fluvoxamine 50 to 100 mg daily was given to 10 male smokers daily for 11 days, with olanzapine 2.5 to 7.5 mg daily on days 4 to 11. During the initial 4 days of concurrent use somnolence was increased by 19 to 115%, when compared to the group taking olanzapine and placebo, but the subjects accommodated to this over the next 4 days. Fluvoxamine increased the olanzapine maximum plasma levels and AUC by 84% and 119%, respectively, and the olanzapine clearance fell by 50%.2 A retrospective study found that in patients taking fluvoxamine and olanzapine the concentration/dose ratio was 2.3-fold higher than the taking olanzapine alone.3 In another study 10 schizophrenic patients were given fluvoxamine 50 mg daily from days 1 to 14 followed by fluvoxamine 100 mg daily from days 15 to 28. A single 10-mg dose of
olanzapine was given on day 10 and again on day 24. The maximum plasma levels of olanzapine were raised by 12% and 64% and the clearance was reduced by about 25% and 35%, by 50 and 100 mg of fluvoxamine, respectively. Increased sedation was also seen, which was more frequent with fluvoxamine 100 mg daily. Other studies have found 50 to 81% increases in olanzapine levels with fluvoxamine 100 mg daily, which took up to 8 weeks to occur. There was a marked variation between individuals in the extent of the interaction. In one study, plasma levels of olanzapine were maintained when the dose of olanzapine was reduced by an average of 4.5 mg daily following the addition of fluvoxamine 25 mg daily. The olanzapine plasma levels of a 21-year-old woman were 6 times the recommended upper limit while she was taking fluvoxamine. During this time she developed rigidity and tremor. After the olanzapine dose was reduced from 15 mg to 5 mg daily the levels were still almost double the recommended level.

(b) Other SSRIs

The manufacturers say that fluoxetine 60 mg daily for 8 days caused an increase of 16% in olanzapine maximum serum levels and a 16% decrease in clear ance. These differences were considered to be too small to necessitate dosage adjustments. Similar results were found in a published study. A case report describes a patient who had been taking fluoxetine 80 mg daily for several weeks with no adverse effects who developed the serotonin syndrome within 3 weeks of starting to take olanzapine 5 mg daily. His symptoms resolved after discontinuing the fluoxetine, and he was later able to tolerate a 20 mg daily dose of fluoxetine and olanzapine with no further adverse effects. The serotonin syndrome has also been reported in a patient taking olanzapine, citalopram and lithium, see ‘Olanzapine + Lithium’, p.756.

A patient taking fluvoxamine had olanzapine levels double the upper recommended limit; when paroxetine was substituted for fluvoxamine the olanzapine levels became almost normal. Another patient taking paroxetine developed retard ed ejaculation 2 months after he started to take olanzapine 15 mg daily. This adverse effect resolved when the olanzapine was given in divided doses.

A retrospective study found that sertraline had no effect on the concentration-dose ratio of olanzapine, suggesting that it does not interact. Another study found that paroxetine, fluoxetine and sertraline increased olanzapine levels by about 32%, but citalopram had no effect.

Mechanism

Fluvoxamine inhibits the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in the metabolism of olanzapine, resulting in increased olanzapine levels and adverse effects. All SSRIs affect CYP2D6 (to differing extents). This isoenzyme has a minor role in olanzapine metabolism, and therefore SSRIs other than fluvoxamine have only a small effect on olanzapine levels.

Importance and management

The manufacturers of olanzapine suggest that lower olanzapine doses may be needed if fluvoxamine is given. Monitor for fluvoxamine adverse effects. Other SSRIs appear not to interact significantly, although the case report with paroxetine suggests that additive adverse effects are a possibility.

Clinical evidence, mechanism, importance and management

A retrospective study found that cigarette smoking reduced olanzapine levels, in one study by 12% and by about 50% in another, and that smokers needed higher doses of olanzapine than non-smokers (10 mg compared with 12.5 mg) yet had lower olanzapine levels (60 nanomol/L compared with 92 nanomol/L).

A study in 17 psychiatric patients found that the olanzapine concentration-dose ratio was directly related to CYP1A2 activity: both CYP1A2 activity and olanzapine levels were sixfold higher in smokers than non-smokers. A case report describes a patient who was successfully treated with olanzapine 15 mg daily whilst in hospital and smoking up to 12 cigarettes a day. However, on discharge his cigarette consumption increased to 80 per day, and his schizophrenic symptoms worsened. Cigarette plasma levels reduced from 52 nanograms/mL to 30 nanograms/mL as his cigarette consumption increased to 80 per day. The manufacturers say that smokers have a 40% greater clearance of olanzapine than non-smokers. The consequences are that the effects of olanzapine will be reduced to some extent by smoking. The manufacturers say that dosage adjustments are not routinely recommended in smokers because of the overall variability in dosing between individuals.

Mechanism

Fluvoxamine inhibits the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in the metabolism of olanzapine, resulting in increased olanzapine levels and adverse effects. All SSRIs affect CYP2D6 (to differing extents). This isoenzyme has a minor role in olanzapine metabolism, and therefore SSRIs other than fluvoxamine have only a small effect on olanzapine levels.

Importance and management

The manufacturers of olanzapine suggest that lower olanzapine doses may be needed if fluvoxamine is given. Monitor for fluvoxamine adverse effects. Other SSRIs appear not to interact significantly, although the case report with paroxetine suggests that additive adverse effects are a possibility.

Clinical evidence, mechanism, importance and management

A retrospective study found that cigarette smoking reduced olanzapine levels, in one study by 12% and by about 50% in another, and that smokers needed higher doses of olanzapine than non-smokers (10 mg compared with 12.5 mg) yet had lower olanzapine levels (60 nanomol/L compared with 92 nanomol/L).

A study in 17 psychiatric patients found that the olanzapine concentration-dose ratio was directly related to CYP1A2 activity: both CYP1A2 activity and olanzapine levels were sixfold higher in smokers than non-smokers. A case report describes a patient who was successfully treated with olanzapine 15 mg daily whilst in hospital and smoking up to 12 cigarettes a day. However, on discharge his cigarette consumption increased to 80 per day, and his schizophrenic symptoms worsened. Cigarette plasma levels reduced from 52 nanograms/mL to 30 nanograms/mL as his cigarette consumption increased to 80 per day. The manufacturers say that smokers have a 40% greater clearance of olanzapine than non-smokers. The consequences are that the effects of olanzapine will be reduced to some extent by smoking. The manufacturers say that dosage adjustments are not routinely recommended in smokers because of the overall variability in dosing between individuals.

No pharmacokinetic interaction occurs between imipramine or mirtazapine and olanzapine, but the additive effects of clo mipramine and olanzapine was thought to have caused a seizure in one patient.

Clinical evidence, mechanism, importance and management

(a) Mirtazapine

In a study in 7 patients, mirtazapine 30 mg daily did not significantly affect the pharmacokinetics of olanzapine, taken in doses ranging from 10 to 20 mg daily.

(b) Tricyclic antidepressants

A randomised, crossover study in 9 healthy men given single doses of olanzapine 5 mg and imipramine 75 mg found no clinically relevant pharmacokinetic or pharmacodynamic interactions between the two drugs. This would seem to confirm in vitro studies using human liver microsomes, which demonstrated that olanzapine causes minimal inhibition of the cytochrome P450 isoenzyme CYP2D6, an enzyme involved in the metabolism of the tricyclic antidepressants. However, one case report describes seizures, thought to be caused by the additive effects of olanzapine...
and clomipramine. Neither drug alone had produced this reaction in the patient. No special precautions would seem to be necessary if both drugs are used concurrently, but be aware that they both have the potential to lower the seizure threshold and that the effect may be additive.

### Perospirone + Miscellaneous

Carbamazepine reduces, and itraconazole increases, perospirone levels.

#### Clinical evidence, mechanism, importance and management

**(a) Carbamazepine**

Carbamazepine reduced the plasma levels of a single 8-mg dose of perospirone to below the detection limit. This is likely to be as a result of carbamazepine-induced induction of perospirone metabolism by CYP3A4.

**(b) Itraconazole**

Administration of itraconazole 200 mg daily for 5 days, with a single 8-mg dose of perospirone given on day 6 resulted in a 6-fold increase in perospirone maximum plasma levels. A similar increase in the AUC and the half-life of perospirone was also seen. As itraconazole is a potent inhibitor of CYP3A4, the increase in levels is likely to be due to inhibition of metabolism of perospirone.

### Perospirone + Disulfiram

A single case report describes a man taking perospirone whose psychotic symptoms re-emerged when he started to take disulfiram.

#### Clinical evidence, mechanism, importance and management

A man taking perospirone 8 mg twice daily developed marked psychosis soon after starting to take disulfiram 100 mg daily. His serum perospirone levels had fallen from a range of 2 to 3 nanomol/L to less than 1 nanomol/L. Doubling the dosage of perospirone had little effect, and no substantial clinical improvement or rise in serum levels occurred until he was given intramuscular perphenazine enantate 50 mg weekly, at which point the levels rose to about 4 nanomol/L. The results of clinical biochemical tests suggested that the disulfiram was acting as an enzyme inducer, resulting in increased metabolism and clearance of the perospirone. However, disulfiram normally acts as an enzyme inhibitor. Too little is known to assess the general importance of this interaction, and there seems to be no information about an interaction with other phenothiazines.

### Phenothiazines + Antimalarials

Chloroquine, amodiaquine and Fansidar (sulfadoxine/pyrimethamine) can markedly increase serum chlorpromazine levels.

#### Clinical evidence

A total of 15 schizophrenic patients (in three groups of five) taking chlorpromazine 400 or 500 mg daily for at least 2 weeks were given single doses of either chloroquine sulphate 400 mg, amodiaquine hydrochloride 600 mg or three tablets of Fansidar (pyrimethamine 25 mg with sulfadoxine 500 mg) one hour before the chlorpromazine. Serum chlorpromazine levels 3 hours later were found to be raised about threefold by the chloroquine and amodiaquine, and almost fourfold by the Fansidar. The plasma level of 7-hydroxychlorpromazine, one of the major metabolites of chlorpromazine, was also elevated, but not those of the other metabolite, chlorpromazine sulphoxide. The serum chlorpromazine levels of the patients given chloroquine or Fansidar were, to some extent, still elevated 4 days later. There was subjective evidence that the patients were more heavily sedated when given the antimalarials.

**Mechanism**

Not understood. Both chloroquine and Fansidar have relatively long half-lives compared with amodiaquine, which may explain the persistence of their effects.

#### Importance and management

Direct information about this interaction seems to be limited to this study. Its clinical importance is uncertain but it seems possible that these antimalarials could cause chlorpromazine toxicity. Monitor the effects of concurrent use closely and anticipate the need to reduce the chlorpromazine dosage. More study is needed. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257. For mention that promethazine may increase chloroquine levels, see ‘Chloroquine + Promethazine’, p.223.

### Phenothiazines + Barbiturates

The levels of chlorpromazine, and possibly thioridazine, are decreased by phenobarbital. Phenothiazines also appear to reduce barbiturate levels. However, the clinical importance of these reductions is uncertain. Pentobarbital, promethazine and hyoscine in combination are said to increase the incidence of peri-operative agitation.

#### Clinical evidence

**(a) Phenothiazine levels reduced**

A study in 12 schizophrenic patients taking chlorpromazine 100 mg three times daily found that phenobarbital 50 mg three times daily reduced plasma chlorpromazine levels by 25 to 30%, which was accompanied by changes in certain physiological measurements, which clearly reflected a reduced response. The conclusion was made that there was no advantage to be gained by concurrent use.

In another study in 7 patients, the plasma levels of thioridazine were reduced by phenobarbital, but the clinical effects of this were uncertain. However, another study found that phenobarbital caused no changes in serum thioridazine levels, but the levels of its active metabolite (mesoridazine) were reduced.

**Notes**

1. Fansidar.
2. Psychotropics, Antidepressants and Hypnotics 311.
3. Antipsychotics, Anxiolytics and Hypnotics 759.
Importance and management

These interactions appear to be established, but the documentation is limited. Their importance is uncertain, but be alert for evidence of reductions in response to both drugs if a phenothiazine and a barbiturate are given, and to increased responses if one of the drugs is withdrawn. So far only chlorpromazine, mesoridazine, phenobarbital and thioridazine are implicated, but it seems possible that other phenothiazines and barbiturates will behave similarly.

Phenothiazines + Hormonal contraceptives or HRT

Oestrogens can increase the plasma levels of butaperazine. A case report describes a marked rise in serum chlorpromazine levels in a woman taking a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

A severe dystonic reaction to a single dose of prochlorperazine in a pregnant woman (presumed to be due to increased plasma levels resulting from high oestrogen levels), prompted further study. Four postmenopausal schizophrenic women. Conjugated oestrogens (Premarin) 1.25 mg daily increased the plasma butaperazine levels by 48% from 231 to 343 nanograms/mL and increased the AUC by 92%.1

A case report describes a woman who had been taking chlorpromazine 100 mg three times daily for one week without problems when a combined oral contraceptive (ethinylestradiol/norgestrel) was started. Four days later she developed severe dyskinesias and tremor, and her chlorpromazine levels were found to have increased by about sixfold.2

The reasons are not understood but increased absorption or reduced liver metabolism of the phenothiazines are suggested.3 The general clinical importance of these findings is not known, and documentation is very limited. There seem to be no other reports of adverse reactions, and the available data are insufficient to justify any general precautions. Further study is needed.

Phenothiazines + Trazodone

Undesirable hypotension occurred in two patients taking chlorpromazine or trifluoperazine with trazodone. Thioridazine causes a moderate rise in trazodone plasma levels. A fatal case of jaundice and hepatic encephalopathy has been reported with the use of trifluoperazine, thioridazine and trazodone.

Clinical evidence, mechanism, importance and management

A depressed patient taking chlorpromazine began to complain of dizziness and unstable gait within 2 weeks of starting to take trazodone 100 mg one to three times daily. His blood pressure had fallen to between 92/58 and 126/72 mmHg. Within 2 days of stopping the trazodone his blood pressure had restabilised.3 A patient taking trifluoperazine was given trazodone 100 mg daily and within 2 days she complained of dizziness and was found to have a blood pressure of 86/52 mmHg. Within one day of stopping the trazodone her blood pressure was back to 100/65 mmHg.1 It would seem that the hypotensive adverse effects of the two drugs can be additive.

A study, undertaken to confirm the involvement of the cytochrome P450 isoenzyme CYP2D6 in the metabolism of trazodone, found that when 11 depressed patients were given trazodone 150 to 300 mg at bedtime for 18 weeks, and then with thioridazine 20 mg twice daily for one week, the plasma levels of the trazodone and its active metabolite, m-chlorophenylpiperazine, rose by 36% and 54%, respectively.6 No adverse reactions were described. In contrast, a case of fatal hepatic necrosis with cholestasis has been attributed to the concurrent use of trazodone and phenothiazines. A 72-year-old woman taking trifluoperazine, trazodone and lithium carbonate developed an elevated alanine aminotransferase level.

Trifluoperazine was replaced with thioridazine, but 9 weeks later she became jaundiced and developed hepatic encephalopathy, and died 6 weeks after the onset of jaundice. The authors consider that the combination of the phenothiazines and trazodone was the cause of her hepatic necrosis: both phenothiazines and trazodone have been reported to individually cause hepatic adverse effects.7

Patients given phenothiazines and trazodone should be monitored for signs of excessive hypotension and should have their liver function tests closely monitored.

Phenothiazines + Tricyclic antidepressants

The concurrent use of tricyclic antidepressants and phenothiazines is common, but the tricyclic levels are increased by many of the phenothiazines, and the levels of some phenothiazines are also increased by the tricyclics. It has been suggested that concurrent use might contribute to an increased incidence of tardive dyskinesia. Nevertheless, fixed-dose combined preparations are available. Tricyclics have also been shown to reverse the therapeutic effects of chlorpromazine.

Clinical evidence

(a) Effect of phenothiazines on tricyclic antidepressants

An extended study of 4 patients given intramuscular fluphenazine decanoate 12.5 mg weekly, with benztrapine 2 mg three times daily and imipramine 300 mg daily, found that the mean combined plasma concentrations of imipramine and its metabolite, desipramine, were 850 nanograms/mL. This appeared high, when compared with 60 other patients who were taking imipramine 225 mg daily and had levels of 180 nanograms/mL.1

A comparative study of 99 patients taking amitriptyline or nortriptyline alone, and 60 other patients also taking perphenazine 10 mg daily, found that although the tricyclic antidepressant dosages were the same, the plasma tricyclic antidepressant levels of the perphenazine group were up to 70% higher.2

Other studies have described increased tricyclic antidepressant levels with phenothiazines. There is currently evidence for this interaction between:

- imipramine,3-5 and chlorpromazine
- nortriptyline,6 and levomepromazine
- amitriptyline,7 imipramine,5,8,9 desipramine or nortriptyline,6,11-13 and perphenazine
- desipramine,14 imipramine15 or nortriptyline,6 and thioridazine.

However, other studies have found no interaction between:

- amitriptyline6,11,16 or nortriptyline17 and perphenazine
- amitriptyline8 and thioridazine
- amitriptyline9 and levomepromazine
- amitriptyline11 or nortriptyline,11 and zuclopenthixol.

It should be noted that in the case of amitriptyline, although the levels were not affected, levels of its metabolite, desipramine, were raised.6

(b) Effect of tricyclic antidepressant on phenothiazines

In a controlled study in 8 schizophrenic patients taking butaperazine 20 mg daily, 6 of them taking desipramine 150 mg or more daily had a rise in serum butaperazine levels of between 50 and 300%. The other
2 patients, taking desipramine 100 mg or less, had no changes in butaperazine levels.28 Other studies have found a rise in phenothiazine levels when tricyclic antidepressants are added. So far, interactions with chlorpromazine and amitriptyline,21 imipramine22 or nortriptyline23 have been documented.

One study in 7 chronic schizophrenics also reported that giving nortriptyline 50 mg three times daily to patients taking chlorpromazine 100 mg three times daily resulted in profound worsening of the clinical state, with marked increases in agitation and tension, despite the fact that the chlorpromazine levels were actually raised. The nortriptyline was withdrawn. A temporary reversion to a disruptive behaviour pattern has been seen in other patients taking chlorpromazine when amitriptyline was given.24 One patient experienced a severe catatonic reaction that was attributed to the use of thioridazine and amitriptyline,25 and the case of a woman who became anxious with widely staring eyes, a persistent jerking of her hands, and at times the inability to speak was thought to be due to the use of imipramine and chlorpromazine.26 Ventricular tachycardia has also been reported in a 38-year-old woman taking desipramine and thioridazine, which responded to treatment with lidocaine.27

Mechanism

The rise in the serum levels of both drugs is thought to be due to a mutual inhibition of the liver enzymes concerned with the metabolism of both drugs, which results in their accumulation.2,4,8,18,20

Importance and management

Established interactions, but the advantages and disadvantages of concurrent use are still the subject of debate. These two groups of drugs are widely used together in the treatment of schizophrenic patients who show depression, and for mixed anxiety and depression. A number of fixed-dose combinations have been marketed, e.g. amitriptyline with perphenazine), and nortriptyline with fluphenazine. However, the safety of using both drugs together has been questioned.

One of the problems of phenothiazine treatment is the development of tardive dyskinesias, and some evidence suggests that the higher the dosage, the greater the incidence.22 The symptoms can be transiently masked by increasing the dosage,22 and so it has been suggested that the presence of a tricyclic antidepressant might not only be a factor causing tardive dyskinesia to develop, but might also mask the condition.23 It has been recommended that the addition of full antidepressant doses of nortriptyline to average antidepressant doses of chlorpromazine should be avoided because the therapeutic actions of the chlorpromazine may be reversed.22 See also ‘Antipsychotics + Antimuscarinics’, p.708.

Attention has also been drawn to excessive weight gain associated with several months use of amitriptyline with thioridazine for the treatment of chronic pain,28 but note that excessive weight gain is a recognised adverse effect of the antipsychotics alone. The tricyclic antidepressants and many antipsychotics increase the QT interval, see ‘Antipsychotics + Antimuscarinics’, p.708.

Inhibition of CYP3A4 results in markedly increased pimozide levels and increases the risk of QT interval prolongation and the development of life-threatening arrhythmias.

Clinical evidence, mechanism, importance and management

The sudden death of a patient taking pimozide and clarithromycin prompted a study of a possible interaction between the two drugs. Using human liver microsomes it was found that pimozide is partly metabolised by the cytochrome P450 isoenzyme CYP3A4, and that 2 micromol of clarithromycin inhibits this enzyme by at least 80%. The practical consequences of this were seen in a later study in 12 healthy subjects, which found that clarithromycin 500 mg twice daily for 5 days more than doubled the AUC of a single 6-mg oral dose of pimozide and raised its maximum serum levels by almost 50%. The QTc interval was prolonged by about 17 milliseconds with pimozide alone and by 24 milliseconds when clarithromycin was added. The results were the same in both poor and extensive CYP2D6 metabolisers (see ‘Genetic factors’, p.4). CYP2D6 status was considered as this is the other main metabolic route of pimozide. The authors of this study concluded that clarithromycin can therefore increase the cardio toxicity of pimozide during chronic use, irrespective of the CYP2D6 status of the patient.22 Pimozide alone has been associated with ventricular arrhythmias, prolongation of the QT interval, T-wave flattening and sudden and unexplained death in the young with no previously evident of cardiac disease. Due to the severity of this interaction the UK manufacturers contraindicate the use of macrolides with pimozide, whereas the US manufacturers contraindicate pimozide with azithromycin, clarithromycin, dirithromycin, erythromycin and troleandomycin. However, note that azithromycin does not usually interact with other drugs by inhibiting CYP3A4.

The use of many inhibitors of the cytochrome P450 isoenzyme CYP3A4 with pimozide is contraindicated since they are expected to increase plasma levels of pimozide, which is likely to result in QT prolongation and associated arrhythmias. The manufacturers specifically mention azole antifungals, fluvoxamine, grapefruit juice, nefazodone, protease inhibitors, and zileuton. Drugs that are known to cause clinically relevant CYP3A4 inhibition are listed in ‘Table 1.4’, (p.6).

Pimozide + SSRIs

Pimozide levels are expected to rise when used with fluoxetine, fluvoxamine, paroxetine, or sertraline, which would increase the risk of potentially fatal torsade de pointes arrhythmias. The use of SSRIs and pimozide has also led to extrapyramidal adverse effects, oculogyric crises and sedation in rare cases.

Clinical evidence, mechanism, importance and management

(a) Fluoxetine

A patient taking fluoxetine and pimozide had a worsening of extrapyramidal symptoms, and another developed marked sinus bradycardia of 35 to 44 bpm with somnolence. 1 This case was the subject of later discussion on the mechanism of the interaction. 2,3 One patient also developed extrapyramidal symptoms, 4 while another became stuporous when given both drugs. 5

(b) Paroxetine

A boy of about 10 years, with various disorders (motor tics, enuresis, attention deficit hyperactivity disorder, Tourette’s disorder, impulsivity, albinism) was treated for a year with pimozide 2 mg twice, and later three times daily. 6 Within 3 days of starting paroxetine 10 mg in the morning, he began to complain of his eyes hurting and his mother noted that about 4 hours after taking the paroxetine his eyes were rolled back in his head but the problem had resolved by the evening. This oculogyric crisis occurred on a further occasion, and so the paroxetine was stopped. There was no other evidence of either extrapyramidal or hyperserotonergic reactions. This case needs to be viewed in its particular context (oculogyric crises are associated with albinism) so that it may not be of general importance. In a study of a single 2-mg dose of pimozide given with paroxetine 60 mg daily, a 151% rise in pimozide AUC and a 62% rise in maximum plasma levels occurred. 7

(c) Sertraline

A study found that sertraline 200 mg daily caused a 40% rise in the AUC and maximum plasma levels of a single 2-mg dose of pimozide. No ECG changes were seen. 8,9

A fatality has been reported with an overdose of moclobemide, sertraline and pimozide, with blood levels suggesting that none of the drugs individually would have been fatal. 10

Mechanism

The SSRIs can, to varying degrees inhibit the cytochrome P450 isoenzyme CYP2D6 (and fluvoxamine possibly also inhibits CYP3A4) by which pimozide is metabolised. Concurrent use would therefore be expected to lead to raised pimozide levels.

Importance and management

Evidence is limited, however the interaction is potentially severe as raised pimozide levels can cause torsade de pointes arrhythmias, which can be fatal. The manufacturers of pimozide contraindicate its use with SSRIs, and in the UK they specifically name sertraline, paroxetine, and citalopram; which has been seen to cause QT prolongation with pimozide, and its isomer, escitalopram. 7 The US manufacturers additionally contraindicate fluvoxamine. 11 Neither manufacturer mentions fluoxetine (except with regard to the possibility of additive bradycardial), but as it is known to have greater effects on CYP2D6 than either sertraline or citalopram, it would seem prudent to also consider it as contraindicated.

Prochlorperazine + Metoclopramide

A single case report describes tongue swelling and respiratory obstruction in a patient given prochlorperazine and then metoclopramide.

Clinical evidence, mechanism, importance and management

A 19-year-old woman experienced progressive swelling of the tongue, partial upper-airways obstruction and a sensation of choking over a period of 12 hours after she was given intramuscular doses of metoclopramide to a total of 30 mg. She had received a 12.5-mg intramuscular dose of prochlorperazine for nausea 24 hours earlier. On examination her tongue was strikingly blue, but within 15 minutes of receiving benznatripne 2 mg it returned to its normal size and colour. The respiratory distress also disappeared. 1 The authors of the report suggested that the dystonic adverse effects of both drugs were additive, leading to the effects seen. 1 However, it should be noted that oedema of the tongue has also been described with metoclopramide alone. 2 Young patients, especially women, are particularly susceptible to the adverse effects of metoclopramide, and this patient received the standard total daily dose over just 12 hours, so an interaction is by no means established.

Promazine + Attapulgite-pectin

An attapulgite-pectin antidiarrhoeal preparation caused a small reduction in the absorption of promazine in one subject.

Clinical evidence, mechanism, importance and management

A study in one healthy subject found that attapulgite-pectin reduced the absorption of a single 50-mg dose of promazine by about 25%, possibly due to adsorption of the phenothiazine onto the attapulgite. 1 The clinical importance of this interaction and whether other phenothiazines behave similarly does not appear to have been studied. If a problem does occur, separating administration as much as possible (2 hours or more) to avoid admixture in the gut has been shown to minimise the effects of this type of interaction with other drugs.

Quetiapine + Antipsychotics

Quetiapine does not appear to interact with haloperidol or risperidone. Thioridazine moderately reduces quetiapine levels and a case report describes a seizure in a patient taking olanzapine and quetiapine.

Clinical evidence, mechanism, importance and management

In patients with schizophrenia or bipolar disorder given quetiapine 300 mg twice daily, thioridazine 200 mg twice daily reduced the steady-state quetiapine AUC and its maximum and minimum plasma levels by about 41%, 48% and 33%, respectively. It was suggested that this was due to an increased metabolism of quetiapine, although the mechanism for this effect was unclear. 1 These reductions are only moderate and their importance is not known, but until more information is available it would seem prudent to monitor concurrent use, being alert for the need to raise the quetiapine dosage.

A study in 19 Chinese patients who received quetiapine 200 mg twice daily and erythromycin 500 mg three times daily found that erythromycin increased the maximum plasma concentration, half-life and AUC of quetiapine by 68%, 92%, and 129%, respectively. These increases probably occurred because erythromycin inhibited the metabolism of quetiapine by CYP3A4.

The UK manufacturers advise caution if quetiapine is given with macrolides and azole antifungals, and suggest that lower quetiapine doses should be considered. The US manufacturers also advise caution, and specifically name itraconazole and fluconazole, erythromycin and protease inhibitors, all of which are inhibitors of CYP3A4.

Quetiapine slightly raised serum sodium levels in one study, but this was not statistically significant. Combined use did not increase the incidence of extrapyramidal symptoms in another study.

The steady-state serum lithium levels of 10 patients with schizophrenia, or schizoaffective or bipolar disorders were studied before, during, and after the concurrent use of quetiapine 250 mg three times daily. The lithium AUC, and the maximum serum levels were raised by 12% and 4.5%, respectively, by quetiapine, and concurrent use was well tolerated. This small rise was not statistically or clinically significant.

Quetiapine dose not appear to interact to a clinically relevant extent with cimetidine, fluoxetine, imipramine or lorazepam. Isolated cases of adverse outcomes have been reported with diphenhydramine, lovatatin and mirtazapine.

Clinical evidence, mechanism, importance and management (a) Antidepressants

Fluoxetine 60 mg daily or imipramine 75 mg twice daily for 5 days had no clinically significant effect on the steady-state plasma levels of quetiapine 300 mg twice daily. No special precautions would therefore appear to be necessary if either of these drugs and quetiapine are used concurrently.

A falsely elevated imipramine level was recorded when HPLC was used to determine serum imipramine levels in a patient taking imipramine, quetiapine, fluvoxamine, lithium and doxycycline. The abnormal readings were found to have been caused by a metabolite of quetiapine, and normal readings were obtained by altering the wavelength for detection of imipramine. Nortriptyline levels have been found to be falsely elevated in a patient also taking quetiapine when blood was analysed using fluorescence polarisation immunoassay, but were normal when an HPLC
analysis was undertaken. Other immunoassay methods for identifying tricyclic antidepressants in blood and urine have also given false positive results in the presence of quetiapine.

An isolated case of increased prolactin levels after the introduction of mirtazapine 15 mg daily has been reported in a woman who was taking quetiapine 400 mg daily. Her prolactin level normalised when the mirtazapine was stopped, but the challenge against this adverse effect was in actin levels, although this was transient and appeared to resolve within one month. The authors suggest that the mirtazapine may have caused an increase in quetiapine-induced dopamine receptor blockade, or alternatively an agonist action at opioid receptors altered dopamine receptor function.

(b) Cimetidine

Quetiapine 150 mg three times daily was given to 7 psychotic men with cimetidine 400 mg three times daily for 4 days. There were some slight alterations in the pharmacokinetics of the quetiapine, but these were within the intridualvar changes seen and so were not considered significant. There would therefore appear to be no reason for avoiding concurrent use.

(c) Diphenhydramine

A patient taking diphenhydramine 100 mg daily developed urinary retention when she increased her dose of quetiapine from 900 mg daily to 2.4 g daily. When the dose of quetiapine was reduced back to 900 mg daily, her urinary retention resolved. A further episode occurred when the patient again increased her quetiapine dose. Although quetiapine does not normally have antimuscarinic adverse effects at usual therapeutic doses, it is suggested by the authors that the likelihood of these adverse effects is increased at doses of quetiapine greater than 900 mg daily. This effect may have occurred as a result of additive antimuscarinic activity of both diphenhydramine and high-dose quetiapine.

(d) Lorazepam

The pharmacokinetics and pharmacodynamic effects of a single 2-mg dose of lorazepam were studied in 10 men taking quetiapine 250 mg three times daily. It was found that the maximum serum lorazepam levels were not significantly changed by quetiapine, and the alterations in the performance of a number of psychometric tests were small and considered not to be clinically relevant.

(e) Lovastatin

A patient taking quetiapine 800 mg daily and sertraline 100 mg daily developed a prolonged QTc interval of 569 milliseconds after starting to take lovastatin 10 mg daily. Following a reduction in the lovastatin dose to 5 mg daily, her QTc interval returned to her baseline of 424 milliseconds. It is suggested that lovastatin competitively inhibited the metabolism of quetiapine by CYP3A4, as both drugs are substrates for this enzyme, resulting in increased quetiapine levels. However, the full contribution of sertraline to this case was only briefly considered, and full details relating to the cardiac effects and calculation of the QTc interval are not given.

(f) Valproate

Analysis of plasma quetiapine levels of 94 patients, 9 of whom were also taking valproate, found a 77% increase in the concentration dose ratio compared with those patients not taking valproate. The US manufacturers report that valproate semisodium (divalproex sodium) increases the maximum plasma levels of quetiapine by 17%, and the UK manufacturers state that these changes are not clinically relevant.

### Risperidone + Carbamazepine or Oxcarbazepine

Carbamazepine increases the metabolism of risperidone, resulting in reduced risperidone levels. Oxcarbazepine does not significantly affect the pharmacokinetics of risperidone.

**Clinical evidence**

**Carbamazepine**

A 22-year-old man taking risperidone 4 mg daily and carbamazepine 600 mg daily for schizophrenia had lower than expected risperidone levels, so his dose was doubled and the carbamazepine tailed off. Ten days after carbamazepine had been discontinued it was noted that his plasma 9-hydroxyrisperidone level was 49 micrograms/L; it had only been 19 micrograms/L when he was taking carbamazepine. There are 4 other cases of this interaction between risperidone and carbamazepine. In one case, the addition of carbamazepine to established risperidone treatment resulted in a reduction in the risperidone and 9-hydroxyrisperidone levels of about 75% and 65%, respectively, accompanied by the return of the patient's psychotic symptoms. In 2 other cases, a 20-year-old and an 81-year-old man developed parkinsonian symptoms when carbamazepine was stopped. The symptoms resolved when the doses of risperidone were reduced by about two-thirds.

These cases are supported by a study in 5 patients taking carbamazepine and risperidone for schizophrenia or bipolar disorders. The dose-normalised plasma level of risperidone and its active metabolite, 9-hydroxyrisperidone, were 68% and 64% lower, respectively, with carbamazepine, when compared to those with risperidone alone. Another study in 11 patients who had been taking risperidone for 2 to 68 weeks found that carbamazepine 200 mg twice daily for a week approximately halved the plasma levels of risperidone and its active moiety (risperidone plus 9-hydroxyrisperidone).

**Oxcarbazepine**

A study in 12 patients taking risperidone 2 to 6 mg daily found that the addition of oxcarbazepine for 5 weeks, at an initial dose of 300 mg daily increased to 900 mg to 1.2 g after one week, had no significant effects on the pharmacokinetics of risperidone. Concurrent use was generally well tolerated.

**Mechanism**

Carbamazepine is a known potent enzyme inducer, which appears to increase the metabolism of risperidone by the cytochrome P450 isoenzyme CYP2D6 (although other isoenzymes may play a part). The extent of the interaction appears to be related to CYP2D6 genotype (see ‘Genetic factors’, (p.4)). Oxcarbazepine is not known to affect CYP2D6-mediated metabolism.

**Importance and management**

It would seem important to monitor the levels of risperidone and 9-hydroxyrisperidone in patients given carbamazepine, being alert for the need to raise the risperidone dosage, possibly by as much as two-thirds. Further mention that risperidone would moderately increase carbamazepine levels see ‘Carbamazepine + Antipsychotics’, p.524.

No special consideration or monitoring appears necessary with concurrent oxcarbazepine and risperidone treatment.
Itraconazole increases the plasma levels of both risperidone and its active metabolite, 9-hydroxyrisperidone.

Clinical evidence
A study in 19 patients who were taking risperidone 2 to 8 mg daily found that the addition of itraconazole 200 mg daily for a week increased the plasma levels of risperidone and its active metabolite, 9-hydroxyrisperidone, by 82% and 70%, respectively. The levels returned to pre-treatment values one week after the itraconazole was stopped. There was a small difference in the increase in the levels of risperidone between CYP2D6 extensive and poor metabolisers of risperidone, with extensive metabolisers showing a rise of 67% and poor metabolisers a rise of 70%.

Mechanism
Inhibition of metabolism of risperidone by the cytochrome P450 isoenzyme CYP3A is thought to cause the increased in levels. The difference in the increase in levels of the extensive and poor metabolisers indicates that CYP2D6 has a minor part in the metabolism of risperidone.

Importance and management

Risperidone + Itraconazole

Risperidone + Lithium

One small study found no interaction between risperidone and lamotrigine, although a case report describes increased risperidone levels on concurrent use, and a retrospective study suggests that lamotrigine increases the variability on risperidone levels.

Clinical evidence
An isolated case report describes markedly increased risperidone levels in a patient given increasing doses of lamotrigine. When the lamotrigine dose was increased from 175 mg daily to 200 mg daily, the risperidone level increased from 69 nanogram/mL to 263 nanogram/mL. A further increase in the lamotrigine dose to 225 mg daily, while maintaining the risperidone dose of 8 mg daily resulted in a risperidone plasma level of 412 nanogram/mL, and the patient complained of dizziness and tiredness.

Risperidone + Lamotrigine

Risperidone is metabolised by CYP2D6, but since lamotrigine is not a known inhibitor of this enzyme, a pharmacokinetic interaction was not thought to explain the change in levels. The retrospective review and small study above failed to find any evidence of a consistent effect of lamotrigine on risperidone pharmacokinetics. However in view of the case report above, and also the fact that some individuals in the review demonstrated large changes in their risperidone levels, it would seem prudent to monitor patients for an increase in adverse effects, or a lack of therapeutic effect, if lamotrigine is given with risperidone.

Mechanism, importance and management
Risperidone is metabolised by CYP2D6, but since lamotrigine is not a known inhibitor of this enzyme, a pharmacokinetic interaction was not thought to explain the change in levels. The retrospective review and small study above failed to find any evidence of a consistent effect of lamotrigine on risperidone pharmacokinetics. However in view of the case report above, and also the fact that some individuals in the review demonstrated large changes in their risperidone levels, it would seem prudent to monitor patients for an increase in adverse effects, or a lack of therapeutic effect, if lamotrigine is given with risperidone.

Clinical evidence, mechanism, importance and management
A case report describes a 42-year-old woman who developed extrapyramidal adverse effects of the mouth after the addition of risperidone to established lithium treatment. Her serum lithium level was 0.7 mmol/L. Symptoms resolved after intravenous promethazine was given. A non-diabetic patient developed diabetic ketoacidosis, 2 years after starting treatment with risperidone and lithium. During this acute illness he also experienced neuroleptic malignant syndrome and a myocardial infarction. The authors consider the combination of these two drugs was a causative factor, as the patient was able to continue treatment with lithium alone with no recurrence of this condition, or the need for antidiabetic medication. The manufacturers of risperidone state that there was no significant change in the AUC and maximum plasma concentration of lithium when it was taken with risperidone. In general no particular caution would seem necessary on concurrent use, but be aware that, in rare cases, adverse effects may occur.

Risperidone + Probenecid

Twelve healthy subjects were given a single 1-mg dose of risperidone alone, or on day 2 of a 4 day course of probenecid 500 mg

Twelve patients taking risperidone 3 mg to 6 mg daily, and who were also given levomepromazine, in doses of 5 mg to 75 mg daily.

Risperidone + Levomepromazine

Twelve changes in the pharmacokinetics of risperidone or its active metabolite, 9-hydroxyrisperidone, and there was no aggravation of extrapyramidal effects.

Clinical evidence, mechanism, importance and management
A case report describes a 42-year-old woman who developed extrapyramidal adverse effects of the mouth after the addition of risperidone to established lithium treatment. The authors consider the combination of these two drugs was a causative factor, as the patient was able to continue treatment with lithium alone with no recurrence of this condition, or the need for antidiabetic medication. The manufacturers of risperidone state that there was no significant change in the AUC and maximum plasma concentration of lithium when it was taken with risperidone. In general no particular caution would seem necessary on concurrent use, but be aware that, in rare cases, adverse effects may occur.
twice daily. There were no significant changes in the pharmacokinetics of risperidone.1

**Risperidone + Protease inhibitors**

The neuroleptic malignant syndrome, ataxia and severe lethargy leading to a coma, and extrapyramidal adverse effects have been seen in patients given risperidone with indinavir and ritonavir.

**Clinical evidence, mechanism, importance and management**

A 35-year-old man with AIDS was diagnosed with a Tourette’s-like disorder and given risperidone 1 mg twice daily. After 2 weeks the risperidone was increased to 2 mg twice daily and he was also given indinavir 800 mg twice daily with ritonavir 200 mg twice daily. He discontinued the antiretrovirals after 5 days due to nausea, but started them again 1 month later when the tic disorder had improved. After 1 week he became short of breath and fatigued with worsening tremor and other extrapyramidal adverse effects. The antiretrovirals were stopped and the risperidone dose increased to 3 mg twice daily. Over the next 3 days his symptoms worsened and began to interfere with daily living. Risperidone was discontinued and clonazepam started, and his symptoms resolved. Another patient developed neureleptic malignant syndrome 3 days after starting to take risperidone with indinavir and ritonavir. This patient also recovered when the risperidone was stopped.2 A third patient taking indinavir and ritonavir was given risperidone 3 mg twice daily to treat symptoms of mania. After 2 doses he became ataxic, drowsy and disoriented, which further developed into lethargy and coma. He recovered 24 hours after stopping all medication.3  

**Indinavir** inhibits the cytochrome P450 isoenzyme CYP3A4 and ritonavir inhibits CYP2D6 and CYP3A4, which are the main isoenzymes involved in the metabolism of risperidone. Therefore concurrent use would be expected to raise risperidone levels. The symptoms reported in the cases above may have all been due to increased risperidone levels.1,3 These appear to be the only reports of an interaction between risperidone and protease inhibitors, and their general significance is unclear. Until more is known it would be prudent to monitor patients taking risperidone who are given these protease inhibitors, particularly ritonavir, for risperidone adverse effects.

**Risperidone + Reboxetine**

No clinically relevant pharmacokinetic interaction appears to occur between risperidone and reboxetine.

**Clinical evidence, mechanism, importance and management**

Reboxetine 8 mg daily was given to 7 schizophrenic patients taking risperidone 8 mg daily for a period of 3 weeks. Reboxetine had no significant effects on the pharmacokinetics of either risperidone or its active metabolite, 9-hydroxyrisperidone, suggesting that no additional precautions are necessary if reboxetine and risperidone are used together.5

**Risperidone + SSRIs**

Fluoxetine, fluvoxamine, and paroxetine appear to raise risperidone levels. Sertraline appears to only moderately increase risperidone levels at high doses. The combination of SSRIs and risperidone is generally useful, but has resulted in a number of adverse effects including priapism, extrapyramidal effects and the serotonin syndrome.

**Clinical evidence**

(a) **Citalopram**

A study in 7 patients found that citalopram had no effect on the plasma levels of risperidone or its active metabolite 9-hydroxyrisperidone.1 A 29-year-old man with idiopathic priapism, about one 4-hour erection every 1 to 2 months, which typically woke him up, began to experience much longer bouts lasting 6 to 8 hours when he was given risperidone 4 mg daily. Within about 4 weeks of adding citalopram 40 mg daily to a slightly reduced risperidone dose (3 mg daily), he began to have almost daily erections lasting 12 hours. Three days after his dosages were changed to risperidone 3 mg twice daily with citalopram 20 mg daily he had an episode of such persistent priapism that emergency detumescence was needed. When both drugs were stopped he improved markedly and then only had occasional 4-hour erections, as before.5

(b) **Fluoxetine**

A pharmacokinetic study in 10 patients found that fluoxetine 20 mg daily raised the levels of risperidone 2 or 3 mg twice daily from 12 to 19 nanograms/mL after 3 weeks and to 56 nanograms/mL after 4 weeks. All patients experienced a rise in risperidone levels, but this varied from two to tenfold. One patient withdrew from the study because of severe akathisia and another two patients needed treatment with biperiden to control parkinsonian adverse effects.1 Similar findings were found in another study.4

A 30-year-old woman taking valproate, clonazepam, and risperidone 3 mg daily for schizophrenia was also given fluoxetine 5 mg daily for a depressive disorder. The depression improved, but she noticed painful bilateral breast enlargement, which resolved when risperidone was stopped. Similar symptoms were noted when the risperidone was later restarted.5 An 18-year-old developed extrapyramidal adverse effects, and later persistent dyskinetic tongue movements when given fluoxetine and risperidone,6 and a 46-year-old man taking risperidone 2 mg daily developed urinary retention, extrapyramidal adverse effects, sedation and constipation, which developed over 10 days after fluoxetine 20 mg daily was started.7 A 26-year-old man developed severe tardive dyskinesia during treatment with risperidone and fluoxetine.8 A deterioration in obsessive-compulsive disorder has been seen when risperidone 3 mg daily was started in a patient who was partially successfully treated with fluoxetine 60 mg daily. After the addition of risperidone his condition returned to his pre-fluoxetine state. His condition gradually improved over a 3-month period once the risperidone was stopped. It was suggested that inhibition of metabolism of risperidone by fluoxetine may have resulted in elevated risperidone levels, leading to a deterioration in his condition.9

(c) **Fluvoxamine**

A 24-year-old woman taking risperidone 3 mg twice daily developed fever, limb rigidity, and confusion 3 days after starting fluvoxamine 50 mg daily. She required ventilation after her condition worsened and was eventually diagnosed as having either the serotonin syndrome or neuroleptic malignant syndrome. Both drugs were stopped and her condition resolved. She was later successfully treated with fluvoxamine 100 mg twice daily.10 A study, 6 patients who had been taking risperidone 3 to 6 mg daily for at least 4 weeks, with fluvoxamine 100 mg daily for a further 8 weeks, found no changes in the pharmacokinetics of risperidone or its metabolite. However, 5 patients also enrolled into this study were increased to fluvoxamine 200 mg daily for weeks 5 to 8, and there was an 85% increase in plasma risperidone levels by the end of week 8. There was no change in the pharmacokinetics of the active metabolite, 9-hydroxyrisperidone and no adverse reactions to risperidone were noted.11

(d) **Paroxetine**

Paroxetine 20 mg daily was given to 10 patients taking risperidone 2 to 4 mg twice daily. After 4 weeks paroxetine had increased the levels of risperidone and its active metabolite, 9-hydroxyrisperidone, by 45%. Although the combination was generally well-tolerated one patient developed parkinsonian adverse effects.12 Another study was undertaken in 12 patients taking risperidone 2 mg twice daily and paroxetine in doses increasing from 10 mg daily to 20 mg and 40 mg at 4 week intervals. The plasma levels of risperidone were increased 3.8-fold, 7.1-fold and 9.7-fold when given with paroxetine 10 mg, 20 mg and 40 mg daily, respectively. There was no change in the pharmacokinetics of the active metabolite,
9-hydroxyrisperidone. Negative symptoms of schizophrenia were improved, but there was an increased incidence of extrapyramidal adverse effects when patients took paroxetine 20 mg or 40 mg daily. 13

A case report describes two elderly patients taking paroxetine who developed the serotonin syndrome within a couple of days of a risperidone dose increase. One patient’s treatment had recently been changed from venlafaxine to paroxetine, which may have contributed to the reaction 14 (see ‘SNRIs; Venlafaxine + Antidepressants’, p.1212). A further case report describes a 53-year-old man who developed the serotonin syndrome 10 weeks after starting to take risperidone 3 mg daily and paroxetine 20 mg daily. A deterioration in his condition occurred within 2 hours of doubling the dose of both drugs. His symptoms resolved 2 days after stopping both drugs. 15

**Mechanism**

Fluoxetine and paroxetine inhibit the cytochrome P450 isoenzyme CYP2D6 by which risperidone is metabolised, hence risperidone levels rise. This can lead to extrapyramidal adverse effects and, it has been suggested, the increased prolactin levels and gynaecomastia seen in one patient. 3 Sertraline is thought to have a dose-dependent effects on CYP2D6 inhibition. 16

Many of the other reactions (sedation, urinary retention, priapism) appear to be a result of additive adverse effects of the SSRIs and risperidone. The serotonin syndrome can result when two drugs with serotonin effects are given together, see ‘Additive or synergistic interactions’, (p.9).

**Importance and management**

The elevated risperidone levels seen with fluoxetine and paroxetine appear to be well-documented and clinically significant. The manufacturers of risperidone 1, 7, 18 say that when adding either of these SSRIs the risperidone dose should be re-evaluated (presumably decreased). A one-third reduction in the risperidone dose has been suggested with fluoxetine. 4 The concurrent use of risperidone and sertraline in usual therapeutic doses appears to be safe and well-tolerated. The significance of the raised risperidone levels in the two patients taking high-dose sertraline is unclear, however neither patient developed risperidone toxicity. The case reports of the serotonin syndrome appear to be rare, but they should be borne in mind when prescribing SSRIs and risperidone together.

**Risperidone + Tetracycline**

A patient experienced a worsening of his tics when tetracycline was added to treatment with risperidone and sertraline.

**Clinical evidence, mechanism, importance and management**

A 15-year-old boy taking risperidone 1.5 mg twice daily and sertraline 100 mg daily was given tetracycline 250 mg twice daily. His tics worsened, and did not respond to an increase in his sertraline dosage from 100 mg to 150 mg daily. After stopping the tetracycline, his tics improved within a few weeks. The exact mechanism of this interaction is unclear, but it has been suggested that the tetracycline somehow reduced the activity of the risperidone. Induction of CYP2D6 by tetracycline was thought unlikely, and inactivation of the risperidone or its active metabolite was considered a possible explanation. 1 This appears to be the only reported case of this interaction and its general significance is unknown.

**Risperidone + Tricyclic and related antidepressants**

No pharmacokinetic interaction normally occurs between risperidone and amitriptyline or mirtazapine, but extrapyramidal reactions have been reported in one patient taking amitryptiline with risperidone.

**Clinical evidence, mechanism, importance and management**

(a) Amitriptyline

A study in 12 schizophrenic patients found that amitriptyline 50 to 100 mg daily had no effect on the serum levels of risperidone 3 mg twice daily. 1 However, a 26-year-old man taking amitriptyline 25 mg daily developed extrapyramidal reactions after his dosage of risperidone was increased from 2 to 4 mg daily. 2 On another occasion extrapyramidal adverse effects developed after risperidone 2 mg daily was added to treatment with amitriptyline 25 mg and fluoxetine 20 mg daily. 3 Both pharmacokinetic and pharmacodynamic reasons for this reaction have been suggested. 3 The cases illustrate that there is the potential for an adverse interaction between these drugs, which should be borne in mind when prescribing both drugs.

(b) Mirtazapine

A study in 8 patients taking risperidone in doses ranging from 3 to 8 mg daily found no significant change in the pharmacokinetics of risperidone and its metabolite, 9-hydroxyrisperidone when they were also given mirtazapine 30 mg daily.

**Risperidone + Valproate**

There are case reports describing oedema in patients taking risperidone and sodium valproate. Studies suggest that risperidone does not alter the pharmacokinetics of sodium valproate or valproic acid.
Risperidone + Venlafaxine

No clinically relevant pharmacokinetic interaction appears to occur between risperidone and venlafaxine.

Clinical evidence, mechanism, importance and management

Risperidone and venlafaxine have been studied in healthy volunteers. A healthy volunteer study showed no change in the pharmacokinetics of risperidone when co-administered with venlafaxine.1

Ritanserin + Miscellaneous

Ritanserin does not interact with alcohol, cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given ritanserin 10 mg with and without alcohol 0.5 g/kg found no pharmacokinetic or pharmacodynamic interactions between these drugs.1 Cimetidine 800 mg daily or ranitidine 300 mg daily given to 9 healthy subjects for 11 days caused only small changes in the pharmacokinetics of a single 10-mg dose of ritanserin given on day 3. These changes were attributed to altered absorption,2 but were of little or no clinical significance.

Sertindole + Miscellaneous

The manufacturers of sertindole contraindicate the concurrent use of cimetidine, diltiazem, erthyromycin, itraconazole, ketoconazole, terfenadine and verapamil because of an increased risk of cardiac arrhythmias. Carbamazepine and phenytoin reduce plasma sertindole levels whereas fluoxetine and paroxetine increase them. No clinically relevant interactions occur with alprazolam, antacids, food or tobacco smoking.

Clinical evidence, mechanism, importance and management

(a) Antacids or Food

A standardized breakfast or Maalox 45 mL had no significant effect on the AUC of a single 4-mg dose of sertindole in 16 healthy subjects, and only minor and unimportant changes occurred in maximum serum levels.3,4 No special precautions are needed if sertindole is given with Maalox, and it may be given without regard to meals.

(b) Antiepileptics

The metabolism of sertindole is markedly increased by enzyme inducers, such as phenytoin and carbamazepine, and plasma sertindole levels may be reduced by 2 to 3-fold. The manufacturers therefore say that the daily dosage of sertindole may need to be increased towards the upper end of the maximum dosage range to accommodate this interaction.3,4

(c) Azoles

No formal studies have been carried out on the use of sertindole with either itraconazole or ketoconazole, but because both of these antifungals are potent inhibitors of CYP3A it is expected that a marked rise in serum sertindole levels may occur if they are given. The manufacturers therefore say that concurrent use is contraindicated because elevated serum levels are associated with a prolongation of the QTc interval and an increased risk of cardiac arrhythmias.

(d) Benzodiazepines

A pharmacokinetic study in 14 healthy subjects found only minor changes in pharmacokinetics of a single 1-mg dose of alprazolam due to the presence of sertindole 12 mg daily. The changes were considered to be clinically unimportant.5

(e) Calcium-channel blockers

Studies in patients found that diltiazem, nifedipine or verapamil resulted in a 20% reduction in the sertindole clearance, attributed to inhibition of CYP3A metabolism.6 The manufacturers contraindicate concurrent use of diltiazem and verapamil (specifically named) as raised sertindole levels may prolong the QT interval.3

(f) Cimetidine

Because cimetidine is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A it is expected that sertindole levels may be increased. The manufacturers therefore contraindicate concurrent use as raised sertindole levels may prolong the QT interval.3

(g) Erythromycin

A single 4-mg dose of sertindole was given to 10 healthy subjects before and after a course of erythromycin 250 mg every 6 hours for 10 days. The mean maximum serum levels were increased by 15%, probably because erythromycin inhibits the cytochrome P450 isoenzyme CYP3A4, but this was not considered to be clinically significant. The incidence of adverse events also rose (diarrhoea, abdominal pain, dizziness) but no ECG changes were seen.6,7 Nevertheless the manufacturers contraindicate erythromycin because raised sertindole levels may prolong the QT interval.3
note that intravenous erythromycin is itself associated with prolongation of the QT interval, see ‘drugs that prolong the QT interval’, (p.257).

(f) Protease inhibitors

The protease inhibitor are all, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4 by which sertindole is metabolised. The manufacturers therefore contraindicate concurrent use, as raised sertindole levels may lead to torsade de pointes arrhythmias, which are potentially life-threatening.

(i) SSRIs

Fluoxetine and paroxetine are inhibitors of the cytochrome P450 isoenzyme CYP2D6. Concurrent use results in a two- to three-fold increase in sertindole plasma levels. The manufacturers advise that low maintenance doses of sertindole may be needed and recommend close ECG monitoring when doses are adjusted. An isolated case report describes a man with paranoid psychosis and unipolar depression whose condition unexpectedly seriously worsened when paroxetine was stopped while continuing to take sertindole.

(j) Terfenadine

A single 120-mg dose of terfenadine was given to 14 healthy subjects who had taken sertindole 20 mg daily for 5 days. The pharmacokinetics of neither drug was significantly changed, nor that of the metabolite of terfenadine (carboxyterfenadine), although it was concluded that sertindole may be a modest inhibitor of the first pass metabolism of terfenadine. However, it was found that the combination caused an additive increase of 49 milliseconds in the QTc interval and therefore these two drugs are contraindicated by the manufacturer.

(k) Tobacco

The clearance of sertindole is increased by tobacco smoking (probably because of the induction of cytochrome P450 isoenzymes) but no sertraline dosage alteration is thought necessary.

Thioridazine + Naltrexone

Extreme lethargy occurred when two patients taking thioridazine were given naltrexone.

Clinical evidence, mechanism, importance and management

Two schizophrenic patients taking thioridazine 50 to 200 mg three times daily for at least one year took part in a pilot project to assess the efficacy of naltrexone for the treatment of tardive dyskinesias. Both patients tolerated the first challenge dose of intravenous naltrexone 800 micrograms without problems, but experienced extreme lethargy and slept almost continuously after the second naltrexone dose of 50 to 100 mg orally. The severe lethargy resolved within 12 hours of stopping the naltrexone. The reasons for this reaction are not understood. Information seems to be limited to this report and the general importance of this interaction is unknown. There seems to be nothing documented about other phenothiazines. Note that a case report has described excessive sleepiness and lethargy in a 58-year-old man who took a single 100-mg dose of naltrexone alone, so an interaction is by no means established.

Thioridazine + Phenylpropanolamine

A single case report describes fatal ventricular fibrillation, which was attributed to the use of thioridazine with phenylpropanolamine.

Clinical evidence, mechanism, importance and management

A 27-year-old schizophrenic woman who was taking thioridazine 100 mg daily and procyclidine 2.5 mg twice daily was found dead in bed 2 hours after taking a single capsule of Contac C (phenylpropanolamine 50 mg with chlorphenamine 4 mg). The principal cause of death was attributed to ventricular fibrillation. Just why this happened is not understood but it is suggested that it may have been due to the combined effects of the thioridazine (known to be cardiotoxic and to cause T-wave abnormalities) and the phenylpropanolamine (possibly able to cause ventricular arrhythmias). The clinical importance of this alleged interaction is uncertain but the authors of the report suggest that ephedrine-like drugs such as phenylpropanolamine should not be given to patients taking thioridazine or mesoridazine.

Tiotixene + Enzyme inhibitors

A group of patients taking enzyme inhibitors (cimetidine, doxepin, ioniazid, nortriptyline, propranolol) had a tiotixene clearance of 9.51 L/minute, which was 71% less than that seen in patients taking tiotixene alone. It seems possible that the tiotixene dose will need to be reduced in those taking these drugs but this needs confirmation. Monitor concurrent use for tiotixene adverse effects and adjust the dose accordingly.

Trifluoperazine + Venlafaxine

A case of neuroleptic malignant syndrome has been reported in a patient taking trifluoperazine 1 mg daily who then took one dose of venlafaxine 75 mg. This may have occurred as a result of dopamine inhibition by the two drugs. A suggestion that the symptoms seen may have been due to ‘the serotonin syndrome’, (p.9), has also been made.

Ziprasidone + Carbamazepine

Low doses of carbamazepine do not appear to affect the pharmacokinetics of ziprasidone.

Clinical evidence, mechanism, importance and management

In a randomised study, healthy subjects were given ziprasidone 20 mg twice daily with either placebo (10 subjects), or carbamazepine 200 mg twice daily for 5 doses (9 subjects). It was found that the AUC$_{0,12}$ and maximum serum levels of ziprasidone were reduced by 36% and 27%, re-
respectively, in the carbamazepine group. It was concluded that while induction of the cytochrome P450 isoenzyme CYP3A4 by carbamazepine is responsible for this modest reduction in the steady-state levels of ziprasidone, the extent is not clinically relevant.1 No special precautions would seem to be needed with this dosage of carbamazepine,1 but there is the possibility that higher doses may interact to a greater extent. In this situation it would be prudent to monitor concurrent use to ensure ziprasidone is effective.

A single 40-mg oral dose of ziprasidone were given to 10 healthy subjects with smoking or non-smoking status. The implication being that any orthostatic hypotension may possibly be worsened. If patients feel faint and dizzy when they stand up, they should be advised to get up more slowly, and if necessary, a smaller dosage should be used.1

Ziprasidone + Ketoconazole

Ketoconazole moderately increases ziprasidone levels but this is not expected to be clinically relevant.

Clinical evidence, mechanism, importance and management

Ketoconazole is effective. It would be prudent to monitor concurrent use to ensure ziprasidone is effective. In this situation it would be prudent to monitor concurrent use to ensure ziprasidone is effective.

Ziprasidone + Lithium

Ziprasidone does not appear to alter the pharmacokinetics of lithium.

Clinical evidence, mechanism, importance and management

Ziprasidone does not appear to alter the pharmacokinetics of lithium. A randomised, placebo-controlled study in 14 healthy subjects were given a 40-mg dose of ziprasidone before and after taking ketoconazole 400 mg daily for 6 days. It was found that ketoconazole increased the AUC and maximum serum levels of ziprasidone by 33% and 34%, respectively. This modest rise in levels probably occurs because ketoconazole inhibits the cytochrome P450 isoenzyme CYP3A4 by which ziprasidone is metabolised. However, it was concluded that the increase is not clinically relevant.1 No special precautions would therefore seem to be needed on concurrent use.

Ziprasidone + Miscellaneous

The manufacturers warn of the possible risks of giving ziprasidone with drugs that prolong the QT interval, and of the possible antagonism that may occur with levodopa and other dopamine agonists. Ziprasidone appears not to interact to a clinically relevant extent with an aluminium/magnesium hydroxide antacid, benzatropine, cimetidine, lorazepam, propranolol or tobacco smoking.

Clinical evidence, mechanism, importance and management

Clinical evidence, mechanism, importance and management

(a) Antacids or Cimetidine

A single 40-mg oral dose of ziprasidone were given to 10 healthy subjects either alone, with cimetidine 800 mg daily for 2 days, or with three 30-mL doses of Maalox (aluminium/magnesium hydroxide). The only change in the pharmacokinetics of ziprasidone was a 6% increase in the AUC with cimetidine. It was concluded that no special precautions are needed if either of these drugs and ziprasidone are given concurrently, and that any inhibition of the cytochrome P450 isoenzyme CYP3A4 is irrelevant because alternative metabolic pathways are available. The results of the study with cimetidine also suggest that other non-specific inhibitors of cytochrome P450 are unlikely to alter the pharmacokinetics of ziprasidone.

(b) Drugs that prolong the QT interval

Studies in healthy subjects found that ziprasidone 160 mg increased the QTc interval by about 10 milliseconds. While only a relatively moderate increase in the QT interval actually occurs with ziprasidone, because of the possibility of additive effects with some other drugs (and the attendant risk of torsade de pointes), to be on the safe side the manufacturers of ziprasidone contraindicate its use with other drugs that can prolong the QT interval.2 A list of QT-prolonging drugs is to be found in Table 9.2, p.257. A case has been reported of a 70-year-old man who took quetiapine and ziprasidone and who developed cardiac arrhythmias with extrasystoles, and a prolonged QTc interval of 482 milliseconds, an increase of 65 milliseconds from his value with quetiapine alone. On stopping quetiapine and reducing the dose of ziprasidone, his QTc interval normalized.

(c) Levodopa and dopamine agonists

The mechanism by which ziprasidone acts to control schizophrenia is not understood, but it is known to be an antagonist of dopamine type 2 (D2) receptors and therefore it may possibly oppose the effects of levodopa and other dopamine agonists. There seem to be no clinical reports of problems during concurrent use, but good monitoring would be advisable if ziprasidone is given with any dopamine agonist.

(d) Miscellaneous drugs

The manufacturers say that population pharmacokinetic analysis of schiz- ophrenic patients who were enrolled in clinical studies showed that no significant pharmacokinetic interactions occurred with benzatropine, lorazepam or propranolol.2 The manufacturers also point out that since ziprasidone is not metabolised by the cytochrome P450 isoenzyme CYP1A2, smoking should not affect its pharmacokinetics. This is borne out by studies in patients, which did not reveal any differences in the pharmacokinetics of ziprasidone between tobacco smokers and non-smokers.2

Zotepine + Zotepine

Zotepine is a dopamine antagonist. It may be additive with other antipsychotics, particularly if high doses of either or both drugs are used.

Zotepine + Miscellaneous

There appears to be little or no information about adverse interactions between zotepine and other drugs, but the manufacturers warn about the concurrent use of antihypertensives, anaesthetics, antipsychotics, and drugs that prolong the QTc interval. Two cases of deep vein thrombosis have been reported in patients taking zotepine with paroxetine.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

Zotepine has alpha-adrenergic blocking properties, which may cause orthostatic hypotension, especially when treatment is first started or if the dosage is increased. The manufacturers advise caution when it is given with hypotensive agents, including some anaesthetics, the implication being that any orthostatic hypotension may possibly be worsened. If patients feel faint and dizzy when they stand up, they should be advised to get up more slowly, and if necessary, a smaller dosage should be used.1

(b) Antimuscarinics

Biperiden 6 mg daily for 2 weeks was found not to affect the pharmacokinetics of zotepine in a study in 21 patients.2

(c) Antipsychotics

The manufacturers point out that, as with some other antipsychotics, zotepine has clear pro-convulsive effects, which may be additive with other antipsychotics, particularly if high doses of either or both drugs are used.
They therefore recommend that zotepine doses above 300 mg daily or the concurrent use of high doses of other antipsychotics should be avoided.1

(d) Desipramine

No pharmacokinetic interaction was seen when zotepine was given with desipramine, indicating that the cytochrome P450 isoenzyme CYP2D6 is not involved in the metabolism of zotepine.1

(e) Diazepam or Fluoxetine

In a clinical interaction study, fluoxetine and diazepam increased the plasma concentrations of zotepine and norzotepine. The manufacturers advise caution if these drugs are given concurrently.1

(f) Drugs that prolong the QT interval

The manufacturers of zotepine advise caution when treating patients taking drugs known to prolong the QTc interval (or those with coronary heart disease or at risk of hypokalaemia) because zotepine also shows a dose-related QTc interval prolongation,1 the implication being that the effects may be additive. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

(g) Paroxetine

Two case reports have described mobile, elderly male patients who developed deep vein thrombosis when taking paroxetine and zotepine. In the first case the patient was taking paroxetine 40 mg daily, and zotepine was added to his treatment 3 weeks later, initially at a dose of 75 mg daily, then increased to 150 mg daily. After 17 days of treatment with zotepine 150 mg daily the patient developed significant swelling of the right leg, and a deep vein thrombosis was diagnosed by Doppler studies and venography. The second patient also received paroxetine 40 mg daily to which was added zotepine 150 mg daily, and within 3 days of starting zotepine, the patient had developed painful swelling of the right calf, dyspnœa and tachycardia. A deep vein thrombosis was confirmed. They were part of a review of 150 patients consecutively admitted to a psychiatric ward. They were the only two patients who received this combination of drugs, and the only two who developed a thromboembolism. The mechanism of this interaction is unclear.3

This section is concerned with the drugs used to treat viral infections. These drugs may be grouped by the viral infections they are used to treat, and also by drug class (see ‘Table 21.1’, (p.773)). Where antivirals affect other drugs the interactions are generally covered elsewhere.

**Antivirals active against herpes**

*(a) Nucleoside analogues*

The nucleoside analogues are principally eliminated unchanged by the kidneys by a process of active tubular secretion as well as glomerular filtration. The few interactions with these drugs mainly involve altered renal clearance (e.g. probenecid), but since they have a wide therapeutic range, even these interactions are of debatable clinical relevance. Cytochrome P450-mediated interactions are not important for this group of drugs.

*(b) Fusion inhibitors*

Fusion inhibitors do not cause cytochrome P450-mediated interactions and CYP3A4 inhibitors (e.g. protease inhibitors) increase its levels. CYP3A4. Because of this, CYP3A4 inducers (e.g. efavirenz) lower its levels. Maraviroc is the nearest to marketing, and is a substrate of CCR5 antagonists.

*(c) Non-nucleoside reverse transcriptase inhibitors (NNRTIs)*

The NNRTIs are extensively metabolised by the cytochrome P450 isoenzyme system, particularly by CYP3A4. All of them inhibit CYP3A4, with ritonavir being the most potent inhibitor, followed by indinavir, nelfinavir, amprenavir, and saquinavir. The protease inhibitors therefore have the potential to interact with other drugs metabolised by CYP3A4, and are affected by CYP3A4 inhibitors and inducers. Ritonavir and nelfinavir also affect some other cytochrome P450 isoenzymes, as summarised in ‘Table 21.2’, (p.773). In addition, protease inhibitors are substrates as well as inhibitors of P-glycoprotein. Protease inhibitors therefore have the potential to interact with each other, and with NNRTIs, but are not likely to interact with NRTIs.

The plasma level of protease inhibitors is thought to be critical in maintaining efficacy and minimising the potential for development of viral resistance. Therefore even modest reductions in levels are potentially clinically important.

</table>
Aciclovir and related drugs + Antacids

Valaciclovir does not interact with an aluminium/magnesium hydroxide antacid.

Clinical evidence, mechanism, importance and management

On three separate occasions, 18 healthy subjects were given a single 1-g oral dose of valaciclovir, either alone, 65 minutes before, or 30 minutes after they took 30 mL of Maalox (aluminium/magnesium hydroxide). The pharmacokinetics of aciclovir (the active metabolite of valaciclovir) remained unchanged. It was concluded that no special precautions are needed if these drugs are taken together, and the authors of the report also suggest that it is unlikely that other antacids will interact.1

Aciclovir and related drugs + Cephalosporins

Retrospective data from children suggest that ceftriaxone might have increased the renal toxicity of intravenous aciclovir. Cefalexin does not appear to alter the absorption of valaciclovir to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Cefalexin

In a single-dose, crossover study involving 16 healthy subjects, the concurrent use of cefalexin 500 mg and valaciclovir 500 mg caused only a minimal mean 7.1% reduction in the AUC of aciclovir (the metabolite of valaciclovir). However, this reduction was only seen if one subject who had an increase in aciclovir AUC was excluded. Furthermore, there was considerable interindividual variability in the effects of cefalexin. Both cefalexin and valaciclovir are substrates for human peptide transporter 1 (hPEPT1), and in vitro and animal data indicated that cefalexin might markedly reduce valaciclovir absorption.1 However, the findings in this clinical study show a minimal interaction. No special precautions appear to be needed on concurrent use.

(b) Ceftriaxone

A retrospective analysis of 17 children who had received intravenous aciclovir and ceftriaxone for suspected meningococcemia revealed that 12 developed a significant increase in serum creatinine, and three of these developed acute renal failure. This rate of renal toxicity is higher than that seen with aciclovir alone, and was attributed to the concurrent use of ceftriaxone. The dose of aciclovir correlated with nephrotoxicity. The authors concluded that caution is required with the combination, and that renal function should be monitored if both drugs are used.2

Aciclovir and related drugs + Cimetidine

Single-dose studies have found that cimetidine increases the AUC of aciclovir and valaciclovir, but this is thought unlikely to be clinically important. No clinically important interaction appears to occur if famciclovir is given with cimetidine.

Clinical evidence

(a) Aciclovir or Valaciclovir

Twelve healthy subjects were given a 1-g dose of valaciclovir alone or with cimetidine 800 mg, taken 10 hours and 1 hour before. The AUC0-3 for the prodrug valaciclovir was increased by 73% by cimetidine, and the AUC0-24 for the active metabolite of valaciclovir, aciclovir, was increased by 27%. The renal clearance of aciclovir was reduced by 22%, although the total urinary recovery of aciclovir was unchanged.1

(b) Famciclovir

In a study, 12 healthy subjects were given cimetidine 400 mg twice daily for 8 days with a single 500-mg dose of famciclovir, a prodrug for penciclovir, on the last day. The AUC of penciclovir was increased by about 18% by cimetidine, but there was no change in renal clearance.2,3

Mechanism

The increase in aciclovir AUC with cimetidine is attributable to a reduction in its renal excretion, probably due to competition for secretion by the kidney tubules.1 When ‘probencid’ (p.775), a renal tubular secretion inhibitor, and cimetidine were both given the effects on aciclovir were greater than either drug alone.4 Cimetidine does not significantly alter the pharmacokinetics of famciclovir/penciclovir.3

Importance and management

These interactions are established but, because aciclovir has such a wide therapeutic index,4 the authors of the study suggest that its interaction with cimetidine is probably clinically unimportant.1 It seems likely that no changes in the usual dosages of aciclovir or valaciclovir will be needed in patients also taking cimetidine. However, the UK manufacturer states that caution is required with high doses of valaciclovir, and that alternatives to cimetidine could be considered in this situation.4 No special precautions would seem necessary if cimetidine is used with famciclovir.

Aciclovir and related drugs + Hydrochlorothiazide

Hydrochlorothiazide does not affect the pharmacokinetics or safety profile of aciclovir.

Clinical evidence, mechanism, importance and management

A study in a group of elderly subjects (65 to 83 years old) given valaciclovir 500 mg or 1 g three times daily for 8 days found that its safety profile was unchanged in the presence of hydrochlorothiazide, and was similar to that in young healthy subjects.1 The pharmacokinetics of the active metabolite of valaciclovir, aciclovir, were not significantly different.1 There would seem to be no reason for avoiding the concurrent use of either valaciclovir or aciclovir and hydrochlorothiazide.

Aciclovir and related drugs + Mycophenolate

The concurrent use of aciclovir or ganciclovir and mycophenolate mofetil does not appear to significantly affect the pharmacokinetics of either drug, but the manufacturers recommend care in renal impairment. There are reports of neutropenia in patients taking mycophenolate with valaciclovir or ganciclovir.

Clinical evidence, mechanism, importance and management

(a) Aciclovir or Valaciclovir

In a three-period crossover study healthy subjects were given a single dose of oral aciclovir 800 mg and mycophenolate mofetil 1 g, both together and alone. The renal clearances of both drugs were not significantly altered by concurrent use. The AUC of aciclovir was increased by about 17% (not statistically significant), that of mycophenolic acid by about 9% (not significant), and that of the glucuronide metabolite of mycophenolate by about 9%. It was concluded that none of these changes was likely to be clinically significant.1,2 In another single-dose study in healthy subjects, a
bigger 31% increase in the AUC of aciclovir was seen when it was given with mycophenolate mofetil: there were no changes to mycophenolic acid pharmacokinetics. The concurrent use of valaciclovir 2 g with mycophenolate mofetil 1 g did not alter aciclovir pharmacokinetics, and the only change in mycophenolate pharmacokinetics was a 12% decrease in AUC of its glucuronide metabolite. None of these changes are likely to be clinically important in patients with normal renal function. The manufacturers of mycophenolate state that, in renal impairment there may be competition for tubular secretion and that further increases in concentrations of both aciclovir and mycophenolate may occur.4,5

Note that some data suggest that mycophenolate potentiates the antiherpes virus activity of aciclovir, which may be clinically useful.9 There is a case report of a renal transplant patient taking, amongst other drugs, mycophenolate mofetil 1 g twice daily who developed neutropenia after starting valaciclovir 6 g daily for prophylactic treatment of a cytomegalovirus infection after successful treatment with ganciclovir. The neutropenia resolved on stopping the valaciclovir. The authors suggested that mycophenolate may increase the haematotoxic effect of valaciclovir especially at high doses.7 Neutropenia is a rare adverse effect of valaciclovir alone. Bear the possibility of an interaction in mind should neutropenia occur with the combination.

(b) Ganciclovir or Valganciclovir

A crossover study in 12 transplant patients found no pharmacokinetic interaction between a single 1.5-g oral dose of mycophenolate mofetil and intravenous ganciclovir 5 mg/kg, but the renal clearance of ganciclovir was slightly reduced, by 12%.8 However, the manufacturers note that it is anticipated that the concurrent use of these two drugs will result in increases in ganciclovir levels, and levels of the inactive metabolite of mycophenolate, due to competition for renal tubular secretion. They suggest careful monitoring in patients with renal impairment given both drugs.4,5,9 These caution is also applied to the ganciclovir prodrug valganciclovir.10,11

Five cases of neutrophil dysplasia in transplant patients appeared to be related to the combination of ganciclovir and mycophenolate, rather than mycophenolate alone.12 This emphasises the need for caution with concomitant use. The manufacturer of valganciclovir says that since both mycophenolate mofetil and ganciclovir have the potential to cause neutropenia and leucopenia, patients should be monitored for additive toxicity.10

Note that some data suggests that mycophenolate potentiates the antiherpes virus activity of ganciclovir, which may be clinically useful.6

5. Adefovir + Miscellaneous

No clinically significant interaction appears to occur between adefovir and co-trimoxazole, didanosine, delavirdine, efavirenz, ibuprofen, indinavir, lamivudine, nelfinavir, nevirapine, paracetamol, tenofovir, or zidovudine. Adefovir possibly reduces saquinavir levels.

Clinical evidence, mechanism, importance and management

(a) Antiretrovirals

The UK manufacturer notes that at doses 6 to 12 times higher than the 10-mg dose of adefovir recommended for hepatitis B infection, there was no interaction with the NRTIs lamivudine or zidovudine, the NNRTIs

| Aciclovir and related drugs + Probencide |

Probencide reduces the renal excretion and increases the plasma levels of aciclovir, valaciclovir, and ganciclovir. Famiclovir and valganciclovir are predicted to interact similarly.
delavirdine, efavirenz or nevirapine, or the protease inhibitors indinavir or nelfinavir. The concurrent use of adefovir 60 mg with saquinavir soft capsules increased the adefovir AUC by 20%, which is not clinically relevant. In a population pharmacokinetic analysis, combination of saquinavir with adefovir appeared to result in a 49% increase in the clearance of saquinavir. The concurrent use of adefovir 60 mg with didanosine buffered tablets increased the didanosine AUC by 29%, which is not clinically relevant. See also Lamivudine and Tenofovir, below.

(b) Drugs undergoing, or affecting, tubular secretion
Adefovir is excreted by the kidneys, by a combination of glomerular filtration and active secretion via the renal transporter, human Organic Anion Transporter 1 (hOAT1). The potential for pharmacokinetic interactions with co-trimoxazole, ibuprofen, lamivudine, paracetamol and tenofovir (other drugs that also undergo, or may affect tubular secretion) has been investigated.

1. Co-trimoxazole (Trimethoprim/Sulfamethoxazole). The manufacturers note that there was no pharmacokinetic interaction between adefovir 10 mg once daily and co-trimoxazole 960 mg twice daily in 18 healthy subjects. 

2. Ibuprofen. The concurrent use of adefovir 10 mg and ibuprofen 800 mg three times daily modestly increased the AUC and maximum level of adefovir by 23% and 33%, respectively. These changes were considered to be due to higher bioavailability rather than a reduction in renal clearance, and are not considered clinically relevant. Adefovir did not alter ibuprofen pharmacokinetics.

3. Lamivudine. The manufacturers note that there was no pharmacokinetic interaction between adefovir 10 mg once daily and lamivudine 100 mg once daily in healthy subjects.

4. Paracetamol. The manufacturers note that there was no pharmacokinetic interaction between adefovir 10 mg once daily and paracetamol 1 g four times daily in healthy subjects.

5. Tenofovir. In 24 healthy subjects there was no pharmacokinetic interaction between a single 10-mg dose of adefovir dipivoxil given alone and on day 7 of tenofovir disoproxil fumarate 300 mg daily for 7 days. In particular, renal clearances of both drugs were not changed on concurrent use. However, the manufacturers still advise close monitoring during concurrent use, since the clinical safety, including renal effects, has not yet been assessed.

Mechanism
It was suggested that cidofovir/probenecid might alter the renal elimination of these drugs.

Importance and management
The modest decreases in trimethoprim and sulfamethoxazole levels, and moderate increases in didanosine levels caused by cidofovir are considered unlikely to be clinically relevant because of the infrequent dosing schedule of cidofovir/probenecid. No dose adjustments are considered necessary.

Cidofovir + Probenecid
Probenecid reduces the nephrotoxicity of cidofovir, and it is recommended it should always be used concurrently. Therefore, when using cidofovir/probenecid the interactions of probenecid should be considered. Of particular note, zidovudine should be temporarily discontinued or the dosage halved when cidofovir/probenecid is used, see ‘NRTIs + Probenecid’, p.803.

Enfuvirtide + Cytochrome P450 isoenzyme substrates
Enfuvirtide had no effect on the metabolism of dapsone or debrisoquine, and had little effect on the metabolism of caffeine, chloroxazone, and mephenytoin. Thus, it is not anticipated that enfuvirtide would cause clinically important drug interactions with drugs metabolised by the cytochrome P450 isoenzymes.

Clinical evidence, mechanism, importance and management
A single oral dose of five drugs (caffeine 100 mg, chloroxazone 250 mg, dapsone 100 mg, debrisoquine 10 mg and mephenytoin 100 mg) was given to 12 HIV-positive subjects, before, and after they were given subcutaneous enfuvirtide 90 mg twice daily for 6 days. Enfuvirtide had no effect on the urinary dapsone recovery ratio (a measure of the activity of the cytochrome P450 isoenzyme CYP3A4), plasma monoacetyldapsone-to-dapsone ratio (a measure of N-acetyltransferase (NAT) activity) or urinary debrisoquine recovery ratio (a measure of CYP2D6 activity). Enfuvirtide had little effect (less than 30% change) on the plasma paraxanthine-to-caffeine ratio (a measure of CYP1A2 activity), the plasma 6-hydroxyclofosoxazone-to-chloroxazone ratio (a measure of CYP2E1 activity) and urinary recovery of 4-hydroxymephenytoin (a measure of CYP2C19 activity). Subjects in this study were taking up to 3 NRTIs in stable doses, and were not taking any NNRTIs or protease inhibitors.

This type of study is being increasingly used to assess the potential for new drugs to cause clinically important cytochrome P450-mediated drug interactions. The results indicate that enfuvirtide is unlikely to cause clinically important changes in the pharmacokinetics of drugs metabolised by CYP3A4, NAT and CYP2D6. They also give some reassurance that drugs metabolised by CYP1A2, CYP2E1 and CYP2C19 are unlikely to be significantly affected, although the modest changes seen introduce some cau-
Enfuvirtide + Protease inhibitors

Ritonavir caused a minor increase in enfuvirtide exposure, which is not clinically relevant. Saquinavir/ritonavir had little effect on enfuvirtide.

Clinical evidence, mechanism, importance and management

Subcutaneous enfuvirtide 90 mg twice daily was given for 7 days to 24 HIV-positive subjects with either ritonavir 200 mg twice daily or saquinavir/ritonavir 1 g/100 mg twice daily given for the last 4 days. Ritonavir caused a minor 24% increase in the AUC of enfuvirtide, and saquinavir/ritonavir caused a 14% increase in the AUC of enfuvirtide. Such small increases in enfuvirtide exposure are not clinically relevant. No special precautions appear warranted during concurrent use.1

Enfuvirtide + Rifampin (Rifamp)in

Rifampicin has no effect on the pharmacokinetics of enfuvirtide.

Clinical evidence, mechanism, importance and management

Subcutaneous enfuvirtide 90 mg twice daily for 3 days was given to 12 HIV-positive subjects before, and during, the last 3 days of a 10-day course of rifampin 600 mg daily. The AUC of enfuvirtide and its metabolite were not significantly altered by rifampicin.1 Enfuvirtide is a peptide, and would not be expected to be affected by enzyme inducers such as rifampicin. The findings of this study support this. No special precautions are required during concurrent use.1

Entecavir + Miscellaneous

There appears to be no pharmacokinetic interaction between entecavir and adefovir, lamivudine or tenofovir. However, interactions with other renally excreted drugs cannot be excluded. No interactions mediated by cytochrome P450 isoenzymes are expected with entecavir.

Clinical evidence, mechanism, importance and management

(a) Renally excreted drugs

Since entecavir is predominantly eliminated by the kidney, the concurrent use of drugs that reduce renal function or compete for active tubular secretion may increase serum concentrations of either entecavir or the concurrent drug. However, the manufacturers note that there was no pharmacokinetic interaction between entecavir and lamivudine, adefovir or tenofovir at steady state.1,2 They say that, apart from these drugs, the enzyme oxidase does not play an important role in the metabolism of famciclovir to penciclovir.1,2

(b) Cytochrome P450-mediated interactions

The manufacturers say that entecavir is not a substrate, an inducer or an inhibitor of cytochrome P450 isoenzymes. Therefore drug interactions are unlikely to occur with entecavir by this mechanism.1,2

Foscarnet + Ciprofloxacin

Two patients developed tonic-clonic seizures when they were given foscarnet with ciprofloxacin.

Clinical evidence

An HIV-positive patient taking multiple drugs (including ciprofloxacin 750 mg twice daily, clarithromycin, cimetidine, fluconazole, morphine, rifampicin and vancomycin) was also given intravenous foscarnet 60 mg/kg every 8 hours for a cytomegalovirus infection. He was only given half of the first dose, but 9 hours later he developed a tonic-clonic seizure. On completion of infusion of the first dose he again experienced similar seizure activity. About 45 minutes after the start of the second foscarnet dose, he had a third grand mal seizure. No further seizures occurred when the foscarnet was stopped.1 Another HIV-positive patient was given foscarnet 60 mg/kg every 8 hours for 10 days without problem, until he started ciprofloxacin 750 mg twice daily, clofazimine, ethambutol, pyrazinamide and rifampicin for mycobacterial sepsis. Within 2 days, a few minutes after the start of the foscarnet infusion, he developed a seizure. This resolved when the foscarnet was stopped, and recurring when the foscarnet was restarted.1

Mechanism

Both foscarnet and ciprofloxacin have the potential to cause seizures and it seems that some enhancement of this activity occurs if they are used in combination. Subsequent study in mice has shown that the combination of ciprofloxacin and foscarnet does increase the likelihood of seizures, and that the interaction is likely to be due to altered GABA-receptor binding. An interaction was not found for enoxacin and foscarnet.2

Importance and management

Direct information seems to be limited to these two cases. It is impossible to know for certain if the seizures were due to the combined effects of these two drugs or not, but the evidence seems to point in that direction. The general importance of this interaction is uncertain, but it would seem prudent to monitor very closely if these drugs are used together.

Foscarnet + NRTIs

No pharmacokinetic interactions occur between foscarnet and didanosine, zalcitabine or zidovudine. The UK manufacturer does not recommend the concurrent use of lamivudine and foscarnet.

Clinical evidence, mechanism, importance and management

(a) Didanosine

In a three-phase study, 12 HIV-positive patients were given 4 doses of intravenous foscarnet 90 mg/kg, 4 doses of oral didanosine 200 mg, and 4 doses of both drugs together. Based on the data obtained from these patients (drug clearance, volume of distribution, half-life, mean residence time), no pharmacokinetic interactions were said to occur between these two drugs. This suggests that no dosage adjustments will be needed during concurrent use. The antiretroviral effects of foscarnet and didanosine were synergistic.

(b) Lamivudine

The UK manufacturer says that lamivudine should not be given with foscarnet, presumably because of possible interference with renal excretion. Note that the US manufacturer does not make any recommendation. Foscarnet does not affect lamivudine intracellular activation.

(c) Stavudine

Foscarnet does not affect stavudine intracellular activation.

(d) Zalcitabine

Intravenous foscarnet 90 mg/kg every 12 hours and oral zalcitabine 750 micrograms every 8 hours were given to 12 HIV-positive subjects for 7 days. There were no clinically significant alterations in the pharmacokinetics of either drug. However, the manufacturers of zalcitabine suggested that the concurrent use of zalcitabine and foscarnet should be well monitored, because foscarnet may possibly decrease the renal clearance of the zalcitabine, thereby increasing its serum levels and its toxicity, particularly peripheral neuropathy. The antiretroviral effects of foscarnet and zalcitabine were synergistic.

(e) Zidovudine

The antiretroviral effects of foscarnet and zidovudine appear to be additive or synergistic. No significant alteration in the pharmacokinetics of either drug was seen in a 14-day study in 5 AIDS patients given both drugs. Foscarnet does not appear to affect zidovudine intracellular activation, and the manufacturer notes that there was no evidence of increased myelotoxicity when foscarnet was used with zidovudine. No special precautions are required on concurrent use.

Foscarnet + Pentamidine

Four patients had marked hypocalcaemia when they were given foscarnet with intravenous pentamidine. One of them died.

Clinical evidence, mechanism, importance and management

Four patients with suspected AIDS-related cytomegaloviral infections of the chest developed signs of hypocalcaemia within 10 days of starting treatment with foscarnet and intravenous pentamidine (dosages not stated). All 4 had paraesthesia of the hands and feet, and 3 of them had Chvostek’s and Trousseau’s signs (signs of tetany). The serum calcium levels of 3 of them fell but normalised when one of the drugs was stopped. The fourth patient died with severe hypocalcaemia of 1.42 mmol/L.

Both drugs have been associated with hypocalcaemia in HIV-positive patients, and in these 4 patients their effects appear to have been additive. Very close monitoring of calcium levels is advised if foscarnet is used with parenteral pentamidine.

Foscarnet + Probenecid

Probenecid does not alter the pharmacokinetics of foscarnet.

Clinical evidence, mechanism, importance and management

A study in 10 HIV-positive patients found that probenecid 1 g twice daily for 3 days had no effect on the pharmacokinetics of foscarnet 90 mg/kg given intravenously over 2 hours. The authors conclude that, because of the lack of interaction with probenecid, almost all of the renal elimination of foscarnet is by glomerular filtration, with only a minimal contribution of active tubular secretion. No special precautions seem to be necessary.

Ganciclovir or Valganciclovir + Imipenem

Based on an early possible report, the manufacturer notes that generalised seizures have been reported in patients who received ganciclovir with imipenem-cilastatin. They recommend that ganciclovir and its produg valganciclovir should not be used with imipenem unless the benefits outweigh the risks. No further reports of this interaction appear to have been published, or reported to the manufacturer. Note that both ganciclovir and imipenem alone may cause seizures.

Ganciclovir + Trimethoprim

There is no clinically relevant pharmacokinetic interaction between ganciclovir and trimethoprim.

Clinical evidence, mechanism, importance and management

Ganciclovir 1 g every 8 hours was given to 12 HIV-positive subjects with trimethoprim 200 mg daily for 7 days. Ganciclovir clearance was decreased by 13%, and the half-life was increased by 18%, while the trimethoprim minimum plasma concentration was raised by 13%. The combination was well tolerated and none of these changes were considered to have any clinical significance, so no dose alteration appears necessary on concurrent use. Both ganciclovir and trimethoprim are known to be myelosuppressive, and the manufacturer of ganciclovir and its prodruk
valganciclovir notes that there is the possibility that the risk of this toxicity may be increased when they are used together. Therefore, they recommend that the combination should only be used if the benefits outweigh the risks of treatment.1,2

### Idoxuridine + Miscellaneous

The topical solution of idoxuridine, Herpид, contains the solvent dimethyl sulfoxide as an absorption enhancer. This can increase the absorption of many substances, and therefore no other topical medications should be used concurrently on the same areas as Herpid.1

### Inﬂuenza vaccines + Paracetamol (Acetaminophen)

Paracetamol does not affect antibody production in response to inﬂuenza vaccination and appears to reduce its adverse effects. The pharmacokinetics of paracetamol do not appear to be affected by inﬂuenza vaccine.

### Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 650-mg dose of intravenous paracetamol were unaffected in healthy subjects when it was given 7 and 21 days after 0.5 mL of trivalent inﬂuenza vaccine given intramuscularly.1 Paracetamol 1 g four times daily for 2 days had no effect on the production of inﬂuenza virus antibodies in a group of 39 elderly patients given an inactivated in- ﬂuenza virus vaccine, and the paracetamol appeared to reduce the adverse effects of the vaccine (e.g. fever), although this was not statistically signiﬁcant.2 There would seem to be no reason for avoiding the concurrent use of paracetamol and inﬂuenza vaccine.

### Inﬂuenza vaccine, live + Antivirals active against inﬂuenza

The manufacturers advise that antivirals active against inﬂuenza such as oseltamivir and rimantadine should not be given until 2 weeks after the administration of live inﬂuenza virus vaccines, and that these vaccines should not be given until 48 hours after stopping the antiviral.1,3 This is because of the theoretical concern that these antiviral drugs will inhibit replication of live vaccine virus, and therefore reduce its effect. Note that most inﬂuenza vacci- nes are inactivated (split virion or surface antigen), and that these would not be expected to be affected by antivirals active against inﬂuenza.

### Interferons + ACE inhibitors

A case series suggests that severe granulocytopenia can develop if ACE inhibitors and interferon are given concurrently.

#### Clinical evidence

Patients with cryoglobulinemia were treated with 3 million units of recombinant interferon alfa-2a (35 patients) or natural interferon beta (3 patients), usually given daily for 3 months, then on alternate days for pe- riods of 6 to 17 months. Severe toxicity developed in 3 patients, who were the only ones amongst the group to also be taking ACE inhibitors. Granu- locytopenia developed in 2 patients within a few days of starting enalapril 10 mg daily or captopril 50 mg daily, and subsided 1 to 2 weeks after both drugs were stopped. Another patient, already taking enalapril 5 mg daily, developed severe granulocytopenia when interferon was started, and again when re-challenged with both drugs. None of the other 35 pa- tients receiving interferon alone developed any signiﬁcant haematological problems. The reasons for this severe reaction are not understood but the authors of the report suggest that it may be an autoimmune response.1

A follow-up letter commenting on this report described 2 further patients with hepatitis C infection, cryoglobulinemia and glomerulonephritis, who took captopril 75 mg or enalapril 20 mg daily for several weeks, and who had granulocytopenia within 9 days of being given 3 million units of recombinant interferon alfa-2a, daily or on alternate days. However, this resolved without any change in treatment. Another patient with multiple myeloma given interferon alfa-2a 3 million units 3 times weekly and long-term benazepril 10 mg daily had a normal gran- ulocyte count after 3 months.2

#### Mechanism

Interferons alone are associated with myelosuppression, particularly granu- locytopenia. ACE inhibitors have, rarely, caused neutropenia and agranu- locytosis.

### Importance and management

These two reports appear to be the only information suggesting an inter- action. Regular full blood counts are generally recommended when interfer- ons are used, and therefore, no extra precautions would appear to be required if ACE inhibitors are also given. Bear the possibility of an inter- action in mind.

### Interferons + Analgesics or Corticosteroids

Prednisone and paracetamol have disparate effects on some measures of the antiviral activity of interferon, but the clinical relevance of this is unclear. Isolated cases of acute hepatitis have been seen when interferon was given with paracetamol.

#### Clinical evidence

A single intramuscular dose of recombinant human interferon alfa-2a 18 million units was given to 8 healthy subjects alone, or after one day of either aspirin 650 mg every 4 hours, paracetamol 650 mg every 4 hours or prednisone 40 mg daily, for a total of 8 days. None of these additional drugs reduced the interferon adverse effects of fever, chills, headache, or myalgia. Only prednisone appeared to reduce one of the two measures of interferon activity.1 In a later similar study by the same research group, the effect of the same drugs and doses (started 3 days before the interferon) was evaluated with a lower dose of interferon alfa-2a (3 million units). When data for aspirin, paracetamol or prednisone was combined the...
subjects had a 47% reduction in symptom score, when compared with control subjects not taking any of these three drugs. The prednisone group also had fewer hours of fever. In this study, neither prednisone nor aspirin consistently altered measures of the antiviral activity of interferon, but paracetamol appeared to enhance them.\(^2\)

Taken together, the results of these two studies suggest that these drugs may reduce the flu-like adverse effects of interferon, perhaps more so at lower doses of interferon. The clinical relevance of the measures of antiviral activity of interferon is uncertain, so the disparate effects found with paracetamol and prednisone are unclear.

The authors of a report describing an unusual acute form of hepatitis, occurring in 3 patients receiving interferon alfa-2a, vinblastine and paracetamol, suggested that this might have been due to a drug interaction.\(^2\) Another two similar cases have been reported with interferon alfa-2b and paracetamol, but no liver toxicity occurred when one of these patients was given ibutametin with interferon instead.\(^2\) The general relevance of these isolated reports is unclear.

3. Kellokumpu-Lehtinen P, Iisalo E, Nordman E. Hepatotoxicity of paracetamol in combination with interferon alfa-2b and paracetamol, but no liver toxicity occurred when one of these patients was given ibutametin with interferon instead.\(^2\)

Interferons + Ribavirin

There was no evidence of any changes in pharmacokinetic parameters when ribavirin and interferon alfa-2b were given together.\(^1\)

Another study using peginterferon alfa-2b also found no pharmacokinetic interactions with ribavirin.\(^2\) The combination of interferon alfa and ribavirin has enhanced efficacy against hepatitis C.\(^3\)

Maraviroc + CYP3A4 inducers

Efavirenz reduces the plasma levels of maraviroc by about 50% and rifampicin reduces them by about two-thirds. A regimen containing nevirapine appeared to have little effect on the levels of a single dose of maraviroc.

Clinical evidence

(a) Efavirenz

In a placebo-controlled study in healthy subjects, efavirenz 600 mg once daily for 14 days reduced the steady-state AUC and maximum plasma level of maraviroc 100 mg twice daily by about 50%. Doubling the dose of maraviroc to 200 mg twice daily overcame this effect. The increase in maraviroc AUC seen with these protease inhibitors was reduced from 877% to 400%, when compared with the AUC for maraviroc alone.\(^3\)

(b) Nevirapine

In 8 patients taking nevirapine, lamivudine and tenofovir the AUC of a single 300-mg dose of maraviroc was unchanged and its maximum plasma level was about 50% higher, when compared with HIV-positive subjects taking maraviroc alone.\(^7\)

(c) Rifampicin (Rifampin)

In a placebo-controlled study in healthy subjects, rifampicin 600 mg once daily for 14 days reduced the steady-state AUC and maximum and minimum plasma levels of maraviroc 100 mg twice daily by about two-thirds. Doubling the dose of maraviroc to 200 mg twice daily overcame this increase in metabolism, resulting in an AUC comparable to that of maraviroc 100 mg twice daily alone.\(^3\)

Mechanism

Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4, and its levels would therefore be expected to be reduced by inducers of this enzyme, such as efavirenz and rifampicin. For a list of CYP3A4 inducers, see ‘Table 1.4’, (p.6).

Importance and management

The pharmacokinetic interactions with efavirenz and rifampicin are likely to be clinically important. The reduction in maraviroc plasma levels seen could result in decreased efficacy and the development of viral resistance. Doubling the dose of maraviroc overcame this interaction, and this is the suggested approach of the manufacturer when maraviroc is used in the absence of protease inhibitors.\(^3\) Efavirenz appears to halve the increase in maraviroc levels seen with ritonavir-boosted protease inhibitors.

Maraviroc was doubled in 5 patients taking lopinavir/ritonavir 400/100 mg twice daily, stavudine and lamivudine when compared with that after one dose in a study in HIV-positive subjects taking maraviroc 300 mg daily alone. Adding efavirenz, (p.780) halved the effect of lopinavir/ritonavir and saquinavir/ritonavir on the maraviroc AUC. In contrast, tipranavir/ritonavir 500/200 mg twice daily had no clinically significant effect on the AUC or maximum level of maraviroc 150 mg twice daily in healthy subjects.

Mechanism
Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4 of which most protease inhibitors and ketoconazole are potent inhibitors.

Importance and management
Established and clinically important interactions. Increases of this magnitude are likely to result in increased adverse effects. The manufacturer has suggested that the dose of maraviroc is halved when it is used with protease inhibitors. For a list of other inhibitors of CYP3A4, which might be expected to interact similarly, see ‘Table 1.4’, (p.6).

Food
In healthy male subjects, food significantly reduced the rate and extent of absorption of maraviroc. However, the manufacturer reported that food appeared to have little effect on the antiviral activity of maraviroc, and so food restriction was not considered necessary.

Ketoconazole
400 mg once daily increased the AUC and maximum level of maraviroc 100 mg twice daily by fivefold and 3.4-fold, respectively, in healthy subjects.

Maraviroc had no clinically relevant effect on the pharmacokinetics of lamivudine, zidovudine, or a combined oral contraceptive containing ethinylestradiol and levonorgestrel. No clinically important effect was seen with the CCR5 antagonist UK-427,857. Food may reduce the absorption of maraviroc, but this is probably not clinically relevant.

Clinical evidence, mechanism, importance and management
(a) Food
In healthy male subjects, food significantly reduced the rate and extent of absorption of maraviroc. However, the manufacturer reported that food appeared to have little effect on the antiviral activity of maraviroc, and so food restriction was not considered necessary.

(b) Hormonal contraceptives
Maraviroc 100 mg twice daily had no effect on contraceptive steroid levels after administration of the combined oral contraceptive ethinylestradiol/levonorgestrel 30/150 micrograms daily for 7 days in a placebo-controlled crossover study in 15 healthy women.

(c) Midazolam
In a placebo-controlled study in 12 healthy subjects maraviroc 300 mg twice daily for 7 days slightly increased the AUC of a single 7.5-mg dose of midazolam given on day 7 by 18%, after to. This increase is unlikely to be clinically relevant. Midazolam is a probe substrate of the cytochrome P450 isoenzyme CYP3A4, and the findings suggest that maraviroc is unlikely to have an important effect on other CYP3A4 substrates. For a list see ‘Table 1.4’, (p.6).

(d) NRTIs
In a placebo-controlled, crossover study in healthy subjects maraviroc 300 mg twice daily had no clinically relevant effect on the pharmacokinetics of zidovudine/lamivudine (Combivir) 300/150 mg twice daily, when they were given together for one week. For the effect of other NRTIs in combination with protease inhibitors or NRTIs on maraviroc, see ‘CYP3A4 inhibitors’, (p.780) and ‘CYP3A4 inducers’, (p.780), and for the effect of tenofovir, see ‘Drugs that affect renal clearance’, (above).

Maraviroc + Drugs that affect renal clearance
Neither co-trimoxazole nor tenofovir had any important effect on maraviroc levels.

Clinical evidence
(a) Co-trimoxazole
Co-trimoxazole (sulfamethoxazole/trimethoprim 800/160 mg) twice daily had no clinically relevant effect on the pharmacokinetics of maraviroc 300 mg twice daily (a 10% increase in AUC and a 19% increase in maximum level).

(b) Tenofovir
In a placebo-controlled, crossover study in healthy subjects, the concurrent use of maraviroc 300 mg twice daily and tenofovir disoproxil fumarate 300 mg once daily had no effect on the pharmacokinetics of maraviroc.

Mechanism
Maraviroc undergoes some renal clearance (about 20% of total clearance). Co-trimoxazole affects renal tubular transport, and tenofovir is predominantly excreted renally, so it was of interest to see if these had any effect on maraviroc levels.

Importance and management
The pharmacokinetic data suggest that no maraviroc dose adjustment is likely to be needed if it is given with tenofovir or co-trimoxazole.

The concurrent use of carbamazepine and efavirenz leads to a modest reduction in the plasma levels of both drugs; similar effects may be expected with phenytoin and phenobarbital. The use of nevirapine and carbamazepine may also result in decreased levels of both drugs.

Clinical evidence
The manufacturer notes that there was a pharmacokinetic interaction between efavirenz 600 mg daily and carbamazepine 400 mg daily in a study in healthy subjects. The steady-state AUC, and maximum and minimum plasma concentrations of carbamazepine decreased by 27%, 20% and 35%, respectively, while the steady-state AUC, and maximum and minimum plasma concentrations of efavirenz decreased by 36%, 21%, and 47%, respectively. The steady-state levels of the active carbamazepine epoxide metabolite remained unchanged.1,2

Mechanism
Efavirenz and carbamazepine are both inducers and substrates of the cytochrome P450 isoenzyme CYP3A4, and so they can both increase the metabolism of the other drug. Nevirapine would be expected to interact similarly (see “Table 21.2”, (p.773)).

Importance and management
The manufacturers of efavirenz note that an alternative to carbamazepine should be considered (especially with doses of greater than 400 mg daily, the study dose).1,2 The US manufacturer of nevirapine recommends caution with the concurrent use of carbamazepine.3

In the UK, the manufacturer states that no data are available on the potential interactions of efavirenz with phenytoin or phenobarbital. They say that when efavirenz is given with these drugs, there is a potential for reduction or increase in the plasma concentrations of each drug. They therefore recommend periodic monitoring of plasma levels.1

Fluconazole doubles nevirapine exposure, and the combination should be used with caution. Fluconazole causes a minor rise in efavirenz steady-state levels, and does not alter delavirdine levels. Fluconazole levels are not altered by these NNRTIs.

Clinical evidence, mechanism, importance and management
(a) Delavirdine
Delavirdine mesilate 300 mg three times daily was given to 13 HIV-positive subjects for 30 days. Fluconazole 400 mg daily was given to 8 of them on days 16 to 30. No differences in the pharmacokinetics of either drug were noted between the two groups.1 On the basis of these results, it would appear that no dosage adjustments are needed if these drugs are used together.

(b) Efavirenz
Fluconazole 400 mg daily for one day, then 200 mg daily for 6 days was given to 20 healthy subjects with efavirenz 400 mg daily. The pharmacokinetics of fluconazole were not affected, and although the AUC of efavirenz was raised by 15%, no clinically significant effects are anticipated.2

(c) Nevirapine
The concurrent use of fluconazole and nevirapine doubled the exposure to nevirapine compared with historical control data, although nevirapine did not have any clinically relevant effect on fluconazole pharmacokinetics.3,4 The manufacturer suggests that patients should be closely monitored for nevirapine-associated adverse effects if fluconazole and nevirapine are used concurrently.3,4 However, in a retrospective study of patients who had received a nevirapine-based HAART regimen, there was no increase in the incidence of clinical hepatitis, elevated aminotransferases or skin rashes, when the outcomes of 225 patients not receiving fluconazole, 392 patients treated with fluconazole 400 mg weekly, and 69 patients receiving fluconazole 200 mg daily with nevirapine were compared.5

Clinical evidence
In a study in healthy subjects, efavirenz 600 mg daily decreased the steady-state maximum plasma levels and the AUC of itraconazole 200 mg twice daily by 37% and 39%, respectively, and caused a similar decrease in hydroxyitraconazole levels. The steady-state maximum plasma levels and the AUC of efavirenz were not affected by itraconazole.1,2

Mechanism
The metabolism of itraconazole by the cytochrome P450 isoenzyme CYP3A4 is induced by efavirenz. Nevirapine might interact similarly as it also induces CYP3A4.

Importance and management
On the basis of the pharmacokinetic study, the manufacturers of efavirenz say that alternatives to itraconazole should be considered.1 If there are no appropriate alternatives, it might be prudent to increase the dose of itraconazole, with increased monitoring for efficacy and toxicity of the combination.

Nevirapine might be expected to interact similarly to efavirenz, therefore monitor itraconazole efficacy carefully and anticipate the need to increase the dose.

NNRTIs + Azoles; Ketoconazole
Nevirapine markedly reduces the AUC of ketoconazole. In theory, efavirenz may interact similarly, whereas delavirdine may increase ketoconazole levels. The NNRTI plasma levels may be raised by ketoconazole.

Clinical evidence
(a) Delavirdine
The manufacturer notes that the minimum level of delavirdine was 50% higher than population pharmacokinetic data in 26 patients taking ketoconazole.1

(b) Nevirapine
The manufacturers of nevirapine quote a study in which nevirapine 200 mg twice daily was given with ketoconazole 400 mg daily. The ketoconazole AUC was markedly reduced by 72% and its maximum plasma levels were reduced by 44%.2,3 In addition, the nevirapine plasma levels were raised by 15 to 28% compared with historical control data.2

Mechanism
Ketoconazole is likely to inhibit the metabolism of the NNRTIs by the cytochrome P450 isoenzyme CYP3A4. Nevirapine induces the metabolism of ketoconazole by CYP3A4, and, in theory, efavirenz is likely to interact similarly, whereas delavirdine is likely to inhibit ketoconazole metabolism by CYP3A4 (see ‘Table 21.2’, (p.773)).

Importance and management
The manufacturer of nevirapine states that ketoconazole and nevirapine should not be used together, because of the likely reduced efficacy of ketoconazole.2,3 Efavirenz might be expected to interact similarly although the manufacturer of efavirenz says that the potential for an interaction has not been studied.4 NNRTI levels might be raised by ketoconazole, which might increase adverse effects. Cautious monitoring of efficacy and adverse effects would be prudent if concurrent use is necessary.

NNRTIs + Azoles; Posaconazole
The manufacturer of posaconazole predicts that it will increase the plasma levels of the NNRTIs because it inhibits the cytochrome P450 isoenzyme CYP3A4, by which they are metabolised. They recommend patients should be carefully monitored for any occurrence of toxicity during concurrent use.1

NNRTIs + Azoles; Voriconazole
Efavirenz markedly decreases voriconazole levels and voriconazole modestly increases efavirenz levels. Voriconazole is predicted to increase levels of both delavirdine and nevirapine. Like efavirenz, nevirapine is predicted to decrease voriconazole levels, whereas delavirdine is predicted to increase voriconazole levels.

Clinical evidence
In a study in healthy subjects, efavirenz 400 mg daily decreased the steady-state maximum plasma levels and the AUC of voriconazole 200 mg twice daily by 61% and 77%, respectively. At the same time, the steady-state maximum plasma levels and the AUC of efavirenz were increased by 38% and 44%, respectively.1 In a dose-adjustment study, when voriconazole 300 mg twice daily and efavirenz 300 mg daily were used together, the AUC of voriconazole was 55% lower than that seen with the standard dose of voriconazole 200 mg twice daily alone, and the efavirenz AUC was equivalent to that seen with efavirenz 600 mg daily alone.2,4 In a further dose-adjustment study, when voriconazole 400 mg twice daily was given with efavirenz 300 mg once daily, the AUC of voriconazole was just 7% lower than that seen with voriconazole 200 mg twice daily alone. The AUC of efavirenz was increased by 17% and the maximum plasma concentration was equivalent, when compared with efavirenz 600 mg once daily alone.2,4

There is one case of a patient taking a variety of antiretrovirals and antibacterials who developed oral candidiasis while taking voriconazole 200 mg twice daily, which was attributed to an interaction with efavirenz. The dose of voriconazole was titrated upwards to 350 mg twice daily to achieve higher trough levels. The candidiasis was eventually found to be resistant to voriconazole, and it was postulated that this developed because of under-dosing in the presence of efavirenz.2

Mechanism
The metabolism of voriconazole by the cytochrome P450 isoenzyme CYP3A4 is induced by efavirenz. Nevirapine is predicted to interact similarly, whereas delavirdine is predicted to inhibit the metabolism of voriconazole. All the NNRTIs are substrates of CYP3A4, which is inhibited by voriconazole.

Importance and management
On the basis of the pharmacokinetic studies the manufacturers contraindicate the concurrent use of efavirenz and voriconazole,2 unless the doses of both drugs are adjusted.2,4 The recommendation is to double the usual dose of voriconazole to 400 mg twice daily, and to halve the usual efavirenz dose to 300 mg once daily.2,4

Nevirapine might be expected to interact similarly to efavirenz, whereas delavirdine might increase voriconazole levels. The manufacturers of voriconazole suggest that patients given delavirdine or nevirapine should be carefully monitored for evidence of drug toxicity and/or loss of efficacy during concurrent use.2,3

NNRTIs + Drugs that affect gastric pH

Antacids roughly halve the AUC of delavirdine, and the H₂-receptor antagonists or proton pump inhibitors would be expected to interact similarly. Aluminium/magnesium antacids do not interact to a clinically relevant extent with efavirenz or nevirapine, and famotidine does not alter the absorption of efavirenz.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

Delavirdine is poorly soluble at pHs greater than 3, so the effect of giving delavirdine 300 mg ten minutes after an antacid was studied in 12 healthy subjects. The AUC and maximum serum levels of delavirdine were reduced by 48% and 57%, respectively, suggesting that delavirdine should not be given with antacids.1 The manufacturer recommends separating administration by at least one hour.2 Although it has not been studied, it is predicted that other drugs that reduce gastric acidity, such as H₂-receptor antagonists and proton pump inhibitors, will also reduce the absorption of delavirdine, and their long-term use with delavirdine is not recommend ed.2

(b) Efavirenz

The manufacturer notes that neither aluminium/magnesium hydroxide antacids nor famotidine had any effect on the absorption of efavirenz.3 No efavirenz dosage adjustment is expected to be necessary with these drugs.4 Other drugs that reduce gastric acidity are not expected to affect efavirenz absorption.3

(c) Nevirapine

In a study in 24 healthy subjects it was found that 30 mL of Maalox (aluminium/magnesium hydroxide) caused some moderate changes in the pharmacokinetics of nevirapine 200 mg, but none of them was considered to be clinically relevant.5 No special precautions would seem to be necessary.6

NNRTIs + Food

Food has no clinically relevant effect on the levels of delavirdine or nevirapine. Food modestly increases efavirenz levels, and the manufacturer suggests that this might increase the frequency of adverse effects.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

In a randomised, crossover study in 13 HIV-positive patients taking delavirdine 400 mg daily, there were no changes in the steady-state serum levels of delavirdine taken with or without food for 2 weeks.1 This differed from a previous single-dose study, in which there was a 26% fall in the AUC of delavirdine given with food.2 There would appear to be no need to avoid taking delavirdine with food. For mention that orange juice increased the absorption of delavirdine in patients with gastric hypochlority, see ‘NNRTIs; Delavirdine + Acids’, p.791.

(b) Efavirenz

The manufacturer of efavirenz notes that taking a 600-mg efavirenz tablet with a high-fat meal increased its AUC by 28%, when compared with fasting conditions, and increased its maximum concentration by 79%.3,4 After a similar meal, the AUC and maximum level of the capsule formulation was increased by 22% and 39%, respectively, and after a low-fat meal the increases were 17% and 51%, respectively.5 The manufacturer says that these increases might increase the frequency of adverse effects. They recommend that efavirenz is taken without food, preferably at bedtime.3,4

(c) Nevirapine

In a study in 24 healthy subjects, a high-fat breakfast caused some moderate changes in the pharmacokinetics of oral nevirapine 200 mg, but the AUC was not affected and none of the changes were considered to be clinically relevant.5 Nevirapine may be taken with or without food.

NNRTIs + Macrolides

Delavirdine may increase the levels of clarithromycin, whereas efavirenz and nevirapine may reduce clarithromycin levels, and increase those of its hydroxy metabolite. Clarithromycin does not appear to affect the pharmacokinetics of delavirdine, efavirenz or nevirapine to a clinically relevant extent. There is no pharmacokinetic interaction between azithromycin and efavirenz. A case of a neuropsychiatric reaction has been attributed to the use of clarithromycin in a man taking nevirapine.

Clinical evidence

(a) Delavirdine

In 7 HIV-positive patients clarithromycin 500 mg twice daily for 15 days did not cause a clinically significant change in the pharmacokinetics of delavirdine 300 mg three times daily, when compared with 4 other HIV-positive patients taking only delavirdine. The combination was well tolerated and no serious adverse events occurred.1 However, although delavirdine levels are unaffected, the manufacturer notes that the AUC of clarithromycin was doubled by delavirdine.2

(b) Efavirenz

The manufacturer notes that the concurrent use of clarithromycin 500 mg twice daily and efavirenz 400 mg daily for 7 days reduced the AUC of clarithromycin by 39% and increased the AUC of its hydroxy metabolite by 34%. Moreover, 46% of subjects receiving the combination developed a rash.3,4 Clarithromycin had minimal effect on the pharmacokinetics of efavirenz.4 The manufacturer also notes that there was no clinically significant pharmacokinetic interaction when a single 600-mg dose of azithromycin was given to healthy subjects who had been taking efavirenz 400 mg daily for 7 days.3,4

(c) Nevirapine

The manufacturer notes that the AUC of nevirapine was increased by 26% by clarithromycin, when compared with historical controls. The AUC of clarithromycin was reduced by 31% and the AUC of its hydroxy metabolite was increased by 42%.5,6 A man developed hyperactivity (poor concentration, anxiety, suicidal and homicidal ideation) when taking clarithromycin and antiretroviral drugs, including nevirapine. This was thought to be due to accumulation of the hydroxy metabolite of clarithromycin.7

Mechanism

The NNRTIs are substrates of the cytochrome P450 isoenzyme CYP3A4, which is inhibited by clarithromycin. Delavirdine is also reported to inhibit CYP3A4, whereas efavirenz and nevirapine induce CYP3A4. Therefore alterations in the metabolism of these drugs by CYP3A4 results in the altered levels seen.

Importance and management

It appears that clarithromycin has minimal effects on the pharmacokinetics of the NNRTIs. However, delavirdine may increase levels of clarithromycin. The manufacturer of delavirdine recommends that when the drugs are used concurrently the dose of clarithromycin should be reduced in pa-
patients with renal impairment. In contrast, efavirenz and nevirapine may decrease clarithromycin levels and increase the levels of the hydroxy metabolite of clarithromycin. The manufacturer of nevirapine suggests that no dose adjustment of clarithromycin is needed; however, they say that alternative NNRTIs to clarithromycin should be considered for the treatment of Mycobacterium-avium complex, as the hydroxy metabolite is not as active as the parent compound.

Moreover they say that concurrent use does not improve the pharmacokinetics of zidovudine. There is no pharmacokinetic interaction between didanosine or zalcitabine and nevirapine 200 mg once daily for 2 weeks on 200 mg twice daily had no effect on the AUC of stavudine 30 to 40 mg twice daily in a study in 22 patients. Nevirapine appears to have no effect on lamivudine clearance, based on a population pharmacokinetic study.}

**NNRTIs + NRTIs**

**Nevirapine modestly reduces the levels of efavirenz, whereas efavirenz has no effect on nevirapine levels.**

**Clinical evidence, mechanism, importance and management**

In a study in HIV-positive patients taking efavirenz 600 mg daily, the addition of nevirapine 400 mg daily resulted in a median decrease in the AUC of effavirenz of 22%, and a decrease in its minimum plasma concentration of 36%. The steady-state pharmacokinetics of nevirapine were not altered by efavirenz, when compared with historical control data. However, the UK manufacturer does not recommend this combination as concurrent use of efavirenz and nevirapine could lead to a higher risk of adverse effects. Moreover they say that concurrent use does not improve efficacy or either NNRTI alone.

**Delavirdine absorption is reduced by the buffered preparation of didanosine. This interaction would not be expected with the enteric-coated preparation of didanosine. Delavirdine does not affect the pharmacokinetics of zidovudine. There is no pharmacokinetic interaction between efavirenz and delavirdine or lamivudine. There is no clinically relevant pharmacokinetic interaction between nevirapine and didanosine, lamivudine, stavudine, zalcitabine or zidovudine.**

**Clinical evidence, mechanism, importance and management**

**Delavirdine**

A study in 34 HIV-positive patients taking zidovudine 200 mg three times daily found that delavirdine mesilate 400 mg to 1.2 g daily for 9 days had no clinically significant effect on the pharmacokinetics of zidovudine. In a steady-state study, 9 HIV-positive patients taking didanosine 200 mg twice daily were also given delavirdine mesilate 400 mg three times daily for 14 days. Didanosine caused a 37% reduction in the maximum delavirdine serum levels, but when the drugs were given 1 hour apart no significant effect occurred. A single-dose study in 12 HIV-positive patients found similar results. The buffered preparation of didanosine contains antacids to increase its absorption, and antacids decrease the absorption of delavirdine (see ‘NNRTIs + Drugs that affect gastric pH’, p.784). The authors of one report suggest that separating the doses by about one hour is preferable. The enteric-coated preparation of didanosine, which does not contain antacids, would not be expected to reduce the absorption of delavirdine.

**Efavirenz**

The manufacturer notes that there were no clinically significant pharmacokinetic interactions between efavirenz and zidovudine or lamivudine in patients with HIV. No dosage adjustments are required on concurrent use. No pharmacokinetic interactions are anticipated with other NNRTIs.

**Nevirapine**

The pharmacokinetics of didanosine and zidovudine with or without nevirapine were assessed in 175 HIV-positive subjects. The bioavailability of didanosine was not affected, but the bioavailability of zidovudine was decreased by about one-third by nevirapine. In a steady-state study in 24 HIV-positive patients, nevirapine 200 mg every 12 hours was added to regimens of didanosine, didanosine with zidovudine, or zidovudine with zalcitabine for a 4-week period. No significant changes in the pharmacokinetics of didanosine or zalcitabine were seen. However, in the didanosine/zidovudine group the peak zidovudine plasma levels and AUC were reduced by 27% and 32%, respectively. The zidovudine pharmacokinetics in the zidovudine/zalcitabine group were not affected. The reasons for these changes are not clear, but the clinical consequences are thought to be small, and the safety data indicate that the concurrent use of these drugs is safe and well tolerated. In another study, the simultaneous administration of nevirapine with didanosine tablets containing antacids had no effect on nevirapine absorption in 4 patients. The manufacturer says that no dosage adjustments are needed if didanosine, zalcitabine or zidovudine is taken with nevirapine.

Nevirapine 200 mg once daily for 2 weeks then 200 mg twice daily had no effect on the AUC of stavudine 30 to 40 mg twice daily in a study in 22 patients. Nevirapine appears to have no effect on lamivudine clear ance, based on a population pharmacokinetic study.

**NNRTIs + Protease inhibitors**

In general, efavirenz and nevirapine decrease the levels of protease inhibitors, whereas delavirdine increases them. Ritonavir is sometimes used to elevate the levels of other protease inhibitors when efavirenz or nevirapine are required. Amprenavir and nelfinavir decrease the levels of delavirdine. Most protease inhibitors do not appear to affect the levels of efavirenz or nevirapine. There is some evidence of increased adverse effects with antiviral doses of ritonavir and efavirenz. This includes raised liver enzymes. Note that NNRTIs are not given with protease inhibitors in current first-line regimens for HIV infection: either an NNRTI or protease inhibitors are combined with dual NNRTIs.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

For a summary of the studies of the pharmacokinetic interactions of delavirdine and various protease inhibitors, see ‘Table 21.3’, (p.786). In general, these studies show that delavirdine can markedly increase protease inhibitor exposure. In addition, amprénavir and nelfinavir have been shown to approximately halve the AUC of delavirdine.

Delavirdine and the protease inhibitors are known to be both inhibitors of, and substrates for the cytochrome P450 isoenzyme CYP3A4, see ‘Table 21.2’, (p.773).

It has been suggested that delavirdine could be used clinically to boost the exposure to protease inhibitors, and this has been tried in at least one study. However, this combination is complicated by the reduction in delavirdine levels with some protease inhibitors, and the combination may not be appropriate if the antiviral effect of delavirdine is required. Moreover, if the combination is used, patients should be closely monitored for toxicity since in one study of nelfinavir and delavirdine, 4 out of 24 subjects had to stop both drugs before completing the study because of neutropenia, which resolved over several days.3 The UK manufacturer of delavirdine says that liver function should be monitored frequently if delavirdine is also given, because in a small preliminary study hepatic enzymes were raised in 13% of subjects (grade 3 or 4 in 6%) receiving the combination.

(b) Efavirenz

For a summary of the studies of the pharmacokinetic interactions of efavirenz and various protease inhibitors, see ‘Table 21.3’, (p.786). Most of the
protease inhibitors did not affect efavirenz levels, although ritonavir caused a 20% increase in levels. Efavirenz is an inducer of the cytochrome P450 isoenzyme CYP3A4, by which the protease inhibitors are metabolised. With the exceptions of nevirapine and ritonavir, which showed minor to modest increases in levels, efavirenz reduces the levels of the protease inhibitors, often to levels likely to lead to reduced antiviral efficacy. Ways to overcome this include the addition of low-dose ritonavir to boost the levels of the protease inhibitor (recommended for amprenavir, atazanavir, fosamprenavir, saquinavir) or increasing the dose for protease inhibitors already boosted by ritonavir (recommended for lopinavir/ritonavir). For a summary of the manufacturers’ recommended regimens for use with efavirenz 600 mg daily see ‘Table 21.4’, (below). However, the manufacturers of efavirenz note that increased adverse effects, including dizziness, nausea, paraesthesia and elevated liver enzyme levels occurred with the combination of efavirenz and ritonavir 500 or 600 mg twice daily (antiretroviral dosage), and the combination was not well tolerated. They recommend monitoring liver enzyme levels with this combination. The UK manufacturer says that the tolerability of low-dose ritonavir with efavirenz has not been assessed, and they caution that the possibility of an increase in the incidence of efavirenz-associated adverse events should be considered with any ritonavir-boosted regimen used with efavirenz, due to a possible interaction. With lopinavir/ritonavir, although an increased dose of 533/133 mg twice daily with efavirenz or nevirapine produced similar plasma levels of efavirenz to those seen with the lower dose of 400/100 mg twice daily without an NNRTI, the proportion of patients with a suboptimal minimum lopinavir level tended to be higher in those patients receiving the NNRTI. This suggests that some patients may need a further increase in lopinavir/ritonavir dose. Another study with atazanavir/ritonavir also found that the increased dose of atazanavir for use with NNRTIs did not appear to overcome the inducer effect of NNRTIs (efavirenz or nevirapine) and led to a 43% lower median minimum atazanavir level, and a greater proportion of patients with suboptimal minimum levels (25% versus 7%).

(c) Nevirapine

For a summary of the studies of the pharmacokinetic interactions of nevirapine and various protease inhibitors, see, ‘Table 21.3’, (p.786). Most protease inhibitors do not appear to affect the levels of nevirapine, although some caused a minor to modest increase. Nevirapine is an inducer of the cytochrome P450 isoenzyme CYP3A4, and so would be expected to reduce the levels of some of the protease inhibitors (see ‘Table 21.2’, (p.773)), sometimes to levels that are unlikely to be effective. Low-dose ritonavir has been used to boost the levels of some protease inhibitors when they were given with nevirapine. For a summary of the manufacturers’ recommended regimens for use with nevirapine see ‘Table 21.4’, (below). If nevirapine is used with protease inhibitors, therapy should be closely monitored. For studies suggesting that increased doses of lopina-

\(^1\) The UK manufacturer of efavirenz advises caution, because the possibility of an increase in the incidence of efavirenz-associated adverse events should be considered with any ritonavir-boosted regimen used with efavirenz, due to a possible interaction. This is because the combination of efavirenz with ritonavir antiviral doses caused increased dizziness, nausea, paraesthesia and elevated transaminase levels.

\(^2\) This dose increase may not be sufficient in some patients, so some caution is required.
NNRTIs + Rifamycins

Rifabutin and rifampicin (rifampicin) cause a very marked fall in delavirdine plasma levels: rifabutin levels are raised when the delavirdine dose is increased to compensate for this. Rifabutin does not affect efavirenz levels, whereas efavirenz decreases rifabutin levels. There is usually no important interaction between rifabutin and nevirapine, although some patients may have a higher risk of rifabutin adverse effects. Neither efavirenz nor nevirapine affect rifampicin levels, but rifampicin modestly reduces the levels of these NNRTIs, and there is some debate about whether it is necessary to increase their dose.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

In a controlled study in 7 HIV-positive patients taking delavirdine mesilate 400 mg three times daily for 30 days, the addition of rifabutin 300 mg daily from days 16 to 30 caused a fivefold increase in the delavirdine clearance, and an 84% fall in the steady-state plasma levels. This was presumably due to the enzyme-inducing effects of the rifampicin. A similar study using rifampicin in place of rifabutin found that rifampicin caused a 27-fold increase in clearance of delavirdine, and the steady-state plasma levels became almost undetectable.

In another study, where the dose of delavirdine was titrated to achieve a trough level of at least 5 micromol/L, the AUC of rifabutin was found to increase by 242%.

It has been recommended that the combination of delavirdine and rifampicin should be considered as contraindicated because the effects of the interaction are so large. The CDC in the US and the manufacturer recommend that neither rifabutin nor rifampicin should be used with delavirdine.

(b) Efavirenz

1. Rifabutin. In a study in healthy subjects the concurrent use of efavirenz 600 mg once daily and rifabutin 300 mg once daily for 2 weeks resulted in a modest 38% decrease in the AUC of rifabutin and a 45% decrease in the minimum levels, but no change in efavirenz levels.

The CDC in the US state that the combination is probably clinically useful, and they suggest increasing the dose of rifabutin to 450 mg or 600 mg daily, or 600 mg two to three times weekly. In one study doubling the rifabutin dose from 300 mg twice weekly to 600 mg twice weekly when starting efavirenz resulted in rifabutin AUCs that were 20% higher than baseline values. However, in one analysis, 8 of 35 patients (23%) taking efavirenz and given rifabutin 450 mg once daily were found to have subtherapeutic rifabutin levels, and they were switched to isoniazid. Concurrent use should therefore be closely monitored.

2. Rifampicin (Rifampin). In patients with HIV and tuberculosis the concurrent use of HAART including efavirenz 600 mg once daily with antitubercular therapy including rifampicin 480 to 720 mg daily decreased the AUC of efavirenz by 22% and decreased the trough concentration by 25% (although large interpatient variability was observed). Overall the pharmacokinetics of efavirenz 800 mg daily with rifampicin were similar to those of efavirenz 600 mg daily without rifampicin. The pharmacokinetics of rifampicin were not substantially altered by efavirenz. A similar 26% reduction in efavirenz AUC was reported in a study in healthy subjects. The CDC in the US suggest that it may be advisable to increase the efavirenz dose to 800 mg daily when used with rifampicin, and the UK manufacturer also recommends this. However, an analysis of 97 patients receiving rifampicin and efavirenz 500 mg daily developed significant clinical toxicity and were found to have efavirenz levels markedly higher than the therapeutic range. In another study in Thai patients taking rifampicin, median efavirenz plasma levels were comparable between those receiving 600 mg daily and 800 mg daily and similar virological outcomes were seen. Therefore, a 600 mg dose of efavirenz may be sufficient in some patients. Concurrent use should be well monitored.

(c) Nevirapine

1. Rifabutin. In one study, the pharmacokinetics of nevirapine were only minimally affected by rifabutin in 19 patients, when compared with historical data. The manufacturer notes that the concurrent use of rifabutin with nevirapine caused a minimal 9% decrease in nevirapine clearance and a 17% increase in its AUC, and a 28% increase in maximum steady-state rifabutin levels. They say that because of the high interindividual variabi

In patients with poor gastric acid production, orange juice and glutamic acid increase the absorption of delavirdine.

**Clinical evidence, mechanism, importance and management**

*When glutamic acid 1.36 g three times daily was given with delavirdine 400 mg three times daily to 8 HIV-positive subjects with gastric hypoaclidcy, the AUC of delavirdine was increased by 50%.*

**Experimental data**

**Conclusion**

There is some evidence to suggest that St John’s wort may decrease the levels of nevirapine. Delavirdine and efavirenz would be expected to be similarly affected.

**Clinical evidence, mechanism, importance and management**

Nevirapine levels, obtained by routine monitoring, were noted to be lower in 5 men who were also taking St John’s wort. Based on a pharmacokinetic modelling analysis, it was estimated that St John’s wort increased the oral clearance of nevirapine by about 35%. This finding supports predictions based on the known metabolism of the NNRTIs by the cytochrome P450 enzymes (AIDS 1999; 13, 2489–90).

**Clinical evidence, mechanism, importance and management**

In a pharmacokinetic study, there was no interaction between efavirenz 600 mg daily and tenofovir disoproxil fumarate 300 mg daily. Similarly, in a retrospective analysis, plasma levels of nevirapine 200 mg twice daily or 400 mg once daily did not differ between patients taking tenofovir disoproxil fumarate 300 mg once daily and those not. Also, efavirenz plasma levels did not differ between patients taking tenofovir and patients not taking tenofovir. It appeared that neither nevirapine nor efavirenz altered tenofovir levels.

**Clinical evidence, mechanism, importance and management**

In a pharmacokinetic study, there was no interaction between efavirenz 600 mg daily and tenofovir disoproxil fumarate 300 mg daily. Similarly, in a prospective analysis, plasma levels of nevirapine 200 mg twice daily or 400 mg once daily did not differ between patients taking tenofovir disoproxil fumarate 300 mg once daily and those not. Also, efavirenz plasma levels did not differ between patients taking tenofovir and patients not taking tenofovir. It appeared that neither nevirapine nor efavirenz altered tenofovir levels.

**Clinical evidence, mechanism, importance and management**

Some clinical data have shown a high rate of treatment failure when tenofovir is given with enteric-coated didanosine and either efavirenz or nevirapine.

**Clinical evidence, mechanism, importance and management**

In a pharmacokinetic study, there was no interaction between efavirenz 600 mg daily and tenofovir disoproxil fumarate 300 mg daily. Also, efavirenz plasma levels did not differ between patients taking tenofovir and patients not taking tenofovir. It appeared that neither nevirapine nor efavirenz altered tenofovir levels.

**Clinical evidence, mechanism, importance and management**

Some clinical data have shown a high rate of treatment failure when a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 200 or 250 mg and either efavirenz 600 mg daily or nevirapine 400 mg daily. These specific combinations should probably not be used. However, there are clinical data supporting the use of other tenofovir and efavirenz-based regimens, and the manufacturers specifically caution against the use of tenofovir with didanosine, see ‘NRTIs + Tenofovir’, p. 806.

**NRTIs; Delavirdine + Acids**

The concurrent use of zidovudine and aciclovir normally appears to be uneventful, but an isolated report describes overwhelming fatigue in one patient given zidovudine and intravenous aciclovir. Famiciclovir did not alter the pharmacokinetics of zidovudine or emtricitabine.

**Clinical evidence, mechanism, importance and management**

(a) Aciclovir

A study in 20 HIV-positive men found no pharmacokinetic interaction between zidovudine 100 mg and aciclovir 400 or 800 mg, both given every 4 hours, 5 times a day, and the combination was well tolerated over a 6-month period. When 41 HIV-positive patients taking zidovudine were given aciclovir, no changes in the pharmacokinetics of the zidovudine occurred and the adverse effects were unchanged. In a group of AIDS patients taking zidovudine, some of whom were also given aciclovir, no obvious problems developed that could be attributed to the use of the aciclovir.

In contrast, a man with herpes who had been treated with intravenous aciclovir 250 mg every 8 hours for 3 days, developed overwhelming fatigue and lethargy within about an hour of starting oral zidovudine 200 mg every 4 hours. This lessened slightly on changing from intravenous to oral aciclovir, which was continued for 3 days, and symptoms resolved when the

**NRTIs + Aciclovir and related drugs**

The concurrent use of zidovudine and aciclovir normally appears to be uneventful, but an isolated report describes overwhelming fatigue in one patient given zidovudine and intravenous aciclovir. Famiciclovir did not alter the pharmacokinetics of zidovudine or emtricitabine.

**Clinical evidence, mechanism, importance and management**

(a) Aciclovir

A study in 20 HIV-positive men found no pharmacokinetic interaction between zidovudine and aciclovir. Both drugs were given every 4 hours, 5 times a day, and the combination was well tolerated over a 6-month period. When 41 HIV-positive patients taking zidovudine were given aciclovir, no changes in the pharmacokinetics of the zidovudine occurred and the adverse effects were unchanged. In a group of AIDS patients taking zidovudine, some of whom were also given aciclovir, no obvious problems developed that could be attributed to the use of the aciclovir.

In contrast, a man with herpes who had been treated with intravenous aciclovir 250 mg every 8 hours for 3 days, developed overwhelming fatigue and lethargy within about an hour of starting oral zidovudine 200 mg every 4 hours. This lessened slightly on changing from intravenous to oral aciclovir, which was continued for 3 days, and symptoms resolved when the
Aciclovir was withdrawn. The symptoms developed again when intravenous aciclovir was given as a test. This isolated case of fatigue is not understood, and no other cases appear to have been reported. There would seem to be no reason for avoiding concurrent use.

**NRTIs + Antacids**

Aluminium/magnesium hydroxide caused a 25% reduction in the bioavailability of zalcitabine. Antacids would not be expected to have any additional pharmacokinetic effect on buffered didanosine preparations.

### Clinical evidence, mechanism, importance and management

**(a) Didanosine**

Didanosine is acid labile. To increase its absorption, some didanosine preparations (e.g. buffered tablets) have been formulated with antacids. Additional concurrent antacids would not be expected to have any further clinically relevant effect on didanosine pharmacokinetics, although the US manufacturers of the oral powder for solution suggest that additional antacids may increase the adverse effects of the components of this preparation (presumably both the antacid and didanosine components).

**(b) Zalcitabine**

A study in 12 HIV-positive patients given a single 1.5-g dose of zalcitabine found that 30 mL of *Maalox* [aluminium/magnesium hydroxide] caused a 25% reduction in the bioavailability of the zalcitabine. The changes are moderate and of uncertain clinical importance. The manufacturer recommended that zalcitabine should not be taken at the same time as aluminium/magnesium-containing antacids.

**NRTIs + Antiepileptics**

Valproate increases the bioavailability of zidovudine, and one case of severe anaemia was attributed to the interaction. A case of liver toxicity with combined use has also been reported. Phenobarbital and phenytoin are predicted to slightly decrease abacavir levels.

### Clinical evidence

**(a) Abacavir**

The UK manufacturer of abacavir says that phenobarbital and phenytoin may slightly decrease abacavir concentrations by affecting glucuronyltransferases. There appears to be no other information on this.

**(b) Zidovudine**

The AUC and mean plasma levels of zidovudine 100 mg every 8 hours were increased by 80% in 6 HIV-positive subjects when they were given valproic acid 250 or 500 mg every 8 hours for 4 days. No adverse reactions, changes in hepatic or renal function, or alterations in the blood picture were reported. A case report describes an AIDS patient taking zidovudine 100 mg five times daily who had a two- to threefold increase in trough and peak serum zidovudine levels, and a 74% increase in the CSF zidovudine levels while taking valproic acid 500 mg three times daily. In another report, a patient taking carbamazepine, clozapam and gabapentin was given zidovudine, lamivudine and abacavir. Nine months later, valproic acid 500 mg twice daily was added because of a seizure frequency of greater than one per month. At this time, his haemoglobin level was normal. About 2 months later, he was found to have severe anaemia, requiring a blood transfusion.

### Importance and management

Information seems to be limited to the papers cited, but an interaction between zidovudine and valproate would appear to be established. It would therefore seem prudent to monitor for any evidence of increased zidovudine effects and possible toxicity if valproate is added. The other NRTIs do not undergo significant glucuronidation (see ‘Antivirals’, (p.772)), and do not interact similarly with abacavir. The other NRTIs may slightly decrease abacavir concentrations by affecting glucuronyltransferases, such as phenobarbital and phenytoin.

---

---

**NRTIs + Antimycobacterials**

Didanosine, stavudine and zalcitabine are not expected to interact with rifabutin, but rifabutin may modestly increase the clearance of zidovudine. An isolated case describes undetectable rifabutin levels in a patient taking antiretrovirals including buffered didanosine. Rifampicin (rifampin) appears to modestly increase the clearance of zidovudine, and is predicted to interact similarly with abacavir.
Isoniazid, pyrazinamide and ethambutol appear not to interact with zidovudine. The clearance of isoniazid is increased by zalcitabine, and there is a theoretical increased risk of peripheral neuropathy.

Clinical evidence, mechanism, importance and management

(a) Abacavir

The UK manufacturer of abacavir\(^4\) says that potent enzyme inducers such as rifampicin (rifampin) may slightly decrease abacavir plasma concentrations due to their ability to induce UDP-glucuronosyltransferases (see also Zidovudine, below). As yet, there appears to be no other information on this.

(b) Didanosine

Rifabutin 300 to 600 mg daily for 12 days did not significantly affect the pharmacokinetics of [buffered] didanosine 167 to 250 mg twice daily in 12 patients with AIDS.\(^2\) The steady-state pharmacokinetics of rifabutin were not affected by didanosine (buffered sachet preparation),\(^3\) which suggests that the buffer used in the didanosine preparation had no effect on rifabutin absorption. However, a case has been reported of a patient taking lopinavir/ritonavir, efavirenz, lamivudine and buffered didanosine who had impaired rifabutin absorption. When rifabutin was taken 30 minutes after didanosine, rifabutin levels were undetectable, but when rifabutin was taken 3 hours after didanosine, rifabutin levels were apparent.\(^6\)

The controlled study\(^3\) suggests that no special precautions are necessary if both drugs are given. However, the case report\(^4\) introduces an element of caution, especially if other drugs that may affect rifabutin pharmacokinetics are used. If indeed rifabutin absorption is affected by antacids (there appear to be no clinical data on this), then giving the drugs at least 2 hours apart, or using the enteric-coated didanosine preparation should avoid the interaction.\(^5\)

(c) Stavudine

A study in 10 HIV-positive subjects found that rifabutin 300 mg daily had no significant effects on the pharmacokinetics of the stavudine 30 or 40 mg twice daily and the incidence of adverse effects did not increase.\(^5\) No special precautions would seem necessary if both drugs are given.

(d) Zalcitabine

A study in 12 HIV-positive patients found that when zalcitabine 1.5 mg three times daily was given with isoniazid 300 mg daily the pharmacokinetics of the zalcitabine remained unchanged but the clearance of the isoniazid was approximately doubled.\(^6\) The UK manufacturer of zalcitabine\(^7\) recommended caution with the combination because of the possibility of an increased risk of peripheral neuropathy; the US manufacturer recommended that the combination should be avoided where possible.\(^8\)

The UK manufacturer of rifabutin suggests that no significant interaction would be expected between rifabutin and zalcitabine.\(^9\)

(e) Zidovudine

The pharmacokinetics of rifabutin are not affected by the concurrent use of zidovudine in AIDS patients.\(^10,11\) and rifabutin does not affect the pharmacokinetics of zidovudine in HIV-positive patients,\(^12\) although one review found a trend towards increased zidovudine clearance.\(^13\) No increase in adverse effects appears to occur when rifabutin is given with zidovudine.\(^11\)

In a retrospective study of healthy subjects and HIV-positive individuals, the clearance of zidovudine was increased by 132% by rifampicin and by 50% by rifabutin, suggesting that the enzyme-inducing effects of rifabutin are less than those of rifampicin, so less significant interactions would be expected.\(^14\)

A comparative study in HIV-positive patients given zidovudine and antitubercular treatment (isoniazid, rifampicin, pyrazinamide, ethambutol initially, then isoniazid and rifampicin) for 8 months found no evidence of an adverse interaction. However, marked anaemia occurred in those subjects given both groups of drugs, but it was not necessary to permanently stop zidovudine in any patient. The authors advise careful monitoring for haematological toxicity.\(^15\) Another study in 4 HIV-positive patients found that rifampicin lowered the AUC and increased the clearance of zidovudine in all patients, probably due to the enzyme-inducing activity of the rifampicin, which increases the glucuronidation of zidovudine. When the rifampicin was stopped in one patient, his zidovudine AUC doubled.\(^16\) A later study of the same interaction in 8 HIV-positive men found that rifampicin significantly increased the glucuronidation of zidovudine and suggested that the effect wore off 14 days after stopping the rifampicin. The authors of this study suggest that dosage alterations may not be necessary on concurrent use.\(^17\)

**NRTIs + Atovaquone**

Moderate increases in the AUC of zidovudine, not usually requiring dose adjustments, have been seen with atovaquone. However, it may be prudent to regularly monitor for adverse effects. Atovaquone decreased the AUC of didanosine. Neither didanosine nor zidovudine affected atovaquone pharmacokinetics.

Clinical evidence

(a) Didanosine

The manufacturer of atovaquone notes that it decreased the AUC of didanosine by 24% in a multiple dose interaction study. There was no change in the pharmacokinetics of atovaquone.\(^1\)

(b) Zidovudine

A study in 14 HIV-positive patients given atovaquone 750 mg every 12 hours and zidovudine 200 mg every 8 hours found that under steady-state conditions the zidovudine had no effect on the pharmacokinetics of atovaquone.\(^2\) This confirmed the findings of a previous analysis of pharmacokinetic data from a small number of patients enrolled in clinical studies.\(^1\) However, the AUC of the zidovudine was increased by about 30%, and its clearance was reduced by 25% by the concurrent use of atovaquone.\(^2\)

**Mechanism**

Atovaquone might inhibit the metabolism (glucuronidation) of zidovudine.\(^2\)

**Importance and management**

The manufacturer of atovaquone notes that the decrease in didanosine levels is unlikely to be clinically relevant.\(^1\) They also say that the increased plasma levels of zidovudine likely with a 3-week course of atovaquone for acute Pneumocystis pneumonia are unlikely to increase the adverse effects of zidovudine,\(^1\) and routine dose adjustments are not required.\(^4\) Nevertheless, the manufacturers of atovaquone and zidovudine do recommend reg-
ular monitoring for zidovudine-associated adverse effects when the drugs are used together, particularly if atovaquone suspension is used, as this achieves higher atovaquone levels, which might have a greater effect.\textsuperscript{1,2} The authors of the study with zidovudine\textsuperscript{7} suggest that increases could possibly be important in patients also taking other drugs causing bone marrow toxicity (such as ganciclovir, amphotericin B, flucytosine). If bone marrow toxicity is seen, it is suggested that the zidovudine dosage may need to be reduced by a third.\textsuperscript{2}

Relationship between steady-state plasma concentrations of atovaquone (C\textsubscript{ss}) and the use of various concomitant medications in AIDS patients with Pneumocystis carinii pneumonia. 9\textsuperscript{th} International Conference AIDS & 4\textsuperscript{th} STD World Congress, Berlin, June 6–11 1993. Abstract PO-B31-2213.

**NRTIs + Azoles**

Fluconazole has no significant effect on the pharmacokinetics of didanosine or stavudine, but it may cause an increase in serum zidovudine levels although the clinical importance of this is uncertain. Fluconazole serum levels remain unchanged.

Itraconazole appears not to affect the pharmacokinetics of zidovudine. Serum levels of stavudine are markedly reduced when buffered didanosine is given at the same time, but itraconazole and ketoconazole are not affected if buffered didanosine is given 2 hours later. Enteric-coated didanosine has no clinically relevant effect on the pharmacokinetics of fluconazole, itraconazole or ketoconazole. The frequency of haematological toxicity with zidovudine was increased.

**Clinical evidence**

(a) Didanosine

1. **Buffered preparation.** A 35-year-old patient with AIDS was given itraconazole capsules 200 mg twice daily following an episode of cryptococcal meningitis. When he relapsed it was noted that he had been taking the itraconazole at the same time as his buffered didanosine. Subsequent study in this patient indicated a marked delay in itraconazole absorption when it was taken with didanosine. Two hours after the dose, plasma itraconazole concentrations of 1.6 micrograms/ml were observed without didanosine, but were undetectable with didanosine. A peak itraconazole level of 1.4 micrograms/ml was observed when it was given 8 hours after a dose of didanosine.\textsuperscript{1} In 6 healthy subjects when [buffered] didanosine was given with a single 200-mg oral dose of itraconazole, the peak levels of itraconazole were undetectable; in the absence of didanosine, itraconazole levels were 0.9 micrograms/ml.\textsuperscript{2} A later study in 12 HIV-positive patients found that the AUC of itraconazole after a single 200-mg dose was not significantly different when buffered didanosine 200 mg was given 4 hours before or 2 hours after itraconazole.\textsuperscript{3}

12 Twelve HIV-positive patients were given buffered didanosine 375 mg twice daily either alone or 2 hours after ketocazole 200 mg daily, for 4 days. Didanosine maximum plasma levels were slightly reduced by 12\% and no significant changes in the pharmacokinetics of the ketoconazole were seen when dosing was separated in this way.\textsuperscript{4} A group of 12 HIV-positive subjects taking buffered didanosine 100 to 250 mg twice daily were also given fluconazole for 7 days (two 200-mg doses on the first day, followed by 200 mg daily). The pharmacokinetics of the didanosine remained unchanged in the presence of the fluconazole, and concurrent use was well tolerated. Fluconazole pharmacokinetics were not assessed.\textsuperscript{5}

2. **Enteric-coated preparation.** Enteric-coated didanosine 400 mg had no significant effect on the pharmacokinetics of fluconazole 200 mg in 14 healthy subjects, and no clinically relevant effect on the pharmacokinetics of itraconazole 200 mg in 25 healthy subjects.\textsuperscript{6} Similarly, enteric-coated didanosine 400 mg had no clinically relevant effect on the pharmacokinetics of ketoconazole 200 mg in 24 healthy subjects. Three of the subjects had increased concentrations of ketoconazole with didanosine, but their values for ketoconazole alone appeared unusually low. When their data were excluded, no effect on AUC was seen in the remaining 21 subjects.\textsuperscript{7}

(b) Stavudine

A study in 10 HIV-positive subjects taking stavudine 40 mg twice daily, found that the addition of fluconazole 200 mg daily for one week had no significant effect on the pharmacokinetics of the stavudine.\textsuperscript{8}

(c) Zidovudine

On two occasions, 12 HIV-positive men were given zidovudine 200 mg every 8 hours with and without fluconazole 400 mg daily for 7 days. While taking fluconazole the AUC of the zidovudine increased by 74\%, the maximum serum levels increased by 84\%, the terminal half-life was increased by 128\% and the clearance was reduced by 43\%.\textsuperscript{9} In contrast, another study in 10 HIV-positive patients found only a very small change in the pharmacokinetics of a single 500-mg dose of zidovudine given before and after 7 days treatment with fluconazole (e.g. a 7\% increase in zidovudine AUC). In another 10 patients, zidovudine had no effect on the pharmacokinetics of a single dose of fluconazole.\textsuperscript{10}

Itraconazole 200 mg daily for 2 weeks was reported to have no effect on the pharmacokinetics of zidovudine in 7 patients, but the serum levels in 2 patients were higher.\textsuperscript{11}

A study of zidovudine use in 282 AIDS patients found that haematological abnormalities (anaemia, leucopenia, neutropenia) were very common, but this was not increased by the concurrent use of ketoconazole in some of these patients.\textsuperscript{12}

**Mechanism**

Itraconazole capsules and ketoconazole depend on stomach acidity for absorption. A raised gastric pH, caused by the antacids in the buffered didanosine formulation appears to reduce itraconazole absorption (consider, ‘Azoles + Antacids’, p.215). The didanosine itself appears to have no part to play in this interaction. The enteric-coated preparation of didanosine does not contain any antacids and therefore does not interact.

*In vitro* data suggest that the altered zidovudine pharmacokinetics may, in part, occur because fluconazole inhibits zidovudine glucuronidation.\textsuperscript{13}

**Importance and management**

The most significant interaction occurs between the buffered preparation of didanosine and itraconazole. Patients should avoid taking both drugs at the same time, but giving the itraconazole at least 2 hours before the didanosine appears to solve any problem. Any possible interaction with ketoconazole can similarly be avoided by giving ketoconazole at least 2 hours before didanosine. Alternatively, the interaction may be avoided by using the enteric-coated preparation of didanosine.

There is no pharmacokinetic interaction between stavudine and fluconazole. No interaction would be expected with other similar NRTIs such as lamivudine and zalcitabine (see ‘Antivirals’, (p.772)). There is evidence of a minor interaction between zidovudine and fluconazole, but this is unlikely to be clinically significant.

NRTIs + Co-trimoxazole or Trimethoprim

Trimethoprim, both alone and as co-trimoxazole (trimethoprim with sulfamethoxazole) reduces the renal clearance of lamivudine, zalcitabine and zidovudine, and therefore raises their plasma levels. However, the extent of the interaction does not usually appear to be clinically significant in patients with normal renal function. No clinically significant adverse pharmacokinetic interaction occurs if didanosine is given with co-trimoxazole or trimethoprim.

Clinical evidence

(a) Didanosine

A study in 10 HIV-positive subjects investigated the pharmacokinetics of didanosine 200 mg, trimethoprim 200 mg and sulfamethoxazole 1 g in combination. Most pharmacokinetic parameters were unchanged. However, didanosine clearance was reduced by 35%, trimethoprim clearance was decreased by 32% and sulfamethoxazole clearance was increased by 39%, when all 3 drugs were given together. When only 2 of the 3 drugs were given, trimethoprim caused a 27% decrease in the clearance of didanosine, and didanosine caused an 82% increase in the clearance of sulfamethoxazole. Despite these alterations in clearance, the maximum serum concentration, AUC and half-life of each of the three drugs were minimally affected.1

(b) Lamivudine

In a study of 14 HIV-positive patients taking co-trimoxazole 960 mg daily for 5 days, it was found that the AUC of a single 300-mg dose of lamivudine given on day 4 was increased by 43% and the renal clearance was decreased by 35%. The pharmacokinetics of the trimethoprim and the sulfamethoxazole were unaffected.2 Similarly, in a population pharmacokinetic analysis, the concurrent use of lamivudine and co-trimoxazole was associated with a 31% reduction in the apparent oral clearance of lamivudine, and an estimated 43% increase in steady-state lamivudine levels.3 The UK manufacturer notes that the interaction is due to trimethoprim, and that sulfamethoxazole did not interact.4

(c) Stavudine

The UK manufacturer notes that an interaction with trimethoprim is possible, since both drugs are actively secreted by the renal tubules.5

(d) Zalcitabine

In a steady-state study, 8 HIV-positive patients received zalcitabine 1.5 mg three times daily with and without trimethoprim 200 mg twice daily. The trimethoprim increased the AUC and decreased the clearance of zalcitabine by about 35%.6

(e) Zidovudine

A study in 9 HIV-positive patients given zidovudine 3 mg/kg by infusion over 1 hour found that neither trimethoprim 150 mg nor co-trimoxazole 960 mg affected the metabolic clearance of the zidovudine. However, the renal clearances of zidovudine were reduced by 48% and 58%, by trimethoprim and co-trimoxazole respectively, and the renal clearances of its glucuronide metabolite were reduced by 20% and 27%, respectively.7 Another study also found that co-trimoxazole did not alter zidovudine pharmacokinetics.8 A further 5 HIV-positive patients had a 30% increase in the AUC of zidovudine when they were given trimethoprim [dosages not stated].9 Zidovudine renal clearance was reduced by 58% in 8 HIV-positive subjects when they were also given trimethoprim 200 mg, but the AUC0-6 of the zidovudine glucuronide/zidovudine ratio was unchanged, suggesting that the metabolism was unaffected.10

Increases in the half-lives of trimethoprim, sulfamethoxazole and N-acetyl sulfamethoxazole of 72%, 39%, and 115%, respectively, were seen when co-trimoxazole was given to 4 patients with AIDS taking zidovudine 250 mg every 8 hours for 8 days.11 A study of zidovudine use in 282 AIDS patients found that hematological abnormalities (anemia, leucopenia, neutropenia) were common. However, the frequency was not increased in the patients [number unknown] also taking co-trimoxazole.12

Mechanism

A likely reason is that the trimethoprim inhibits the secretion of both zidovudine and its glucuronide by the kidney tubules. It is not known why the half-life of co-trimoxazole is increased. The other NRTIs that interact are likely to do so by the same mechanism.

Importance and management

Established interactions. With the NRTIs that are actively excreted via the kidneys (e.g. lamivudine, stavudine, and zalcitabine), it is unlikely that dosage alterations are necessary unless the patient has renal impairment. However, when both drugs are needed, patients should be closely monitored for signs of toxicity. Moreover, the UK manufacturer of lamivudine recommends that the use of lamivudine with high-dose co-trimoxazole for the treatment of Pneumocystis pneumonia and toxoplasmosis should be avoided.4 Since renal clearance represents only 20 to 30% of the total clearance of zidovudine, the authors of two of these reports,10 suggest that this interaction is unlikely to be clinically important for zidovudine unless the glucuronidation by the liver is impaired by liver disease or other drugs. Didanosine also does not appear to interact to a clinically relevant extent.

Nevertheless concurrent use should be well monitored, especially because co-trimoxazole alone has been associated with a high incidence of adverse effects in patients with AIDS.13

NRTIs + Cytokines

Interferon alfa does not alter the pharmacokinetics of didanosine or lamivudine to a clinically relevant extent. Interferon alfa and, particularly, interferon beta can cause an increase in the serum levels of zidovudine. HIV-positive patients infected with hepatitis C and treated with interferon alfa and ribavirin may be at special risk of NRTI-associated lactic acidosis. Interleukin-2 appears not to interact significantly with zidovudine.
Clinical evidence

(a) Interferon

AIDS patients who had been taking zidovudine 200 mg every 4 hours for 8 weeks were also given subcutaneous recombinant beta interferon 45 million units daily. After 3 and 15 days the zidovudine metabolism was reduced by 75% and 97%, respectively. By day 15 the zidovudine half-life was increased by about twofold.¹ Another study in 6 children aged 3 months to 17 years found that after 5 weeks of concurrent use interferon alfa increased the AUC of zidovudine by 36%, increased its maximum serum level by 69% and reduced its clearance by 20%.²

Interferon alfa 1 to 15 million units daily was given to 26 HIV-positive patients taking didanosine sachets 100 to 375 mg twice daily. The interferon appeared to have no clinically significant effects on the pharmacokinetics of the didanosine.³ Similarly, a single subcutaneous injection of interferon alfa 10 million units had no clinically significant effects on the pharmacokinetics of lamivudine 100 mg daily, given to 19 healthy subjects for 7 days (the lamivudine AUC was decreased by about 10%). Lamivudine did not appear to alter the pharmacokinetics of interferon alfa.⁴

(b) Interleukin-2

A study found that a 4-week course of interleukin-2 (0.25 million units/m² daily) by continuous infusion had no clinically significant effect on the pharmacokinetics of a 100-mg intravenous dose of zidovudine.⁵ Another study in 8 HIV-positive men given oral zidovudine 200 mg every 4 hours found similar results.⁶ No special precautions would seem necessary.

Mechanism

Interferon beta appears to inhibit the metabolism (glucuronidation) of the zidovudine by the liver.

Importance and management

Information seems to be limited to these reports. The results of the first report suggest that the zidovudine dosage may need to be reduced if interferon beta is added in order to avoid increased zidovudine toxicity. A dosage reduction of two-thirds, or even more, may be necessary. More study is needed to confirm these observations. Interferon alfa appears to interact to a lesser extent. The manufacturers warn that the risk of haematological toxicity may be increased if zidovudine and interferon are used together, and combined use in hepatitis C may increase the risk of NRTI-associated lactic acidosis: patients at risk should be carefully monitored.⁷ Interferon alfa does not appear to affect the pharmacokinetics of didanosine or lamivudine. Nevertheless, all manufacturers note that, because of the risk of NRTI-associated lactic acidosis, caution should be exercised when giving NRTIs (abacavir, didanosine, emtricitabine, lamivudine, stavudine, zidovudine) to any patient with hepatomegaly, hepatitis or other known risk factors for liver disease and hepatic steatosis, and that HIV-positive patients infected with hepatitis C and treated with interferon alfa and ribavirin may constitute a special risk. Patients at increased risk should be monitored closely.

NRTIs + Dapsone

Buffered didanosine does not alter the pharmacokinetics of dapsone, but there is some circumstantial evidence to suggest that it may reduce the prophylactic effects of dapsone in preventing Pneumocystis pneumonia. Dapsone has no effect on the pharmacokinetics of zalcitabine, whereas zalcitabine causes a small rise in the serum levels of dapsone, and there is a theoretical increased risk of peripheral neuropathy with the combination. Dapsone appears not to affect the pharmacokinetics of zidovudine, although concurrent use may be associated with increased blood dyscrasias.

Clinical evidence, mechanism, importance and management

(a) Didanosine

An early report of the use of buffered didanosine described the development of Pneumocystis pneumonia in 11 out of 28 HIV-positive patients taking dapsone prophylaxis, compared with only 1 of 12 taking aerosolised pentamidine, and none of 17 taking co-trimoxazole. Of the 11 patients where prophylaxis failed, 4 died from respiratory failure.¹ The authors suggested that the most likely explanation of the high failure rate of dapsone with didanosine, was reduced dapsone absorption due to the citrate-phosphate buffer in the didanosine formulation.² This has led to some recommending that the drugs be taken at least 2 hours apart.

However, in a controlled study in 6 HIV-positive subjects, dapsone pharmacokinetics were not altered when a dose of buffered didanosine was taken within 5 minutes.³ Similarly, in 6 healthy subjects, dapsone pharmacokinetics were not altered by the lamivudine, zidovudine or other excipients contained in didanosine tablets.⁴ Another study in healthy subjects also failed to confirm that a marked rise in gastric pH affects the absorption of dapsone, see ‘Dapsone + Antacids’, p.303. Furthermore, low dapsone levels have been found in patients receiving a weekly dapsone regimen who took dapsone at least 2 hours before or 6 hours after didanosine, and in patients taking zidovudine or no antiretrovirals (although this study did not look at whether dapsone levels were correlated with efficacy).⁵ In a retrospective analysis, other authors found no evidence to confirm a correlation between failure of Pneumocystis pneumonia prophylaxis with dapsone and use of drugs that increase gastric pH (didanosine, H₂-receptor antagonists, antacids).⁶

It has therefore been adequately demonstrated that the buffered preparation of didanosine and antacids do not affect dapsone absorption. The explanation for the apparent failure of Pneumocystis pneumonia prophylaxis in the original report¹ is unresolved. Despite the use of both didanosine and dapsone in the management of HIV and opportunistic infections there do not appear to be any further reports of problems with the combination.

(b) Zalcitabine

A pharmacokinetic study in 12 HIV-positive patients who were given zalcitabine 1.5 mg three times daily and dapsone 100 mg daily, alone or together, found that dapsone did not significantly affect the kinetics of the zalcitabine. However, zalcitabine decreased the clearance of dapsone by 21%, increased its maximum serum levels by 19% and increased its half-life by 34%.⁷ These changes are relatively small and seem unlikely to have much clinical relevance, but until this is confirmed it would seem prudent to monitor the concurrent use of these two drugs. The UK manufacturer⁸ recommended caution with the combination because of the possibility of an increased risk of peripheral neuropathy; the US manufacturer advised avoiding the combination where possible.

(c) Zidovudine

Dapsone 100 mg daily had no effect on the pharmacokinetics of a single 200-mg dose of zidovudine in 8 HIV-positive subjects.⁹ In a further study, which considered the safety of dapsone in combination with zidovudine, dapsone was shown to increase the risk of zidovudine-related blood dyscrasias.¹⁰ Therefore it would seem that dapsone and zidovudine can be given concurrently, but monitoring for an increase in adverse events would seem advisable.

Additive pancreatic toxicity has been described with zalcitabine and intravenous pentamidin, and is expected when didanosine or stavudine are given with other drugs that can cause pancreatitis. An isolated case describes pancreatitis with lamivudine and azathioprine.

Clinical evidence

(a) Lamivudine

A single case report describes a 51-year-old woman with a kidney transplant who developed pancreatitis after starting lamivudine. Azathioprine had been discontinued only 3 days before and it is possible (although the evidence is weak) that the residual serum azathioprine had interacted with lamivudine to cause the pancreatitis.1

(b) Zalcitabine

Fatal fulminant pancreatitis occurred in a patient given zalcitabine and intravenous pentamidine.2

Mechanism

Possible additive toxicity.

Importance and management

Of the NRTIs, didanosine, stavudine and zalcitabine have been associated with fatal pancreatitis.3-7 The manufacturers of zalcitabine recommended that if a drug that has the potential to cause pancreatitis is required, treatment with zalcitabine should be interrupted.2,7 They specifically applied this to the use of pentamidine to treat Pneumocystis pneumonia.2,7

The manufacturers of didanosine have a similar recommendation and state that, if concurrent use is unavoidable, there should be close observation.3,4 Similarly, other authors recommend temporarily discontinuing didanosine in patients needing systemic pentamidine or sulfonamide-containing regimens.8 The UK manufacturer of stavudine recommends that patients receiving concurrent treatment with drugs known to cause pancreatitis should be carefully observed,9 and the US manufacturer specifically recommends caution with combined use of didanosine and stavudine,10 see ‘NRTIs + NRTIs’, p.800. Note that hydroxy carbamide (hydroxyurea) may increase the risk of pancreatitis with didanosine and stavudine, and the combination should probably be avoided, see ‘NRTIs + Hydroxy carbamide’, p.799.

The UK manufacturer states that lamivudine is rarely associated with pancreatitis, but recommend that treatment with lamivudine should be stopped if there is any suspicion of pancreatitis.11 No firm conclusions can be drawn from the case discussed above.

NRTIs + Drugs that cause pancreatitis

Clinical evidence, mechanism, importance and management

(a) Abacavir

The manufacturer of abacavir notes that food delayed its rate, but not extent, of absorption. Therefore, abacavir can be taken with or without food.1,2

(b) Didanosine

1. Buffered preparations. Didanosine (as two 150-mg chewable tablets) was given to 10 HIV-positive subjects on four occasions: 30 minutes before breakfast, 1 hour before breakfast, 1 hour after breakfast, and 2 hours after breakfast. When the dose was given before breakfast the results were very similar to those obtained for subjects in the fasting state. When given after a breakfast, the didanosine AUC and maximum plasma concentration were both decreased by about 50%.3 Similar results were found in another study.4 A further study5 using sachets containing didanosine, sucrose and citrate-phosphate buffer, similarly found that food reduced the bioavailability by 41% (a reduction from 29% to 17%). The reason would appear to be that food delays gastric emptying so that the didanosine is exposed to prolonged contact with gastric acid, which causes decomposition (see ‘Antivirals’, (p.772)), with a resultant fall in bioavailability.6 To achieve maximum bioavailability the didanosine buffered preparations should be taken on an empty stomach at least 30 minutes before food6,7 or 2 hours after food.7

2. Enteric-coated preparation. Giving didanosine gastro-resistant capsules with a high-fat meal or a light meal reduced the AUC by 19% and 27%, respectively, compared with the fasting state. A similar 24% decrease in the AUC was also seen when didanosine was taken 1 hour before a light meal. However, the effect on the AUC was negligible when it was taken 1.5 to 3 hours before a light meal.8 Sprinkling the capsule contents on yoghurt or apple sauce also decreased the AUC by 20% or 18%, respectively.9 Despite these modest changes in AUC, the manufacturer recommends that didanosine gastro-resistant capsules are taken intact on an empty stomach,9 at least 2 hours before or 2 hours after a meal.

(c) Emtricitabine

The manufacturer says that giving emtricitabine hard capsules with a high-fat meal did not affect the AUC of emtricitabine but slightly reduced the maximum level by 29%. Similarly, giving emtricitabine oral solution with a low-fat or high-fat meal did not affect the AUC or maximum level of emtricitabine. Therefore, both these formulations of emtricitabine may be given with or without food.10,11

(d) Lamivudine

The manufacturer notes that food delayed the rate and reduced the maximum plasma concentration (by about 45%), but not the extent (AUC), of lamivudine absorption. Therefore, lamivudine can be taken with or without food.12,13

(e) Stavudine

The UK manufacturer of stavudine notes that a standardised high-fat meal reduced, and delayed the time to reach the maximum plasma concentration (specific details not given), but did not alter the extent of systemic exposure of stavudine, when compared with the fasting state. Nevertheless, they recommend that, for optimal absorption, stavudine should be taken on an empty stomach at least 1 hour before meals. However, if this is not possible, they suggest giving stavudine with a light meal; in addition the contents of the capsule may be mixed with food.14 The US manufacturer states that stavudine can be taken with food or on an empty stomach.15

(f) Zalcitabine

The manufacturers of zalcitabine16,17 noted that food decreased the maximum plasma concentration by 39% and prolonged the time to achieve maximum concentrations from 0.8 to 1.6 hours compared with the fasting state. The extent of absorption was decreased by 14%. The UK manufacturer stated that zalcitabine could be taken with or without food.16
Zidovudine was given to 13 AIDS patients either with breakfast or when fasting. The maximum plasma level of zidovudine was 2.8-fold greater in the fasted patients, and the AUC was reduced by 22% when zidovudine was given with food. Zidovudine rate and extent of absorption was reduced in another study by a standard breakfast (14% decrease in AUC with a 200-mg dose and 33% with a 100-mg dose). In a study of 8 patients, a high-fat meal reduced the maximum zidovudine serum levels by about 50%. In all these cases inter-individual variation in zidovudine absorption was high. However, when a sustained-release formulation of zidovudine was used, the absorption was delayed, but the AUC was increased by 28% by a high-fat meal. In contrast zidovudine AUC was not affected by 25 g of a protein supplement.

Inter-individual variation appears high and the practical consequences of the changes caused are uncertain. Some have suggested that zidovudine should be taken on an empty stomach, but the UK manufacturer states that zidovudine can be taken with or without food, but the UK manufacturer gives no specific recommendations regarding its administration in relation to food.

Clinical evidence

(a) Didanosine

Buffered didanosine 200 mg twice daily was given to 12 HIV-positive patients with oral ganciclovir 1 g three times daily. When the didanosine was given 2 hours before ganciclovir, the maximum serum levels and AUC of didanosine were raised by about 47% and 83%, respectively, and those of ganciclovir were decreased by about 26% and 22%, respectively. When the didanosine was given simultaneously with ganciclovir, the maximum serum levels and AUC of didanosine were similarly raised, by about 53% and 77%, respectively, but those of ganciclovir were unchanged. The renal clearance of didanosine was not significantly changed by ganciclovir.

Similar increases in didanosine levels with ganciclovir gave no specific recommendations regarding its administration in relation to food.

(b) Lamivudine

The UK manufacturer of lamivudine says that concurrent use with intravenous ganciclovir is not recommended until further information becomes available, although they give no reason for this advice. They do not mention oral ganciclovir.

(c) Stavudine

In a study of 11 HIV-positive patients, oral ganciclovir 1 g three times daily had no significant effect on the pharmacokinetics of stavudine 40 mg twice daily, nor were the pharmacokinetics of ganciclovir affected by stavudine. There were no serious or severe adverse events attributed to the combination.

(d) Zalcitabine

In a study in 10 HIV-positive patients, zalcitabine 750 micrograms every 8 hours increased the AUC of oral ganciclovir 1 g three times daily by 22%. There was no change in zalcitabine pharmacokinetics. There were no serious or severe adverse events attributed to the combination.

(e) Zidovudine

The efficacy of zidovudine 100 or 200 mg every 4 hours, given alone or with intravenous ganciclovir 5 mg/kg twice daily for 14 days, then once daily for 5 days of each week, was assessed in 40 patients for the treatment of cytomegalovirus infection (CMV). Severe haematological toxicity occurred in all of the first 10 patients given zidovudine 1.2 g daily and ganciclovir. Consequently the dose of zidovudine was reduced to 600 mg daily. Over all 82% of the 40 patients enrolled experienced profound and rapid toxicity (anaemia, neutropenia, leucopenia, gastrointestinal disturbances). Zidovudine dosage reductions to 300 mg daily were needed in many patients. No change in the pharmacokinetics of zidovudine or ganciclovir was noted.

Another study in 6 AIDS patients with CMV retinitis given zidovudine and ganciclovir found increased bone marrow toxicity but no improved efficacy over ganciclovir alone. Increased toxicity (myelotoxicity and pancytopenia) following the use of both drugs has also been reported elsewhere.

In contrast to the first study, a specific study on the pharmacokinetics of zidovudine and ganciclovir in HIV-positive subjects reported that oral ganciclovir increased the maximum levels and AUC of zidovudine by 38% and 15%, respectively, without altering renal clearance. Zidovudine did not alter ganciclovir pharmacokinetics.

Mechanism

It is not known why ganciclovir increases the levels of didanosine and zidovudine: it does not appear to be due to competition for active secretion by the kidney tubules.

The toxicity of the zidovudine/ganciclovir combination may be simply additive, but in vitro studies with three human cell lines found synergistic cytotoxicity when both drugs were used.

There is some in vitro evidence to suggest that ganciclovir antagonises the anti-HIV activity of zidovudine and didanosine.

The concurrent use of zidovudine and ganciclovir produces a very marked increase in haematological toxicity, without any apparent increase in efficacy. Didanosine serum levels are raised by ganciclovir, but there is some evidence suggesting that the efficacy of ganciclovir prophylaxis is reduced. Ganciclovir does not appear to interact with stavudine, and there is no clinically important pharmacokinetic interaction between ganciclovir and stavudine. Until further information is available, the manufacturers of lamivudine advise the avoidance of intravenous ganciclovir.
Importance and management

The interactions between ganciclovir and didanosine or zidovudine would appear to be established, but the clinical importance of this is uncertain. Didanosine seems to be associated with greater toxicity than didanosine. However, there is also some evidence suggesting reduced ganciclovir efficacy in the presence of didanosine, and this requires further study. Close and careful monitoring is required if either combination is used.

Ganciclovir does not appear to alter the pharmacokinetics of stavudine or zalcitabine. Zalcitabine increased ganciclovir levels to a minor extent, although this is probably not clinically important.

2. Franciosa RJ, Anderson RD, Griffin KG, Jung D, Yu S. Two multiple dose crossover studies of IV ganciclovir (GCV) and didanosine (ddI) in HIV infected persons. Intersc Conf Antiimi-

(c) Zalcitabine

A study in 12 HIV-positive patients given a single 1.5-mg dose of zalcitabine found that zalcitabine 800 mg caused a 24% reduction in the renal clearance of zalcitabine (assumed to be due to a reduction in renal tubular secretion) and a 36% increase in the AUC of zalcitabine. These changes are relatively moderate and of uncertain clinical importance. Monitor concurrent use for possible toxicity.

(d) Zidovudine

In a randomised crossover study zidovudine 600 mg daily was given to 5 HIV-positive men and one man with AIDS. The zidovudine was given either alone, with cimetidine 300 mg four times daily, or with ranitidine 150 mg twice daily, each for 7 days. Cimetidine reduced the renal elimination of the zidovudine by 56%, but had no effect on its AUC. It was suggested that the reduction in clearance was due to inhibition of tubular secretion. Ranitidine had no effect on zidovudine pharmacokinetics. No clinical toxicity occurred and the immunological parameters measured (CD4 and CD8) were not significantly altered. The authors concluded that no change in the dosage of zidovudine is needed if either of these H2-receptor antagonists is given concurrently. Information about other H2-receptor antagonists seems to be lacking.

1. Knupf CA, Graziano FM, Dixon RM, Barbhaiya RH. Pharmacokinetic-interaction study of di-

NRTIs + Hydroxycarbamide

Hydroxycarbamide appears to increase the antiviral activity of NRTIs, particularly didanosine. However, the combination of hydroxycarbamide and didanosine may carry a higher risk of adverse effects, including neuropathy and pancreatitis, especially if stavudine is also given.

Clinical evidence, mechanism, importance and management

Data from in vitro studies have shown that hydroxycarbamide increases the antiviral activity of NRTIs, particularly didanosine, possibly by increasing their intracellular activation (phosphorylation). The combination is therefore under clinical investigation. Some randomised studies have shown that the addition of hydroxycarbamide to reverse transcriptase inhibitors improves virologic response, whereas others have not demonstrated this.

Of concern is that a number of studies have shown increased toxicity. One study reported that the relative risk of neuropathy when didanosine was given with hydroxycarbamide was 2.35, compared with didanosine alone, and increased to 7.8 when stavudine was also added. Another study reported an increased incidence of nephropathy, and an increased incidence of fatigue and nausea and vomiting. The risk of pancreatitis may also be increased. In one study, 3 patients randomised to indinavir, didanosine, stavudine and hydroxycarbamide developed pancreatitis and died, compared with no deaths in those receiving the same antivirals without hydroxycarbamide. Another case of pancreatitis (non-fatal) has been reported when hydroxycarbamide was given with stavudine, didanosine and nevirapine. Hepatotoxicity and hepatic failure resulting in death have also been reported in patients given hydroxycarbamide, didanosine and stavudine. In response to these data, the manufacturers of didanosine and stavudine specifically state that use of these two NRTIs with hydroxycarbamide should be avoided. Moreover, the UK manufacturers go as far as to say that hydroxycarbamide should not be used in the treatment of HIV infection.

Further studies are needed to define the role of hydroxycarbamide in combination with NRTIs in HIV infection.

(b) Lamivudine

Lamivudine is cleared predominantly from the body by the kidneys using the organic cationic transport system; however, cimetidine and ranitidine, which partly use this mechanism, do not interact with lamivudine.
Clarithromycin causes some reduction in the bioavailability of zidovudine, but this is minimised if the two drugs are given at least 2 hours apart. Clarithromycin does not appear to interact with didanosine, stavudine or zalcitabine, and azithromycin does not interact with didanosine or zidovudine.

**Clinical evidence**

(a) Didanosine

When azithromycin 1.2 g daily for 14 days was given to 12 HIV-positive subjects with didanosine 200 mg twice daily there was no significant change in the pharmacokinetics of either drug.1

**Clarithromycin** 1 g twice daily for 7 days was given to 4 HIV-positive patients and 4 AIDS patients already taking oral didanosine. For the group as a whole the pharmacokinetics of the didanosine remained unchanged, but there were large differences in the AUC between subjects that could have hidden an interaction.2

(b) Stavudine

A study in 10 HIV-positive subjects found that the addition of clarithromycin 500 mg twice daily to stavudine 30 or 40 mg twice daily had no significant effects on the pharmacokinetics of the stavudine and the incidence of adverse effects did not increase.3 No special precautions would seem necessary if both drugs are given.

(c) Zalcitabine

A 7-day course of clarithromycin 500 mg twice daily was given to 12 HIV-positive subjects already taking zalcitabine. The addition of clarithromycin caused no change to the pharmacokinetics of zalcitabine.4

(d) Zidovudine

Azithromycin 600 mg to 1.2 g daily for 14 days did not affect the pharmacokinetics of zidovudine 100 mg five times daily in 12 HIV-positive subjects.1 Similarly, azithromycin 1 g given weekly to 9 HIV-positive subjects caused no change in the pharmacokinetics of zidovudine 10 mg/kg daily. The azithromycin pharmacokinetics also remained unchanged.5,6

Fifteen HIV-positive patients were given zidovudine 100 mg every 4 hours 5 times a day and oral clarithromycin 500 mg, 1 g or 2 g every 12 hours, both together and alone. The pharmacokinetics of the clarithromycin were not substantially changed but the zidovudine levels and AUCs were reduced by 23 to 58% and 12 to 36%, respectively. However, these effects were not seen in all patients.6,7 Another study similarly found that clarithromycin caused a moderate reduction in the AUC of oral zidovudine (by up to 27%). No changes were seen when the zidovudine was given 4 or more hours after the clarithromycin.8 Zidovudine and clarithromycin were given to 16 AIDS patients 2 hours apart for 4 days. The maximum plasma levels of the zidovudine rose by about 50%, but the minimum levels and the AUC over 8 hours did not change.9

**Mechanism**

Not understood but the interaction between clarithromycin and zidovudine may possibly be due to some changes in absorption.

**Importance and manufacture**

The overall picture is slightly confusing, but it seems that some reductions in zidovudine levels are likely if clarithromycin is taken at the same time, but no important changes seem to occur if the administration of the drugs is separated. The authors of one study recommend that the clarithromycin is given at least 2 hours before or after the zidovudine.7 The UK manufacturer of zidovudine includes this recommendation,10 but the US manufacturer does not include any information on use with clarithromycin.11

The authors of the report on didanosine conclude that clarithromycin may not be used with didanosine,2 and it also seems likely that didanosine or zidovudine and azithromycin; stavudine and clarithromycin; and zalcitabine and clarithromycin can be used safely together.

change is not thought to be clinically significant and so no dose alteration would seem necessary on concurrent use.\(^1\) In UK and US guidelines, the combination of abacavir plus lamivudine is currently a recommended dual NRTI option for use with an NNRTI or a protease inhibitor for the treatment of HIV-infection in treatment naïve patients.\(^2,3\) The triple NRTI combination of abacavir, lamivudine and zidovudine may also be considered if protease inhibitors or NNRTIs cannot be used.\(^3\)

(b) Zidovudine

A single 300-mg dose of zidovudine was given with abacavir 600 mg to 13 HIV-positive subjects. The pharmacokinetics of abacavir were not significantly affected. The zidovudine maximum plasma level decreased by 20\%, but the AUC was unchanged. This change is not thought to be clinically significant and so no dose alteration would seem necessary on concurrent use.\(^1\) These results were confirmed in a steady-state study in which 79 HIV-positive subjects received 8 weeks of treatment with abacavir 600 mg to 1.8 g daily, in divided doses, and zidovudine 600 mg daily, in divided doses.\(^3\) The triple NRTI combination of abacavir, lamivudine and zidovudine may also be considered if protease inhibitors or NNRTIs cannot be used.\(^3\)

B. Didanosine

(a) Emtricitabine

In UK and US guidelines, the combination of didanosine with emtricitabine is currently a recommended alternative dual NRTI option for use with an NNRTI or a protease inhibitor, for the treatment of HIV-infection in treatment naïve patients.\(^2,3\)

(b) Lamivudine

Lamivudine is cleared predominantly from the body by the kidneys using the organic anionic transport system. Didanosine is not cleared by this mechanism and so is unlikely to interact with lamivudine by this mechanism.\(^5\) Didanosine does not affect the intracellular activation of lamivudine in vitro.\(^6\) In UK and US guidelines, the combination of didanosine with lamivudine is currently a recommended alternative dual NRTI option for use with an NNRTI or a protease inhibitor, for the treatment of HIV-infection in treatment naïve patients.\(^2,3\)

(c) Stavudine

Didanosine does not interfere with the intracellular activation of stavudine in vitro.\(^7\) Didanosine 100 mg twice daily was given to 10 HIV-positive subjects with stavudine 40 mg twice daily for 9 doses. The didanosine pharmacokinetics were unchanged by concurrent use. The half-life of the stavudine increased from 1.56 to 1.96 hours, but the AUC was unchanged and adverse effects were minimal. The authors of the report concluded that no clinically significant pharmacokinetic interaction, and no change in acute safety and tolerance, are likely if both drugs are given concurrently.\(^7\)

However, both didanosine and stavudine can cause peripheral neuropathy and pancreatitis, and there is some evidence that this risk may be additive. In one early study, combination treatment with stavudine and didanosine was given to 13 HIV-positive subjects for 8 weeks. Neuropathy occurred in 3 patients, with only 2 restarting treatment.\(^9\) In another study, the relative risk of neuropathy was 1.39 for stavudine alone relative to didanosine alone, and 3.5 for combined use of both drugs.\(^10\) In 1999, the manufacturer of didanosine issued a stronger warning about the risk of pancreatitis with didanosine, and noted this risk was higher in patients also taking stavudine.\(^1\) see also ‘NRTIs + Hydroxycarbamide’, p. 799. Combined use should be carefully monitored. See also ‘NRTIs + Drugs that cause pancreatitis’, p. 797.

A case of symptomatic hyperlactataemia occurred in a patient after changing his antiretroviral therapy to didanosine, stavudine and nevirapine.\(^1\) The combination of stavudine and didanosine has been associated with a high incidence of toxicity, particularly peripheral neuropathy, pancreatitis, and lactic acidosis. The development of lactic acidosis has resulted in fatalities in pregnant women.\(^1\) It has been suggested that this combination of NRTIs is associated with the greatest toxicity.\(^1\) US guidelines say that the combination of didanosine and stavudine should not be recommended at any time, with the exception of when no other antiretroviral options are available, and only if the potential benefits outweigh the risks.\(^3\) UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.\(^2\)

(d) Zalcitabine

In vitro, didanosine had no significant effect on the intracellular activation of zalcitabine.\(^1\) A 29-year-old man with persistent mild neuropathy due to zalcitabine developed severe neuropathy when given didanosine 3 weeks after discontinuing zalcitabine. As the didanosine neuropathy developed so rapidly it was suggested that it was caused by additive toxicity with zalcitabine.\(^1\) Note also that both drugs are associated with pancreatitis. The manufacturers advise caution and careful monitoring if drugs that share these serious adverse effects are used concurrently. See also ‘NRTIs + Drugs that cause pancreatitis’, p. 797. US guidelines say that the combination of didanosine and zalcitabine should not be recommended at any time because of additive peripheral neuropathy.\(^3\)

(e) Zidovudine

A study in 8 HIV-positive patients found that when they were given zidovudine 250 mg with didanosine 250 mg (buffered sachet formulation), the pharmacokinetics of the didanosine were unaltered but the zidovudine AUC was raised by 35\%, possibly due to altered absorption.\(^15\) Conversely, in another study zidovudine plasma levels were lower in 4 out of 5 HIV-positive patients when given didanosine (chewable tablets) and there was an average 14\% reduction in the zidovudine AUC. The zidovudine clearance was increased by 29\% but the didanosine pharmacokinetics were unchanged.\(^10\) A study in over 50 young subjects ranging in age from 3 months to 21 years found that when compared with day 3 (start of concurrent use), no significant changes in AUCs occurred after 4 or 12 weeks of them taking zidovudine 60 to 180 mg/m\(^2\) every 6 hours with didanosine 60 to 180 mg/m\(^2\) every 12 hours (given 2 minutes after an antacid).\(^1\) Several other studies have not found a pharmacokinetic interaction or evidence of increased toxicity when didanosine and zidovudine are used concurrently.\(^1,8-21\)

The reports are slightly contradictory, but the weight of evidence seems to be that no clinically relevant interaction occurs. UK guidelines say there are no data on the use of zidovudine with enteric-coated didanosine as part of HAART, and that the combination cannot be recommended.\(^3\)

C. Emtricitabine

US guidelines state that the combination of emtricitabine and lamivudine should not be offered at any time because of the similar resistance profile of the two drugs and there being no potential benefit.\(^3\)

(b) Stavudine

There was no important pharmacokinetic interaction between single doses of emtricitabine 200 mg and stavudine 40 mg in 6 healthy subjects.\(^2\) UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.\(^2\)

(c) Zidovudine

In a single-dose study in 6 healthy subjects the AUC and maximum level of zidovudine 300 mg were increased by 26\% and 66\%, respectively, by emtricitabine 200 mg. The pharmacokinetics of emtricitabine were not altered.\(^1\) The authors suggest that these increases in zidovudine levels are unlikely to be clinically relevant based on experience of using the two drugs together for 48 weeks in a phase III clinical study.\(^2\) Further experience is needed.

D. Lamivudine

(a) Stavudine

Nucleoside reverse transcriptase inhibitors such as lamivudine need to be activated by phosphorylation within cells to a triphosphate anabolite. Since stavudine does not affect this phosphorylation in vitro\(^6\) it is predicted that no interaction is likely to occur by this mechanism. The manufacturer briefly states that no clinically relevant pharmacokinetic interaction was noted between stavudine 40 mg and lamivudine 150 mg in a single-dose study.\(^25,24\) Nevertheless, current US guidelines state that the combination of stavudine and lamivudine is not a preferred or alternative dual NRTI combination for use in initial antiretroviral regimens because of significant toxicities including lipoatrophy, peripheral neuropathy and serious, life-threatening lactic acidosis with hepatic steatosis, with or without pancreatitis, and rapidly progressive neuromuscular weakness.\(^1\) Similarly, UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.\(^2\)

(b) Zalcitabine

Lamivudine is cleared predominantly from the body by the kidneys using the organic cationic transport system. Zalcitabine is not cleared in this way and so is unlikely to interact with lamivudine by this mechanism.\(^2\) However, the manufacturers\(^13,25,26\) and US guidelines\(^1\) say that lamivudine is not recommended to be used with zalcitabine, since lamivudine may inhibit the intracellular activation of zalcitabine.
Lamivudine 300 mg twice daily was given to 12 HIV-positive patients for 5 doses, with a 200-mg dose of zidovudine with the last dose. No major changes in the pharmacokinetics of the lamivudine occurred and it was concluded that dosage adjustments are not needed if these two drugs are given concurrently. Another study found the same results, and an extensive study in over 200 patients has shown that combined use can be safe and effective. However, there are case reports of blood dyscrasias occurring with concurrent use. Zidovudine 500 to 600 mg daily was given with lamivudine 300 mg daily to 8 HIV-positive men. Lamivudine or lamivudine alone had previously been given to 6 of these 8 without problem. However, when the drugs were combined, blood dyscrasias occurred in all patients within 7 weeks. Anaemia, with a 50% fall in haemoglobin, occurred in 7 patients, while the other patient developed leucopenia and thrombocytopenia. The drug combination was stopped, blood transfusions were given, and all patients improved or recovered over 5 weeks. Zidovudine or lamivudine alone was later started in 5 patients without further haematological problems. Similar precipitous falls in haemoglobin occurred in another 2 patients when lamivudine 300 mg daily was added to their long-term zidovudine treatment. Again both recovered when the drugs were stopped and blood was given. Anaemia is a common adverse effect of zidovudine, but these patients had no problems until the lamivudine was added. The available evidence indicates that concurrent use can be safe and effective, with the adverse interactions cited here being uncommon. It has been suggested that a complete baseline blood count should be done, both when combined treatment is started, and every month for the first 3 months of treatment. In UK and US guidelines, the combination of zidovudine with lamivudine is currently a preferred dual NRTI option for use with an NNRTI or a protease inhibitor for the treatment of HIV-infection in treatment-naive patients. The triple NRTI combination of abacavir, lamivudine and zidovudine may also be considered if protease inhibitors or NNRTIs cannot be used.

E. Stavudine

(a) Zalcitabine

In vitro, stavudine had no significant effect on the intracellular activation of zalcitabine. Both stavudine and zalcitabine have the potential to cause peripheral neuropathy and pancreatitis. Combined use of drugs causing these serious adverse effects should be closely monitored (see also ‘NRTI + Drugs that cause pancreatitis’, p.797). US guidelines say that the combination of stavudine and zalcitabine should not be recommended at any time because of additive peripheral neuropathy.

(b) Zidovudine

Nucleoside reverse transcriptase inhibitors such as stavudine need to be phosphorylated within cells to a triphosphate anabolite before they be effective. In vitro studies using mononucleated blood cells found that zidovudine significantly inhibited this phosphorylation. Antagonism between zidovudine and stavudine has also been seen in a clinical study. The manufacturers and US guidelines currently do not recommend the combination.

F. Zalcitabine

In vitro, zalcitabine had no significant effect on the intracellular activation of zidovudine. In a study in 56 patients with advanced HIV infection, taking zidovudine 50 to 200 mg every 8 hours and zalcitabine 5 to 10 micrograms/kg every 8 hours, neither drug affected the pharmacokinetics of the other nor was toxicity increased. No special precautions would appear to be necessary. Nevertheless, current US guidelines state that the combination of zalcitabine and zidovudine is not recommended as a dual NRTI combination for use in initial antiretroviral regimens because of inferior virological activity and a higher rate of adverse effects than other dual NRTI alternatives.

References

hepatitis and pancreatitis was diagnosed, which slowly resolved over the following 3 weeks.1

(b) Zidovudine

An early study of zidovudine use in 282 AIDS patients found that haematological abnormalities (anaemia, leucopenia, neutropenia) were very common and 21% needed multiple red cell transfusions. Some of the patients also received paracetamol, which increased the haematological toxicity (neutropenia) by an unstated amount.2

Short-term clinical studies using paracetamol 650 mg up to every 4 hours found that it had no clinically significant effects on the pharmacokinetics of zidovudine,3-5 although in one case clearance was slightly increased.1 An 8-month study in a single patient suggested that long-term concurrent use did not affect the pharmacokinetics of either drug. However, in this individual very rapid absorption and a high peak serum level of zidovudine were seen, so for safety the zidovudine dosage was reduced from 200 mg every 4 hours to 100 mg every 6 hours.8

A patient taking zidovudine and co-trimoxazole took 3.3 g of paracetamol over 36 hours. Within 2 days he developed severe hepatotoxicity, and as other causes were excluded, the reaction was attributed to the paracetamol. The authors suggested that zidovudine may have augmented the paracetamol toxicity.3 However, in a single-dose study, reduced paracetamol glucuronidation and increased formation of hepatotoxic metabolites was seen in patients with advanced HIV infection compared with healthy HIV-positive subjects and those without HIV, and this effect was independent of zidovudine use.10 In contrast, in another study, disease state (AIDS versus healthy HIV-positive subjects) was not found to alter paracetamol metabolism, and zidovudine was found to increase paracetamol glucuronidation in some patients.11

Mechanism

Not understood. Paracetamol does not increase the serum levels of zidovudine,3-5-7 which might have provided an explanation for the apparent increased toxicity. One in vitro study found that paracetamol does not affect the glucuronidation of zidovudine,12 whereas another found that paracetamol did inhibit zidovudine metabolism to the glucuronide.13 The effect of zidovudine on paracetamol metabolism is also unclear.

Didanosine may cause pancreatitis or hepatic disease, and zidovudine may also rarely cause hepatic disease. It has been suggested that the hepatotoxicity of didanosine and paracetamol are augmented when they are given together.1

Importance and management

The authors suggest extreme caution when potentially hepatotoxic drugs such as paracetamol are used with didanosine.1 Note that paracetamol is a precursor of N-acetyl-p-benzoquinone imine (NAPQI), which is the hepatotoxic metabolite of paracetamol.10

In 12 patients with AIDS or AIDS-related complex the concurrent use of zidovudine and probenecid 500 mg every 8 hours for 3 days increased the AUC of zidovudine by an average of 80% (range 14 to 192%).2 Other studies in patients3,5 and healthy subjects6 found that probenecid roughly doubled the AUC of zidovudine when given in a variety of dosing schedules.3,4 However, the effects on zidovudine pharmacokinetics were minimal if the two drugs were given 6 hours apart.5 Another report described a high incidence of rashes in 6 out of 8 HIV-positive men given zidovudine with probenecid 500 mg every 6 hours. The rash and other symptoms (such as malaise, fever and myalgia) were sufficiently severe for the probenecid to be withdrawn in 4 of them.2 A later study found that when using only 250 mg of probenecid every 8 hours the AUC of zidovudine was increased by 70% but the adverse effects still occurred, although the incidence was possibly somewhat lower.8 Conversely, others reported the successful use of probenecid 500 mg three times daily with a reduced dose of zidovudine (600 mg daily) in 7 patients without any occurrence of rash.9

Mechanism

Experimental clinical evidence indicates that probenecid reduces metabolism (glucuronidation) of zidovudine by the liver enzymes, and inhibits renal secretion of the zidovudine glucuronide metabolite.2,4,6,10,11 The interaction with zalcitabine is presumably due to inhibition of zalcitabine secretion in the renal tubules.1

Importance and management

The concurrent use of zidovudine and probenecid should be well monitored to ensure that zidovudine levels do not rise excessively. Reduce the zidovudine dosage as necessary. However, the apparent increase in adverse effects during concurrent use seen by one group of researchers7,8 should be borne in mind.

The concurrent use of zalcitabine and probenecid was well tolerated, and because the zalcitabine half-life is short compared to its dosing schedule significant accumulation would not be expected. It would seem prudent to monitor for any signs of toxicity if either drug combination is used long-term. The safety of combined use needs further assessment.

NRTIs + Probenecid

Probenecid reduces the loss of zalcitabine and zidovudine, increasing their serum levels. The combination of zalcitabine and probenecid is well tolerated, but the incidence of adverse effects appears to be greatly increased with the combination of probenecid and zidovudine.

Clinical evidence

(a) Zalcitabine

In a single-dose study, 12 HIV-positive or AIDS patients were given zalcitabine 1.5 mg alone or with probenecid 500 mg, given 8 and 2 hours before then 4 hours after. The renal clearance of the zalcitabine was decreased 42% by probenecid, its half-life was increased by 47% and its AUC was increased by 54%.1

(b) Zidovudine

In 12 patients with AIDS or AIDS-related complex the concurrent use of zidovudine and probenecid 500 mg every 8 hours for 3 days increased the AUC of zidovudine by an average of 80% (range 14 to 192%).2 Other studies in patients3,5 and healthy subjects6 found that probenecid roughly doubled the AUC of zidovudine when given in a variety of dosing schedules.3,4 However, the effects on zidovudine pharmacokinetics were minimal if the two drugs were given 6 hours apart.5 Another report described a high incidence of rashes in 6 out of 8 HIV-positive men given zidovudine with probenecid 500 mg every 6 hours. The rash and other symptoms (such as malaise, fever and myalgia) were sufficiently severe for the probenecid to be withdrawn in 4 of them.2 A later study found that when using only 250 mg of probenecid every 8 hours the AUC of zidovudine was increased by 70% but the adverse effects still occurred, although the incidence was possibly somewhat lower.8 Conversely, others reported the successful use of probenecid 500 mg three times daily with a reduced dose of zidovudine (600 mg daily) in 7 patients without any occurrence of rash.9

Mechanism

Experimental clinical evidence indicates that probenecid reduces metabolism (glucuronidation) of zidovudine by the liver enzymes, and inhibits renal secretion of the zidovudine glucuronide metabolite.2,4,6,10,11 The interaction with zalcitabine is presumably due to inhibition of zalcitabine secretion in the renal tubules.1
Buffered didanosine decreases the AUC of indinavir, and the drugs should be given one hour apart. Buffered didanosine interacts similarly with atazanavir. Tipranavir with low-dose ritonavir modestly reduced the AUC of abacavir and zidovudine, and such combinations are not recommended in the UK. The changes in pharmacokinetics seen when giving other combinations of protease inhibitors with NRTIs do not appear to be clinically significant. Protease inhibitors do not affect the intracellular activation of NRTIs.

Clinical evidence, mechanism, importance and management

The protease inhibitors indinavir, ritonavir, and saquinavir had no effect on intracellular activation of various NRTIs (didanosine, lamivudine, stavudine, zalcitabine and zidovudine).1 No interaction would be expected by this mechanism. Other potential interactions are discussed below.

(a) Abacavir

1. Amprenavir. A phase 1 study in HIV-positive patients given amprenavir 900 mg twice daily with abacavir 300 mg twice daily for 3 weeks found that neither drug had any clinically significant effect on the pharmacokinetics of the other.2 The manufacturer of amprenavir notes that its AUC, and minimum and maximum levels were increased by 29%, 27%, and 47%, respectively, by abacavir,3,4 without any change in abacavir pharmacokinetics, but no dosage adjustments are considered necessary.3

2. Lopinavir/Ritonavir. The manufacturer of lopinavir/ritonavir notes that it induces glucuronidation and therefore has the potential to reduce abacavir plasma levels. However this, and its clinical relevance, have yet to be studied.5,6

3. Tipranavir with Ritonavir. Tipranavir given with low-dose ritonavir decreased the AUC of abacavir by approximately 40%. The clinical relevance of this reduction has not been established,5,6 but it may decrease the efficacy of abacavir.7 Therefore the UK manufacturer states that the concurrent use of tipranavir and low-dose ritonavir with abacavir is not recommended unless there are no other available NRTIs suitable for patient management.7

(b) Didanosine

1. Amprenavir. The AUC and the minimum level of amprenavir 600 mg twice daily were not altered to a clinically relevant extent when it was given simultaneously with, or one hour before, buffered didanosine; or simultaneously with the enteric-coated preparation of didanosine. The only notable change was a 15% decrease in the maximum levels of amprenavir when it was given with buffered didanosine, which was not considered clinically significant.8 Nevertheless, the manufacturers of amprenavir suggest that it should be given at least one hour apart from didanosine,3,4 and this has also been recommended for regimens containing amprenavir and ritonavir.9

2. Atazanavir. The manufacturer of atazanavir found that buffered didanosine markedly decreased atazanavir plasma levels, with little change in didanosine levels,10 and they recommend that administration should be separated.10,11 Conversely, although enteric-coated didanosine did not alter atazanavir levels, simultaneous administration with food reduced didanosine levels, and therefore administration should be separated.10 Note that ‘didanosine’, (p.797), is preferably taken on an empty stomach, whereas ‘atazanavir’, (p.818), should be taken with food.

3. Indinavir. The concurrent use of [buffered] didanosine and indinavir reduced the AUC of indinavir by 80%, but when indinavir was given one hour before didanosine its pharmacokinetics were not significantly affected.12 Similarly, another study found that the pharmacokinetics of indinavir 800 mg were unchanged when it was given one hour after buffered didanosine 400 mg.13 An enteric-coated preparation of didanosine had no effect on the pharmacokinetics of indinavir in a single-dose study in 23 healthy subjects.14 Indinavir may require a normal acidic gastric pH for optimal absorption, whereas some didanosine preparations are formulated with buffering agents to raise gastric pH. Any increase in pH would therefore be expected to reduce indinavir absorption.15 The manufacturers of indinavir recommend that indinavir and didanosine should be given at least one hour apart.15,16 This recommendation would not apply to the enteric-coated preparation of didanosine.15 Note that both ‘didanosine’, (p.797), and ‘indinavir’, (p.818), are preferably taken on an empty stomach.

4. Nelfinavir. The pharmacokinetics of nelfinavir were not significantly altered after concurrent use with didanosine.17 Note that ‘nelfinavir’, (p.818), should preferably be taken with food, and all ‘didanosine preparations’, (p.797), without food.

5. Ritonavir. Buffered didanosine 200 mg twice daily was given with ritonavir 600 mg twice daily to 13 HIV-positive subjects. Administration of the two drugs was separated by 2.5 hours, and treatment was given for 4 days. Treatment was staggered in this way since ‘ritonavir’, (p.818), should be given with food, and ‘didanosine’, (p.797) without food. There was little or no change in the pharmacokinetics of ritonavir, and the maximum serum levels and AUC of didanosine were reduced by 16% and 13%, respectively, which was not considered to be clinically significant. It was suggested that these changes may have been due to altered absorption in the presence of ritonavir.18

6. Saquinavir. In 8 healthy subjects a single 400-mg dose of didanosine decreased the AUC and maximum plasma concentration of saquinavir (as saquinavir/ritonavir 1600/100 mg soft capsules) by approximately 30% and 25%, respectively, but did not significantly affect the minimum plasma concentration of saquinavir. The manufacturer considers these changes are of doubtful clinical significance.19 Note also that ‘saquinavir’, (p.818), should preferably be taken with food, and all ‘didanosine preparations’, (p.797) without.

7. Tipranavir with Ritonavir. Tipranavir plus low-dose ritonavir caused a 33% reduction in the AUC of didanosine in one of 3 studies,8 but the clinical relevance of this has not been established.7,8 Consequently, the manufacturer recommends that dosing of enteric-coated didanosine and tipranavir plus low-dose ritonavir should be separated by at least 2 hours to avoid formulation incompatibility.7,8

(c) Lamivudine

Lamivudine metabolism does not involve the cytochrome P450 isoenzyme CYP3A4. Therefore it is unlikely that it will interact with drugs, such as the protease inhibitors, which are metabolised by this system.20 No pharmacokinetic interaction appears to occur between lamivudine and amprenavir,3,4 atazanavir,10,11 indinavir,16 and nelfinavir.21,22 The manufacturer of lopinavir/ritonavir notes that lamivudine did not alter the pharmacokinetics of lopinavir,5,6 and tipranavir plus low-dose ritonavir did not cause a significant change in the AUC of lamivudine.7,8

(d) Stavudine

The manufacturer of atazanavir,10,11 notes that there was no pharmacokinetic interaction with stavudine. The AUC of stavudine was increased by 25% when stavudine 40 mg twice daily was given with indinavir 800 mg every 8 hours for a week, which was not considered to be clinically significant. The serum levels of indinavir were unchanged.23 Similarly, indinavir/ritonavir 800 mg/200 mg twice daily increased the AUC of stavudine by 24% in a study in 24 healthy subjects, but this change was not considered clinically relevant and does not require dosage modification.24 The manufacturer of lopinavir/ritonavir notes that stavudine did not alter the pharmacokinetics of lopinavir.5,6

In an early pilot study, combined nelfinavir and stavudine was well tolerated, and the adverse effects were similar to those seen when stavudine was given alone, although the incidence of diarrhea did increase.25 The manufacturer of nelfinavir notes that no clinically significant interactions have been observed with stavudine.21,22

In a study in HIV-positive children, ritonavir oral clearance was about 50% slower and the AUC about 2.5-fold higher in 6 children who received

NRTIs + Protease inhibitors

Buffered didanosine decreases the AUC of indinavir, and the drugs should be given one hour apart. Buffered didanosine interacts similarly with atazanavir. Tipranavir with low-dose ritonavir modestly reduced the AUC of abacavir and zidovudine, and such combinations are not recommended in the UK. The changes in pharmacokinetics seen when giving other combinations of protease inhibitors with NRTIs do not appear to be clinically significant. Protease inhibitors do not affect the intracellular activation of NRTIs.
stavudine than in 7 who received zidovudine and lamivudine, although these differences did not reach statistical significance.26

Tipranavir plus low-dose ritonavir did not cause a significant change in the AUC of stavudine.3,4

Zalcitabine

The manufacturer of zalcitabine noted that there is no pharmacokinetic interaction with saquinavir.27,28 They stated that pharmacokinetic interactions with protease inhibitors would not be expected, since zalcitabine is mainly excreted unaltered in the urine.27

Ritonavir.

1. Amprenavir. The AUC and maximum levels of zidovudine were increased by 31% and 40%, respectively, when given with amprenavir. The pharmacokinetics of amprenavir were unchanged.3,5 The UK manufacturer of amprenavir states that no dose adjustment of either drug is necessary when amprenavir and zidovudine are used together.3

2. Atazanavir. The manufacturer of atazanavir stated that there was no clinically relevant pharmacokinetic interaction with zidovudine.3

3. Indinavir. A study found that when zidovudine 200 mg every 8 hours and indinavir 1 g every 8 hours were given together for a week the AUC of zidovudine was increased by 17% and the AUC of indinavir was increased by 13%.23 In another study, combined use of indinavir and zidovudine with lamivudine increased the zidovudine AUC by 39% but did not change indinavir pharmacokinetics.19 These changes are not clinically relevant.

4. Lopinavir/Ritonavir. The manufacturer of lopinavir/ritonavir notes that it induces glucuronidation and therefore has the potential to reduce zidovu-

dine levels. However this, and its clinical relevance, have yet to be studied.5,6

5. Nelfinavir. The manufacturer of nelfinavir notes that clinically significant interactions have not been observed with zidovudine, and no dose adjust-

ments are needed.21,22

6. Ritonavir. A crossover study in 18 HIV-positive subjects found that the pharmacokinetics of ritonavir 300 mg every 6 hours were unchanged by zidovudine 200 mg every 8 hours. However, the maximum plasma levels and AUC of the zidovudine were both reduced by about 25%. The lack of change in the other pharmacokinetic parameters suggested that these changes were not due to altered metabolism.26 Nevertheless, dose alterations are not considered necessary.26

7. Saquinavir. The UK manufacturer of saquinavir notes that there was no pharmacokinetic interaction with zidovudine.19

8. Tipranavir with Ritonavir. Tipranavir plus low-dose ritonavir decreased the AUC of zidovudine by approximately 35%, without affecting glucuronidated-zidovudine levels. The clinical relevance of this reduction has not been established,23 but it may decrease the efficacy of zidovudine. Therefore, the UK manufacturer states that concurrent use of tipranavir plus low-dose ritonavir with zidovudine is not recommended unless there are no other available NRTIs suitable for patient management.7

NRTIs + Ribavirin

The use of ribavirin with the NRTIs may result in increased toxicity (lactic acidosis, blood dyscrasias and hepatotoxicity), which may be more frequent with didanosine than other NRTIs. These effects may also be exacerbated by the additional use of interferon for hepatitis C. Early in vitro data suggested that ribavirin may reduce the antiretroviral effects of some NRTIs but this does not appear to have been demonstrated in practice.

Clinical evidence, mechanism, importance and management

In the UK, the manufacturers of all NRTIs state that patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis. Patients at increased risk should be monitored closely.

(a) Didanosine

Ribavirin did not alter the pharmacokinetics of didanosine in HIV-positive adults or children.1,2 However, in vitro, ribavirin increases the intracellular activation of didanosine, and the manufacturers note that this could result in increased adverse effects.3,5 In one early study, no increase in adverse effects was seen when ribavirin 600 mg daily was given to 16 HIV-positive patients who had already been taking didanosine 125 to 200 mg twice daily for 4 weeks. Ribavirin was given 6 hours after the morning dose of didanosine. Over the 8 or 20 weeks of the study the combination was well tolerated. Nevertheless, cases of mitochondrial toxicity (hepatoparesis, pancreatitis, lactic acidemia) have been reported when ribavirin was added to didanosine-containing antiretroviral regimens,8,9 and fatalities have occurred.6,9 In an analysis of data from the adverse event reporting system of the FDA in the US, 31 patients were identified who had adverse events suggestive of mitochondrial toxicity while taking ribavirin with an NRTI. Of these, nearly 90% had received didanosine, 71% stavudine, and 65% both didanosine and stavudine. Five patients died; all of who were taking didanosine, with stavudine in three of these cases. Use of ribavirin with dina-

nosine was associated with an increased risk of mitochondrial toxicity (odds ratio 12.4) compared with patients receiving ribavirin in combination with other NRTIs (odds ratios: didanosine with stavudine, 8; stavu-
dine, 3.3; abacavir, 1.1; lamivudine, 0.2; zidovudine, 0.06).9 Some other studies have shown an increased risk of mitochondrial toxicity when ribavirin was given with didanosine.10,11 As a result of these data, the manufacturers of ribavirin12-14 and the US manufacturer of didanosine say that concurrent use of ribavirin and didanosine is not recommended. Conversely, the UK manufacturer of didanosine1 just advises that if these drugs need to be given together, caution is necessary and that patients should be monitored closely. They advise that treatment with nucleoside analogues [such as didanosine] should be discontinued in the setting of
symptomatic hyperlactataemia and metabolic/ lactic acidosis, progressive hepatomegaly, or rapidly elevating aminotransferase levels. Similarly, others consider that didanosine should not be systematically replaced in patients requiring treatment for hepatitis C because the risk of lactic acidosis is only small. Nevertheless, they suggest that if a modification of antiretroviral treatment is needed then it is best to avoid didanosine.

(b) Lamivudine

In vitro, ribavirin reduced the intracellular activation and antiretroviral activity of lamivudine. However, in a study in 22 HIV-positive patients with hepatitis C, ribavirin 800 mg daily had no statistically significant effect on the pharmacokinetics of lamivudine (a 27% increase in AUC), and no effect on the intracellular activation of lamivudine, when compared with 24 similar patients who received placebo. As with all NRTIs, lamivudine has, rarely, been associated with lactic acidosis, and the UK manufacturers of lamivudine state that patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis. Patients at increased risk should be monitored closely.

(c) Stavudine

In vitro, stavudine reduced the intracellular activation and antiretroviral activity of stavudine. However, in a study in 5 HIV-positive patients with hepatitis C, stavudine 800 mg daily had no statistically significant effect on the pharmacokinetics of stavudine (a 45% increase in AUC), and no effect on intracellular activation of stavudine, when compared with similar patients who received placebo. Similarly, no decrease in antiviral activity of stavudine (as assessed by plasma HIV-RNA levels) has been seen when ribavirin was given with interferon for hepatitis C infection in patients with HIV 20. Nevertheless, the UK manufacturers of stavudine continue to recommend that plasma HIV-RNA levels are closely monitored in patients taking stavudine with ribavirin to ensure continued efficacy. In contrast, based on an analysis of data from the adverse event reporting system of the FDA in the US, (see didanosine above), the UK manufacturers of stavudine consider that concurrent use of stavudine should be avoided to limit the risk of mitochondrial toxicity.13 The UK manufacturer of stavudine notes that patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of NRTI-associated lactic acidosis. Patients at increased risk should be monitored closely. Similarly, the UK manufacturer of stavudine states that patients receiving interferon with or without ribavirin and stavudine should be closely monitored for treatment-associated toxicities, especially hepatic decompensation.

(d) Zidovudine

In vitro, zidovudine reduced the intracellular activation and antiretroviral activity of zidovudine. However, in a study in 7 HIV-positive patients with hepatitis C, zidovudine 800 mg daily had no statistically significant effect on the pharmacokinetics of zidovudine (a 22% increase in AUC), and no effect on the intracellular activation of zidovudine, when compared with similar patients who received placebo. Moreover, in a study in 8 patients taking zidovudine, there was no significant variation in HIV viral load or CD4 counts after 3 or 6 months of ribavirin treatment, compared with baseline values. Nevertheless, the UK manufacturers of zidovudine continue to recommend that plasma HIV RNA levels are closely monitored in patients given ribavirin with zidovudine to ensure continued efficacy.13 The UK manufacturer of zidovudine states that nucleoside analogues that antagonise the antiretroviral activity of zidovudine, such as ribavirin, should be avoided. However, they also state that patients receiving interferon alfa with or without ribavirin and zidovudine should be closely monitored for treatment-associated toxicities, especially hepatic decompensation, neutropenia, and anaemia.

NRTIs + Tenofovir

Tenofovir increases the levels of didanosine; an increased risk of pancreatitis and peripheral neuropathy has been reported, and a high level of treatment failure. There is no pharmacokinetic interaction between tenofovir and abacavir, entricitabine, lamivudine or stavudine. However, the combination of tenofovir, lamivudine and abacavir was unexpectedly associated with a high level of treatment failure. Triple-NRTI regimens involving tenofovir are not recommended, with the possible exception of tenofovir, lamivudine and zidovudine.

Clinical evidence, mechanism, importance and management

Tenofovir is a nucleotide (nucleoside monophosphate) analogue and is often classed as an NRTI.

(a) Abacavir

There was no clinically relevant pharmacokinetic interaction between tenofovir and abacavir in 8 healthy subjects. However, the combination of tenofovir, lamivudine and abacavir was unexpectedly associated with a high rate of treatment failure (early virological non-response) in clinical studies. Consequently, in July 2003 the manufacturer and others recommended that this triple therapy should not be used alone, and if these three drugs are used with other antiretrovirals, virological response should be closely monitored.14 US guidelines (October 2006) for treatment of HIV infections state that these NRTI regimens like this should not be used routinely (with 2 specific exceptions) because of suboptimal virological activity or lack of data. Similarly, UK guidelines (2006) state that non-nucleoside-containing triple NRTI regimens such as tenofovir, abacavir and lamivudine should not be used because of unnecessarily high rates of virological failure.
(d) Lamivudine

The manufacturer briefly notes that there was no pharmacokinetic interaction between tenofovir and lamivudine.24 UK guidelines (2006) for treatment of HIV infections recommend the combination of tenofovir and lamivudine plus either an NNRTI or a protease inhibitor.3

However, for studies showing a high rate of virological failure with the combination of tenofovir, lamivudine and one other NNRTI, see Abacavir, and Didanosine, above. UK and US guidelines say to avoid sole use of all regimens of tenofovir plus two NRTIs (triple-NRTI regimens), with the possible exception of tenofovir plus lamivudine and zidovudine when a protease inhibitor or NNRTI-based regimen cannot be used.4,5

(e) Stavudine

There is information to suggest that tenofovir disoproxil fumarate 300 mg does not alter levels of stavudine 100 mg.25

NRTIs; Didanosine + Allopurinol

Allopurinol markedly raises didanosine levels.

Clinical evidence, mechanism, importance and management

Buffered didanosine 400 mg was given to 14 healthy subjects, with and without allopurinol 300 mg daily for 7 days. The allopurinol significantly increased didanosine absorption, shown by a twofold increase in the AUC and a 69% rise in its maximum serum levels. Similar findings were seen in HIV-positive subjects. Moreover, the addition of allopurinol 300 mg daily allowed the dosage of didanosine to be halved from 400 mg to 200 mg daily in 4 patients taking buffered didanosine, hydroxycarbamide and chloroquine. Didanosine plasma levels and antiviral efficacy were unchanged.

The manufacturer notes that allopurinol may increase the exposure to didanosine by inhibiting xanthine oxidase, an enzyme involved in didanosine metabolism. This interaction has been studied for its therapeutic benefit. However, if the dose of didanosine is not reduced, there is the potential for an increase in didanosine adverse effects.

The UK manufacturer recommends close monitoring for adverse effects if allopurinol is used with didanosine, but the US manufacturer says that coadministration is not recommended.

3. Boelaert JR, Dom GM, Huitema ADR, Beijnen JH, Lange JMA. The boosting of didanosine with loperamide or metoclopramide is not recommended.

NRTIs; Didanosine + Loperamide or Metoclopramide

Loperamide and metoclopramide do not appear to alter didanosine pharmacokinetics.

Clinical evidence, mechanism, importance and management

In 6 men and 6 women who were HIV-positive, the pharmacokinetics of oral buffered didanosine 300 mg were not altered to a clinically relevant extent by 4 mg of loperamide, given 19, 13, 7 and 1 hour before the didanosine. The rate of didanosine absorption was slightly decreased but the extent of absorption was unchanged. Similarly, the pharmacokinetics of oral buffered didanosine 300 mg were found to be unaffected by 10 mg of intravenous metoclopramide. It appears that neither delaying nor accelerating gastrointestinal transit time appreciably alters the pharmacokinetics of didanosine, which is acid labile. On the basis of this study the authors conclude that neither the dose nor the frequency of didanosine administration need be altered if either loperamide or metoclopramide is given concurrently.

NRTIs; Stavudine + Doxorubicin

In vitro evidence suggests that doxorubicin may inhibit the activation of stavudine.

Clinical evidence, mechanism, importance and management

Nucleoside reverse transcriptase inhibitors such as stavudine need to be phosphorylated within cells before they become effective. In vitro studies using mononucleated blood cells found that doxorubicin may interfere with stavudine phosphorylation at clinically relevant concentrations. The clinical importance of this interaction awaits assessment. Until then, caution is required on concurrent use.

NRTIs; Zidovudine + Benzodiazepines

Oxazepam causes a modest increase in the bioavailability of zidovudine, and the combination can increase the incidence of headaches. Lorazepam possibly behaves similarly.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 6 HIV-positive patients found that oxazepam did not significantly affect the bioavailability of zidovudine. All of the patients were sleepy and fatigued while taking oxazepam (as expected), but 5 of the 6 complained of headaches while taking both drugs, compared with only 1 of 6 while taking zidovudine alone and none while taking oxazepam alone. The authors of the report suggest that if headaches occur during concurrent use, the benzodiazepine should be stopped.

1. Unadkat JD, Chien J. Lorazepam and oxazepam inhibit the metabolism of zidovudine to its glucuronide, and lorazepam behaves in the same way. However, if the dose of zidovudine is not reduced, there is the potential for an increase in zidovudine adverse effects. The UK manufacturer recommends close monitoring for adverse effects if allopurinol is used with didanosine, but the US manufacturer says that coadministration is not recommended.

NRTIs; Zidovudine + Drugs that inhibit glucuronidation

In vitro evidence suggests that chloramphenicol, indometacin and naproxen inhibit the glucuronidation of zidovudine. However, neither indometacin nor naproxen altered zidovudine pharmacokinetics in subsequent clinical studies. Dipyridamole did not alter zidovudine pharmacokinetics.

Clinical evidence and mechanism

(a) Aspirin or NSAIDs
A study of zidovudine use in 282 AIDS patients found that haematological abnormalities were not increased by aspirin in 47 patients. An in vitro study using human liver microsomes found that indometacin and naproxen inhibited the glucuronidation of zidovudine by 50% or more, and aspirin also had some inhibitory effect. This suggested that these drugs might possibly increase the effects and the toxicity of zidovudine. However, other clinical studies found no changes in the pharmacokinetics of zidovudine given with indometacin 25 mg twice daily for 3 days or naproxen 500 mg to 1 g daily for 3 or 4 days.

(b) Chloramphenicol
An in vitro study using human liver microsomes found that chloramphenicol inhibited the glucuronidation of zidovudine by 50% or more, suggesting that the effects and toxicity of zidovudine may be increased. The effect of concurrent use in patients awaits assessment.

(c) Dipyridamole
Theoretically, dipyridamole and zidovudine might inhibit the metabolism of each other by competing for glucuronidation, the major clearance mechanism for both drugs. However, a study in 11 asymptomatic HIV-positive patients found that dipyridamole 75 to 100 mg every 4 hours for 5 days caused no significant changes in the pharmacokinetics of zidovudine 500 mg daily, but the dipyridamole adverse effects (headaches, nausea) when taking the higher dose were found to be intolerable.

Importance and management

Many drugs that inhibit the glucuronidation of zidovudine in vitro appear to have only modest effects on zidovudine levels, which are unlikely to be...
clinchically important in most patients. Consider also ‘NRTIs + Atovaquone’, p.793.

NRTIs; Zidovudine + Lithium

Lithium can apparently oppose the neutropenic effects of zidovudine.

Clinical evidence, mechanism, importance and management

A study in 5 patients with AIDS found that serum lithium carbonate levels of 0.6 to 1.2 mmol/L increased their neutrophil counts sufficiently to allow the re-introduction of zidovudine, which had previously been withdrawn due to neutropenia. Withdrawal of the lithium resulted in a rapid fall in neutrophil levels in two patients. Improvement in neutropenia occurred in another AIDS patient taking zidovudine 1.2 g daily when lithium carbonate 300 mg three times daily was also given. Lithium has been found to induce granulopoiesis, and these reports suggest that no adverse reaction occurred in patients taking zidovudine and lithium, and that there may be some advantages to their use. However, lithium itself has a narrow therapeutic range and its toxic symptoms might be difficult to distinguish from neurological complications caused by the disease. The addition of lithium could also increase the risk of interactions with other drugs. A study of 3 further patients found a lack of beneficial effect with lithium in 2 of the patients and only a short-term improvement in the neutrophil count in the third. In addition, one patient experienced severe diarrhoea necessitating discontinuation of the lithium.

NRTIs; Zidovudine + Megestrol

Megestrol acetate does not affect the pharmacokinetics of zidovudine.

Clinical evidence, mechanism, importance and management

In 12 asymptomatic HIV-positive subjects megestrol acetate 800 mg daily for 13 days had no effect on the steady-state pharmacokinetics of zidovudine or its glucuronide metabolite. Megestrol does not appear to affect the metabolism of zidovudine. No dose adjustments appear necessary.

NRTIs; Zidovudine + Myelosuppressive drugs

There have been reports of serious myelotoxicity when zidovudine was given with vancomycin or antineoplastic drugs, and, on theoretical grounds, any drug causing bone marrow suppression might be additive with the effects of zidovudine. Moderate pharmacokinetic changes have been seen when zidovudine was given with chemotherapy regimens used for Kaposi’s sarcoma, Hodgkin’s disease, and non-Hodgkin’s lymphoma.

Clinical evidence and mechanism

(a) Antineoplastics

In one preliminary report, the addition of vinblastine to zidovudine resulted in severe bone marrow depression. Similarly, 9 of 21 patients could not tolerate zidovudine while receiving a chemotherapy regimen (cyclophosphamide, doxorubicin, teniposide, prednisone, vincristine and bleomycin) because of haematological toxicity.

The pharmacokinetic interaction of chemotherapy with zidovudine was assessed in HIV-positive patients being treated for Kaposi’s sarcoma, non-Hodgkin’s lymphoma or Hodgkin’s disease. The antineoplastics used were: bleomycin, cyclophosphamide, doxorubicin, epirubicin, etoposide, vinblastine, vincristine, vindesine and vinorelbine. The zidovudine metabolism was unchanged, but a 43% decrease was noted in the maximum plasma levels of zidovudine and the time to peak level was prolonged by 51%, which was independent of the chemotherapy given. The authors concluded that dose changes of zidovudine were not needed with the antineoplastics used, based on these pharmacokinetic changes alone, since the zidovudine AUC remained unchanged and maximum plasma levels have not been shown to clearly correlate with its activity. Thus it appears that any interaction is likely to be attributable to additive myelosuppressive effects.

(b) Vancomycin

A report describes marked neutropenia in 4 HIV-positive patients receiving zidovudine when they were given vancomycin (which can also, rarely, have neutropenic effects).

Importance and management

On theoretical grounds any drug causing bone marrow suppression might be additive with the effects of zidovudine. The UK manufacturer recommends that extra care be taken in monitoring haematological parameters if concurrent treatment with any myelosuppressive drug and zidovudine is required. They specifically mention systemic pentamidine, ‘dapsone’, pyrimethamine, ‘co-trimoxazole’, amphotericin B, mycophenolic acid and nephrotoxicity seen in a study in dogs, fluycytosine, ‘gan- ciclovir’, ‘interferon’, vinblastine, and doxorubicin. However, they also state that limited clinical data do not indicate a significantly increased risk of adverse reactions to zidovudine if it is given with prophylactic doses of co-trimoxazole, aerosolised pentamidine, pyrimethamine, and ‘aciclovir’.

Oseltamivir + Drugs that affect renal clearance

Oseltamivir inhibits the renal secretion of the active metabolite of oseltamivir and markedly raises its plasma levels, but this is not clinically relevant because of the wide safety margin of oseltamivir. There was no pharmacokinetic interaction between amoxicillin and oseltamivir, and cimetidine did not alter oseltamivir pharmacokinetics.

Clinical evidence

(a) Amoxicillin

In a study in healthy subjects, oseltamivir 75 mg twice daily for 4.5 days had no effect on the pharmacokinetics of a single 500-mg dose of amoxi-
Interactions involving competition for renal tubular secretion are unlikely, similarly, the amoxicillin had no effect on the pharmacokinetics of the active metabolite of oseltamivir.\(^1\)

(b) Cimetidine

In a crossover study in 18 healthy subjects cimetidine 400 mg every 6 hours for 4 days had no effect on the pharmacokinetics of a single 150-mg dose of oseltamivir given on day 2.\(^1\)

(c) Probenecid

In a crossover study in 18 healthy subjects probenecid 500 mg every 6 hours for 4 days approximately halved the renal clearance of the active metabolite of oseltamivir, and increased its AUC by about 2.5-fold when a single 150-mg dose of oseltamivir was given on day 2.\(^1\)

**Mechanism**

Probenecid appears to completely inhibit the renal tubular secretion of the active metabolite of oseltamivir via the anionic renal transporter process. Oseltamivir does not alter amoxicillin pharmacokinetics, suggesting minimal potential to inhibit the renal anionic transport process. Cimetidine, which inhibits the renal tubular secretion of drugs via the cationic secretion transport process, had no effect on oseltamivir.

**Importance and management**

Probenecid markedly increased the AUC of the active metabolite of oseltamivir, but because of the large safety margin of oseltamivir, this increase is not considered to be clinically relevant.\(^1,2\) Oseltamivir did not alter amoxicillin pharmacokinetics, and is therefore unlikely to interact with other renally secreted organic acids. Other drugs that are involved in the active anionic tubular secretion mechanism are also unlikely to interact. Cimetidine does not interact with oseltamivir, and other drugs that are inhibitors of the renal cationic secretion transport process are unlikely to interact.\(^1\)

Although the UK manufacturer does state that clinically important drug interactions involving competition for renal tubular secretion are unlikely, they recommend care should be taken when prescribing oseltamivir to patients taking other similarly excreted drugs with a narrow therapeutic margin, and they give chlorpropamide, methotrexate, and phenytoin as examples.\(^2\)

**Oseltamivir or Zanamivir + Miscellaneous**

Antacids do not affect the pharmacokinetics of oseltamivir, and there is no pharmacokinetic interaction between aspirin or paracetamol (acetaminophen) and oseltamivir. Aspirin and a variety of other drugs used for influenza management do not affect the antiviral activity of zanamivir *in vitro*.

**Clinical evidence, mechanism, importance and management**

(a) Oseltamivir

1. Antacids. In a single-dose study, the pharmacokinetics of oseltamivir 150 mg and its active carboxylate metabolite were not affected by antacids. The antacids used were an aluminium/magnesium hydroxide suspension (*Maalox*) and calcium carbonate tablet (*Titratrol*).\(^1\)
2. Aspirin. In a study, 12 healthy subjects were given a single 900-mg dose of aspirin before, during and/or after oseltamivir 75 mg twice daily for 9 doses. There was no pharmacokinetic interaction between aspirin and oseltamivir.\(^2\) A possible interaction was postulated since both drugs are hydrolysed by esterases and secreted by anionic tubular secretion.\(^3\)
3. Paracetamol (Acetaminophen). The manufacturer notes that there is no pharmacokinetic interaction between paracetamol and oseltamivir.\(^3,4\)

(b) Zanamivir

The *in vitro* antiviral potency of zanamivir was not affected by aspirin, paracetamol, ibuprofen, phenylephrine, oxymetazoline, promethazine, or co-amoxiclav.\(^5\) Zanamivir is used as an inhalation, and has low systemic bioavailability, so interactions would not generally be expected.

**Protease inhibitors + Antiepileptics; Barbiturates**

It is likely that phenobarbital and other barbiturates will increase the metabolism of the protease inhibitors, thereby reducing their levels and possibly resulting in failure of the antiretrovirals. However, one case suggested that this may not have occurred with primidone and ritonavir/saquinavir, although this should be viewed with caution.

**Clinical evidence, mechanism, importance and management**

The manufacturers of many of the protease inhibitors predict that their levels may be reduced by *phenobarbital*, due to induction of the cytochrome P450 isoenzyme CYP3A4 by which they are metabolised (see ‘Table 21.2’, (p.773)). There do not appear to be any controlled studies to demonstrate the extent of the pharmacokinetic interaction with different protease inhibitors. Data from one case report of carbamazepine toxicity with ‘ritonavir/saquinavir’, (p.810), provide indirect evidence to suggest the interaction with *primidone* is not clinically important. In this report, a patient taking an antiretroviral regimen including *ritonavir* and *saquinavir* had his antiepileptic medication changed from carbamazepine to *primidone* 500 mg daily. The authors noted that during follow-up (duration not stated), viral load was still undetectable and seizures remained under control. \(^1\) Primidone is metabolised to *phenobarbital*, and might have been expected to cause antiretroviral therapy failure. Alternatively, the effect of *ritonavir*, which is a potent inhibitor of CYP3A4, may have been sufficient to offset the increased clearance associated with phenobarbital. Another patient taking phenobarbital, phenytoin and carbamazepine was found to have an unchanged phenobarbital level 2 days after switching from an antiretroviral regimen including indinavir to one containing ritonavir 300 mg twice daily and saquinavir. His plasma levels of ‘carbamazepine’, (p.810), had doubled, and there was a 32.7% drop in the levels of ‘phenytoin’, (p.812). The combination of protease inhibitors and barbiturates should be used with caution, with increased monitoring of antiviral efficacy.

**Protease inhibitors + Antiepileptics; Carbamazepine**

Case reports suggest that ritonavir markedly increases carbamazepine levels and toxicity. Cases have also been reported with lopinavir/ritonavir and nelfinavir. Carbamazepine reduces indinavir levels and efficacy, and would also be expected to decrease levels of other protease inhibitors.

**Clinical evidence**

(a) Indinavir

A report describes a 48-year-old man whose antiretrovirals (indinavir 800 mg every 8 hours, lamivudine 150 mg twice daily and zidovudine 200 mg three times daily) became ineffective after a 10-week course of carbamazepine for postherpetic neuralgia. Over this time indinavir levels were up to 16 times lower than those measured in the absence of car-
barmazepine. In two further cases, patients taking carbamazepine had partial failure of indinavir-containing antiretroviral regimens, which prompted a change in their therapy to include ritonavir rather than indinavir.  

In 3 of the case reports described under Ritonavir, below, in which ritonavir increased carbamazepine levels, patients had previously received indinavir (800 mg three times daily) and carbamazepine (600 mg daily) or 400 mg three times daily without experiencing carbamazepine toxicity (therapeutic carbamazepine levels were reported in 2 of the cases). This suggests that indinavir does not increase carbamazepine levels. However, in the case described above, carbamazepine levels reached the therapeutic range for epilepsy even though the dosage of carbamazepine was only 200 mg daily, suggesting indinavir may increase carbamazepine levels.

(b) Ritonavir

An HIV-positive patient who had a serum carbamazepine level of 10.3 mg/L while taking carbamazepine 400 mg three times daily reported feeling very drowsy within 3 days of starting to take ritonavir, lamivudine and ritonavir/ritonavir 400/100 mg twice daily. His carbamazepine serum level was found to have increased by 46%, to 15 mg/L. The carbamazepine dose was reduced to 400 mg twice daily, and 2 days later the carbamazepine level was 7.4 mg/L.  

(c) Nelfinavir

An HIV-positive patient who had a serum carbamazepine level of 9.8 mg/L while taking carbamazepine 400 mg three times daily started feeling more tired and unsteady on his feet 3 days after starting to take tenofovir, lamivudine and nelfinavir/ritonavir 400/100 mg twice daily. His carbamazepine level was found to have increased by 53%, to 15 mg/L. The carbamazepine dose was reduced to 400 mg twice daily, and 2 days later the carbamazepine level was 9.3 mg/L.  

(d) Ritonavir

An 20-year-old HIV-positive man with epilepsy, who had his seizures controlled with carbamazepine 350 mg twice daily and zonisamide 140 mg twice daily, was admitted to hospital for review of his antiretrovirals. He started taking ritonavir 200 mg three times daily, but after the first dose of ritonavir his serum carbamazepine levels rose from 9.5 to 17.8 mg/L. This was accompanied by intractable vomiting and vertigo, so after 2 days the ritonavir was stopped. Symptoms resolved over the next few days. Subsequently ritonavir 200 mg daily was started, with the same effect, so the dose of carbamazepine dose was reduced to one-third, which resulted in carbamazepine levels of 6.2 micrograms/mL. Levels of ritonavir were not measured. Three other cases also document two- to threefold rises in carbamazepine levels with associated toxicity caused by the addition of ritonavir 300 mg, 400 mg or 600 mg twice daily and saquinavir 400 mg twice daily. In one case a carbamazepine dose reduction from 600 to 100 mg daily was needed to keep the levels within the therapeutic range before ritonavir was discontinued.  

Mechanism

Ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and consequently markedly increases carbamazepine levels. Other protease inhibitors would be expected to interact similarly, although to a lesser degree (see also ‘Antivirals’, (p.772)). Moreover, carbamazepine is an inducer of CYP3A4 and therefore can increase the metabolism of the protease inhibitor causing the levels to become subtherapeutic. Use of ritonavir-boosted protease inhibitors could theoretically offset this effect, but it may lead to increased carbamazepine toxicity.

Importance and management

Although the evidence is limited, these interactions seem to be established. It would therefore appear that the use of carbamazepine with protease inhibitors should be avoided where possible (mainly because of the risk of antiviral treatment failure). If both must be used then extremely close monitoring of both antiviral efficacy and carbamazepine levels/toxicity is warranted. Symptoms of carbamazepine toxicity include nausea, vomiting, ataxia and drowsiness. The authors of one report suggest that amitriptyline or gabapentin would be possible alternatives for carbamazepine used for pain, or valproic acid or lamotrigine for carbamazepine used for seizures.  

Protease inhibitors + Antiepileptics; Lamotrigine

Lopinavir/ritonavir halved lamotrigine plasma levels, whereas the protease inhibitor levels did not appear to be altered. Saquinavir/ritonavir had similar effects in another patient and therefore reduced lamotrigine levels should be anticipated with any ritonavir-boosted regimen.

Clinical evidence

In a study in 18 healthy subjects taking lamotrigine 100 mg twice daily, lopinavir/ritonavir 400/100 mg twice daily for 10 days decreased the steady-state minimum plasma level of lamotrigine by 55%, decreased the AUC of lamotrigine by 46%, and increased its clearance by 85%. Doubling the dose of lamotrigine to 200 mg twice daily increased the AUC to a similar level to that seen with the lower dose without lopinavir/ritonavir. Pharmacokinetic parameters for lopinavir and ritonavir were similar to those in historical controls. The authors of a review describe a patient taking lamotrigine 25 mg twice daily who had a favourable decline in viral load 2 months after starting to take lopinavir/ritonavir, lamivudine and stavudine. There was no toxicity and no recurrence of seizures. A 30-year-old woman taking nevirapine, saquinavir 1.2 g daily, and ritonavir 600 mg daily with an undetectable viral load had her epilepsy medication changed from gabapentin and lorazepam to lamotrigine and phenytoin because of an increased frequency and severity of seizures. The lamotrigine dose was eventually increased to 1.8 g daily to achieve serum levels of 5 to 8 mg/L. The ritonavir dose was doubled and the saquinavir dose increased to 2 g daily to compensate for the enzyme-inducing effects of ‘phenytoin’, (p.812). The patient’s viral load remained undetectable, and her seizures decreased over the next 6 months, but she died suddenly of unexplained causes following a tonic-clonic seizure (autopsy not performed).  

Mechanism

Lopinavir/ritonavir probably decreases lamotrigine levels by induction of glucuronidation (suggested by the increase in the AUC ratio of lamotrigine 2N-glucuronide to lamotrigine).  

Importance and management

The pharmacokinetic interaction would appear to be established; however, since the relationship between lamotrigine levels and efficacy is not clear, the clinical relevance of the decrease is uncertain. Lamotrigine efficacy should be monitored in patients taking lopinavir/ritonavir, and probably any ritonavir-boosted regimen. Anticipate the need to increase the lamotrigine dose.  

Protease inhibitors + Antiepileptics; Miscellaneous

Stiripentol did not alter single-dose saquinavir pharmacokinetics in a controlled study. In one case report, ritonavir did not alter zonisamide levels.

Clinical evidence, mechanism, importance and management

(a) Stiripentol

In a crossover study in 12 healthy subjects,1 stiripentol 1 g twice daily for 8 days had no effect on the pharmacokinetics of a single 400-mg dose of saquinavir given on day 8.

(b) Zonisamide

A 20-year-old HIV-positive man with epilepsy, who had his seizures controlled with carbamazepine 350 mg twice daily and zonisamide 140 mg twice daily, was admitted to hospital for review of his antiretrovirals. He started taking ritonavir, and after the first 200-mg dose of ritonavir his zonisamide levels remained unchanged.2 However, his levels of ‘carbamazepine’, (p.810), were almost doubled.

Protease inhibitors + Antiepileptics; Phenytoin

Nelfinavir and lopinavir/ritonavir modestly reduced phenytoin levels in pharmacokinetic studies. In case reports, ritonavir has decreased, increased or not altered phenytoin levels. Phenytoin levels decreased lopinavir levels, and possibly also indinavir and ritonavir levels, but did not alter nelfinavir levels.

Clinical evidence

(a) Indinavir

A 39-year-old HIV-positive man, taking phenytoin 300 mg daily, started to take indinavir 800 mg three times daily. When the phenytoin dose was reduced to 200 mg daily, the viral load dropped by almost half and his CD4 count doubled.3

(b) Lopinavir/Ritonavir

The concurrent use of phenytoin 300 mg once daily and lopinavir/ritonavir 400/100 mg twice daily resulted in a 30% decrease in the AUC of lopinavir and a 23% decrease in the AUC of phenytoin in studies in healthy subjects.4

(c) Nelfinavir

An HIV-positive man taking phenytoin and phenobarbital for epilepsy had been taking nelfinavir 750 mg three times daily and stavudine 30 mg twice daily for nearly 3 months when he had a tonic-clonic seizure. After starting nelfinavir and stavudine, serum phenytoin levels were found to have dropped from around 10 mg/L to around 5 mg/L.5 Similarly, nelfinavir 1.25 g twice daily for 7 days decreased the AUC of phenytoin by about 30% and the maximum serum level by 21%, in healthy subjects, whereas the nelfinavir levels were not altered.6

(d) Ritonavir

A case report describes the intentional use of ritonavir 600 mg twice daily to boost phenytoin levels in a 14-year-old boy who had been having seizures for 28 days, despite the use of several antiepileptics. Phenytoin at 20 mg/kg daily had originally failed to produce satisfactory plasma levels, although it did reduce the rate of seizures. After starting the ritonavir his seizures were controlled and the phenytoin level became therapeutic. Seizures started again after the ritonavir was stopped.7 Conversely, an HIV-positive patient taking carbamazepine and phenytoin had little change in his phenytoin levels, which remained at around 15 mg/L, 2 months after switching from an antiretroviral regimen including indinavir to one containing ritonavir 600 mg twice daily and saquinavir.8 This was despite a 2.8-fold increase in the levels of ‘carbamazepine’, (p.810). Another patient taking phenobarbital, phenytoin and carbamazepine had a 32.7% drop in his phenytoin level 2 days after switching from an antiretroviral regimen including indinavir to one containing ritonavir 300 mg twice daily and saquinavir. The level of ‘carbamazepine’, (p.810) had doubled, and the level of ‘phenobarbital’, (p.810) was unchanged.7

A 30-year-old woman taking nevirapine, saquinavir 1.2 g daily and ritonavir 600 mg daily with undetectable viral load had her epilepsy medication changed from gabapentin and lorazepam to lamotrigine and phenytoin because of increased frequency and severity of seizures. She required phenytoin 8 mg/kg daily to maintain therapeutic serum levels. The ritonavir dose was doubled and the saquinavir dose increased to 2 g daily to compensate for the enzyme-inducing effects of phenytoin. The patient’s viral load remained undetectable, and her seizures decreased over the next 6 months but she died suddenly of unexplained causes following a tonic-clonic seizure (autopsy not performed).9

Mechanism

Phenytoin is an inducer of the cytochrome P450 isoenzyme CYP3A4, and would be expected to increase the metabolism of the protease inhibitors, although nelfinavir levels were not altered, possibly because it is a substrate for several other isoenzymes. Phenytoin is principally metabolised by CYP2C9 and CYP2C19, and would therefore, not be expected to be substantially affected by most protease inhibitors. However, both increases and modest decreases in phenytoin levels have been seen.

Importance and management

Although information is limited, some of these interactions are expected. Phenytoin may decrease plasma levels of indinavir, lopinavir and possibly ritonavir, and the manufacturers of darunavir10 and saquinavir11,12 also predict that their levels may be reduced by phenytoin, although they note that the effect on ritonavir-boosted saquinavir has not been assessed.11,12 Phenytoin appears not to alter nelfinavir levels.

In addition, protease inhibitors appear to alter phenytoin levels. Therefore an alternative antiepileptic, such as sodium valproate, which does not affect cytochrome P450 isoenzymes, may be more appropriate in patients taking protease inhibitors. However, if there is no option but to use phenytoin, close monitoring of antiviral efficacy and phenytoin levels is essential.

about 50% in the valproic acid level, which resulted in an exacerbation of mania. A case of hepatotoxicity has occurred in a patient taking valproic acid with nevirapine and saquinavir/ritonavir.

Clinical evidence

In a study in 8 HIV-positive patients taking lopinavir/ritonavir 400/100 mg twice daily plus various NRTIs, the median AUC of lopinavir increased by 75% without any change in the estimated half-life after taking valproic acid 250 mg twice daily for 7 days. Although the maximum and minimum lopinavir levels were also higher, the difference was not statistically significant. Ritonavir levels were not assessed. Valproic acid levels achieved in the patients taking lopinavir/ritonavir were not significantly different from those in 11 HIV-positive control patients mainy taking NRTI antiretrovirals, even when the 3 patients taking a protease inhibitor or NNRTI (amprenavir, indinavir, or nelfinavir plus nevirapine) were excluded.1

However, there is one report of a possible decrease in valproate levels in a 30-year-old man after starting lopinavir/ritonavir.2 This patient, who had been taking valproic acid 375 mg daily as divalproex sodium for 7 months after an episode of mania, had a subtherapeutic valproic acid level of 197 micromol/L, and the dose was increased to 250 mg three times daily. After 25 days his trough valproic acid level was 495 micromol/L, and an antiretroviral regimen of lamivudine, zidovudine, lopinavir/ritonavir was started, and paroxetine for depression. Four days later he had become manic, and the valproate level was found to be 238 micromol/L, about 50% lower than the previous level. An increase in valproic acid dose to 1.5 g daily was eventually required to achieve a therapeutic level of 392 micromol/L. A case of valproate-associated hepatotoxicity occurred in a 51-year-old man about 3 weeks after starting nevirapine 200 mg twice daily, saquinavir 400 mg twice daily, ritonavir 400 mg twice daily, and stavudine. Serum valproate levels remained therapeutic.3

Mechanism

Lopinavir/ritonavir might decrease the plasma levels of valproic acid by induction of glucuronidation. See also ‘lamotrigine’, (p.811), which is similarly affected.

Importance and management

It has been predicted that ritonavir might reduce valproate levels, but the case report1 appears to be the first clinical evidence of this occurring. Other evidence from the earlier study1 suggested valproate levels were not affected by ritonavir to a statistically significant extent, although there was a downward trend in valproic acid levels. In addition, this study unexpectedly found that lopinavir levels appeared to be higher in patients taking valproic acid, although the increase is probably not clinically relevant.1 If possible, monitor valproate levels when any antiretroviral regimen that includes ritonavir is used. Further study is needed. Note that there has been some concern about using valproate in HIV infection but there seems to be no established reason to avoid or specifically promote the use of valproate in HIV-infection per se.

Clinical evidence, mechanism, importance and management

(a) Indinavir

Preliminary results from a study in healthy subjects suggest that the concurrent use of atovaquone 750 mg twice daily and indinavir 800 mg 3 times daily results in a minor 5% decrease in the AUC of indinavir, and a 13% increase in the AUC of atovaquone.1 The UK manufacturer of atovaquone notes that concurrent use decreased the minimum level and AUC of indinavir by 23% and 9%, respectively. They recommend that caution should be exercised on concurrent use because of the potential risk of failure of indinavir treatment.2 However, note that the effect was small and that indinavir is often used with other antiretrovirals, which might modify the interaction by affecting indinavir levels.

(b) Ritonavir and ritonavir-boosted protease inhibitors

The manufacturer of ritonavir predicts that it will decrease the plasma levels of atovaquone,3,4 by inducing atovaquone glucuronidation.4 They say that the clinical significance of this prediction is unknown, but that an increase in the atovaquone dose might be needed.3 Careful monitoring of serum levels and/or therapeutic effects is recommended when atovaquone is given with ritonavir as a pharmacokinetic enhancer or as an antiretroviral.4 This predicted interaction would therefore apply to lopinavir/ritonavir2 and any other boosted protease inhibitors. However, there does not appear to be any actual data to prove that the interaction occurs or is clinically relevant.

Protease inhibitors + Azoles; Fluconazole

Fluconazole may modestly increase the levels of saquinavir and tipranavir, but does not significantly affect ritonavir, indinavir or nelfinavir levels.

Clinical evidence

Fluconazole 400 mg on day one, followed by 200 mg daily for 4 days did not alter any of the pharmacokinetic parameters of ritonavir 200 mg every 6 hours by more than 15%, when given to 8 healthy subjects.1 Similarly, fluconazole had no effect on the pharmacokinetics of ritonavir in 3 HIV-positive subjects.2 The pharmacokinetics of both indinavir 1 g every 8 hours and fluconazole 400 mg daily were not significantly affected by concurrent use in 11 HIV-positive patients.3 Another study failed to find any significant interaction between indinavir and fluconazole.4 A population pharmacokinetic analysis estimated that fluconazole decreased nelfinavir clearance by 26 to 30%, but this was not considered clinically significant.5

Fluconazole 400 mg on day 2, followed by 200 mg daily for 6 days increased the median AUC of saquinavir by 50%, and the maximum level by 56% in 5 HIV-positive subjects.2 Fluconazole increased the AUC of tipranavir, and its maximum and minimum levels by 50%, 32%, and 69%, respectively, when tipranavir/ritonavir 500/200 mg was given twice daily. Fluconazole levels were not affected.6

Mechanism

Fluconazole is a moderate inhibitor of CYP3A4 by which the protease inhibitors are metabolised.1,3

Importance and management

The small to modest changes in protease inhibitor pharmacokinetics seen with fluconazole are unlikely to be of clinical significance. Because fluconazole causes a more significant increase in tipranavir levels, the manufacturer of tipranavir states that fluconazole, in doses of greater than

Protease inhibitors + Atovaquone

Atovaquone modestly reduces the minimum level of indinavir. Ritonavir alone and ritonavir-boosted protease inhibitors are predicted to decrease atovaquone levels.
200 mg daily is not recommended. No dosage adjustments are recommended for lower doses of fluconazole.6,7

The information about the interactions of protease inhibitors with itraconazole is limited. On the basis of the available data, it is possible that itraconazole may increase the bioavailability of itraconazole, since they are potent inhibitors of CYP3A4.

**Mechanism**

Itraconazole is a known substrate and inhibitor of the cytochrome P450 isoenzyme CYP3A4, and the protease inhibitors also inhibit and share this pathway of metabolism. Thus enzyme inhibition, and competition for metabolism results in raised serum levels of both drugs.

**Importance and management**

The importance of the available data, it is possible that itraconazole has greater effects than ‘ketoconazole’, (below), on protease inhibitor levels. The manufacturers of indinavir advise modestly reducing the indinavir dose to 600 mg every 8 hours if it is to be given with itraconazole.5,8 The UK manufacturer of saquinavir recommends monitoring for saquinavir toxicity if itraconazole is used.10 Some protease inhibitors, especially ritonavir and possibly indinavir, may increase itraconazole levels and most manufacturers say that doses of itraconazole greater than 200 mg a day are not recommended. The US manufacturers of amprenavir recommend increased monitoring for adverse effects and state that the dose of itraconazole may need to be reduced if it is greater than 400 mg daily.11

**Clinical evidence**

The AUC of amprenavir was increased by 32% in one study,1 but in another, the pharmacokinetics of amprenavir were not affected when ketoconazole was given with fosamprenavir/ritonavir.2 In a single-dose study amprenavir 1.2 g caused a 44% rise in the AUC of ketoconazole 400 mg.3 Similarly, the AUC of ketoconazole was increased by 2.7-fold by fosamprenavir/ritonavir.3

(b) Atazanavir

The pharmacokinetics of atazanavir 400 mg daily were not affected by the concurrent use of ketoconazole 200 mg daily for 7 days.3

(c) Darunavir

Pharmacokinetic changes have been seen with the concurrent use of ketoconazole and darunavir/ritonavir: the darunavir AUC was raised by 42% and the ketoconazole AUC was increased about threefold.4

(d) Indinavir

Ketoconazole raises the AUC of indinavir by 62%.5

(e) Lopinavir

A single 200-mg dose of ketoconazole had no effect on the pharmacokinetics of lopinavir.6 However, ketoconazole 200 mg once daily for 14 days was associated with a 68% increase in trough lopinavir levels and a 33% increase in ritonavir levels in an HIV-positive patient.7 The AUC of a single 200-mg dose of ketoconazole was increased threefold in patients taking lopinavir/ritonavir 400/100 mg twice daily.6

(f) Nelfinavir

Ketoconazole raises the AUC of nelfinavir by 35%.8

(g) Ritonavir

Ritonavir increased the AUC of ketoconazole 3.4-fold and the maximum plasma level 1.6-fold.9

(h) Saquinavir with Ritonavir

In one early clinical study, patients who received the combination of ketoconazole and saquinavir had a greater drop in viral load after 3 months than those not receiving ketoconazole.10 However, in one pharmacokinetic study, ketoconazole 200 mg for 7 days then 400 mg daily for 7 days had no consistent effect on saquinavir peak and trough plasma levels in 7 HIV-positive patients, although inter-individual variability was great. Saquinavir [as hard gelatin capsules11] was given at the low dose of 600 mg three times daily.12 Conversely, when saquinavir (soft gel capsule) 1.2 g three times daily was given to 12 healthy subjects with ketoconazole 400 mg daily for 7 days, the saquinavir AUC and maximum plasma levels were raised by 190% and 171%, respectively.13 A similar study in 22 HIV-positive patients, using ketoconazole 200 mg daily, found that the saquinavir AUC and maximum plasma levels were raised by 69% and 36%, respectively.14 In 12 HIV-positive patients, ketoconazole 200 or 400 mg increased the AUC of saquinavir and ritonavir in combination (both 400 mg twice daily) by 37% and 29%, respectively. The distribution of ritonavir was also affected, with disproportionate rises seen in CSF con-

**Protease inhibitors + Azoles; Itraconazole**

Itraconazole increases the levels of amprenavir, indinavir, lopinavir/ritonavir, and saquinavir, and may theoretically increase the levels of other protease inhibitors.
centrations. All these changes appeared to be unrelated to the dose of ketoconazole used.1,13

The peak plasma level of ketoconazole 400 mg daily was similar to that usually seen with ketoconazole 800 mg alone when saquinavir/ritonavir were given.14 Moreover, in this study, dose escalation to higher doses of ketoconazole was discontinued after the first patient given ketoconazole 600 mg daily stopped treatment early because of adverse gastrointestinal effects.1,13 However, saquinavir alone did not affect ketoconazole pharmacokinetics.11

Mechanism
Ketoconazole is a known substrate and inhibitor of the cytochrome P450 isoenzyme CYP3A4, and the protease inhibitors also inhibit and share this pathway of metabolism.1,11,13 Thus enzyme inhibition, and competition for metabolism results in raised serum levels of both drugs. Ketoconazole may also inhibit P-glycoprotein transport of saquinavir and ritonavir, causing a decrease in their clearance, and raising serum levels.1,13 Inhibition of P-glycoprotein may reduce efflux of protease inhibitors from the CSF, so increasing CSF levels.13

Importance and management
The magnitude of the changes in protease inhibitor pharmacokinetics seen with ketoconazole are unlikely to warrant dose changes of the protease inhibitors or cause significant increase in their adverse effects. However, the US manufacturer of indinavir recommends that the dose of indinavir be reduced to 600 mg every 8 hours when used with ketoconazole.1,13 Whether the ability of ketoconazole to boost CSF exposure to protease inhibitors has a role in improving therapeutic efficacy in the CNS remains to be seen.13

The data on the effect of protease inhibitors on ketoconazole are more limited. Amprenavir caused a modest increase in ketoconazole levels, and the UK manufacturer of amprenavir suggests that no ketoconazole dose adjustment is necessary with amprenavir alone,1,13 although the US manufacturer recommends increased monitoring for adverse effects and states that a dose reduction may be needed in patients receiving ketoconazole in doses of more than 400 mg daily.1,13 However, a marked effect was seen for ritonavir alone and for ritonavir combined with darunavir, fosamprenavir, lopinavir, saquinavir and theoretically tipranavir.1 This may increase the adverse effects of ketoconazole. Most protease inhibitor manufacturers say that doses greater than 200 mg a day of ketoconazole are not recommended. Similarly, the UK manufacturers of ketoconazole and ritonavir say that a dose reduction of ketoconazole should be considered when it is given with ritonavir.1,17

The current use of protease inhibitors and voriconazole is predicted to interfere with the metabolism of both drugs. Studies suggest that ritonavir decreases voriconazole levels, but no interaction was seen between indinavir and voriconazole in one study.1

Clinical evidence
In a study in 18 healthy subjects, the pharmacokinetics of both indinavir 800 mg three times daily and voriconazole 200 mg twice daily were unaffected by at least a week of concurrent use.1 However, in vitro studies suggest that the metabolism of HIV-protease inhibitors may be inhibited by voriconazole, and the metabolism of voriconazole may be inhibited by HIV-protease inhibitors. The manufacturer therefore suggests that patients should be carefully monitored for evidence of drug toxicity and/or loss of efficacy during concurrent use of other HIV-protease inhibitors (amprenavir, nelfinavir and saquinavir are specifically mentioned).2

In healthy subjects ritonavir 400 mg twice daily for 9 days decreased the steady-state maximum levels and AUC of oral voriconazole (400 mg twice daily for 1 day, then 200 mg twice daily for 8 days) by 66% and 82%, respectively.3 The pharmacokinetics of the ritonavir remained unchanged. Low-dose ritonavir (100 mg daily) decreased the AUC of voriconazole by 39% and the AUC of the ritonavir was decreased by 14%.3

Mechanism
Voriconazole is an inhibitor and a substrate of the cytochrome P450 isoenzyme CYP3A4; protease inhibitors are also metabolised by this route, and can, to varying degrees, also inhibit this isoenzyme.

Importance and management
The manufacturers of voriconazole say that the concurrent use of ritonavir (at doses of 400 mg and above twice daily) is contraindicated,2,3 presumably because the efficacy of the voriconazole is expected to be markedly reduced. The manufacturer of ritonavir also recommends that when it is used as a pharmacokinetic enhancer (usually 100 mg twice daily) voriconazole should only be given if the benefits outweigh the risks.4 Most protease inhibitors are given with ritonavir as a pharmacokinetic enhancer; however, caution is also warranted if they are given alone, as all the protease inhibitors can inhibit CYP3A4 to some extent and may therefore also increase voriconazole levels. Voriconazole may also affect protease inhibitor levels, but other than ritonavir and indinavir, which are not affected this does not appear to have been studied. Be aware that some increase in their levels is theoretically possible if voriconazole is given.
Protease inhibitors + Cannabinoids

The short-term use of cannabis cigarettes or dronabinol did not appear to adversely affect indinavir or nelfinavir levels or viral loads in HIV-positive patients.

Clinical evidence

In 9 HIV-positive patients on a stable regimen containing indinavir (mostly 800 mg every 8 hours), smoking a cannabis cigarette (3.95% tetrahydrocannabinol) three times a day before meals for 14 days resulted in a median 14% decrease in AUC and maximum level and a 34% decrease in minimum indinavir level. However, only the change in maximum level was statistically significant. Similarly, dronabinol 2.5 mg three times daily for 14 days had no significant effect on indinavir pharmacokinetics.

In another 11 patients on a stable regimen containing nelfinavir 750 mg three times daily, there was a non-significant 10% decrease in AUC, 17% decrease in maximum level, and 12% decrease in minimum nelfinavir level after 14 days of cannabis cigarettes. Similarly, dronabinol 2.5 mg three times daily for 14 days had no significant effect on nelfinavir pharmacokinetics.

There was no adverse effect on viral load or CD4 count in the patients receiving cannabis cigarettes or dronabinol.

Mechanism

Unknown.

Importance and management

Short-term use of cannabis cigarettes or dronabinol does not appear to have any important effect on levels of indinavir or nelfinavir, nor on markers of HIV infection.

Protease inhibitors + Co-trimoxazole

Minor pharmacokinetic changes have been seen when co-trimoxazole is given with the protease inhibitors, but these changes are not considered to be clinically significant.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given indinavir 400 mg every 6 hours with co-trimoxazole 960 mg every 12 hours found that there was no change in the AUC of indinavir, but a small 17% decrease in indinavir trough levels. In addition, there was an 18% increase in the AUC of trimethoprim, and a 5% increase in the AUC of sulfamethoxazole. None of these changes were considered to be clinically important.

Ritonavir 500 mg twice daily caused a 20% increase in the AUC of trimethoprim and a 20% decrease in the AUC of sulfamethoxazole when a single 960-mg dose of co-trimoxazole was given to 15 healthy subjects. These changes were considered too small to be of clinical relevance. The pharmacokinetics of ritonavir were not assessed.

The combination of saquinavir 600 mg three times daily and co-trimoxazole 960 mg three times weekly caused no changes in the pharmacokinetics of saquinavir.

There would seem to be no reason for avoiding the use of co-trimoxazole with any of the protease inhibitors.

Protease inhibitors + Drugs that affect gastric pH

Proton pump inhibitors (marked effect) and H2-receptor antagonists (modest effect) reduce atazanavir levels. Other drugs that increase gastric pH are also predicted to reduce plasma levels of atazanavir. Fosamprenavir may be similarly affected (moderate effects seen with ranitidine), although antacids and esomeprazole had little effect in one study. Omeprazole decreases indinavir levels and an antacid modestly decreased tipranavir levels. Neither ranitidine nor omeprazole had any effect on darunavir/ritonavir or lopinavir/ritonavir levels. In contrast, cimetidine, ranitidine and omeprazole have been shown to increase saquinavir levels.

Clinical evidence

(a) Atazanavir

1. H2-receptor antagonists. In a study in healthy subjects famotidine 40 mg twice daily reduced the atazanavir AUC, maximum, and minimum levels by 18%, 14%, and 28%, respectively, when given simultaneously with atazanavir/ritonavir 300/100 mg once daily. A greater effect (41% reduction in AUC) was seen when the drugs were given again without ritonavir, but little effect was seen when the atazanavir was given 10 hours after and 2 hours before the famotidine. In a randomised study in healthy subjects, ranitidine 150 mg one hour before breakfast reduced the atazanavir AUC, maximum, and minimum levels by 48%, 52%, and 43%, respectively, when atazanavir/ritonavir 300/100 mg once daily was taken 30 minutes after breakfast.

2. Proton pump inhibitors. The AUC of atazanavir was reduced by 76% and the trough plasma level by 78% when atazanavir/ritonavir 300/100 mg was given with omeprazole 40 mg. Increasing the dose of atazanavir/ritonavir to 400/100 mg did not negate the effects of this interaction. An even greater effect (94% reduction in AUC) was seen when atazanavir alone was given with omeprazole, and the same effect was seen with lansoprazole. Similar results were found in another study with omeprazole: ritonavir levels were not affected.

Atazanavir trough levels were significantly lower in patients taking proton pump inhibitors than in those taking H2-receptor antagonists in another study. A 65-year-old HIV-positive man had a marked reduction in atazanavir trough levels and AUC in a 12-hour study while receiving esomeprazole and atazanavir/ritonavir. However, 9 of 12 subjects had a successful virological outcome while taking atazanavir with or without ritonavir together with a proton pump inhibitor (esomeprazole, lansoprazole, omeprazole, pantoprazole, rabeprazole) in a retrospective analysis of concurrent use. Another retrospective analysis also found no difference in virological outcome in patients taking atazanavir/ritonavir with proton pump inhibitors (rabeprazole, omeprazole; 10 patients) and 66 patients not taking proton pump inhibitors. Similarly, in one patient taking atazanavir/ritonavir 300/100 mg once daily, tenofovir and lamivudine, and lansoprazole 30 mg twice daily, the AUC, maximum, and minimum levels of atazanavir were higher than those seen historically with atazanavir/ritonavir plus tenofovir. Another patient maintained virological suppression when omeprazole 20 mg daily was taken with ritonavir-boosted atazanavir 150 mg twice daily.

(b) Darunavir with Ritonavir

In a crossover study in 16 healthy subjects, neither omeprazole 20 mg daily nor ranitidine 150 mg twice daily had a significant effect on the AUC or minimum level of darunavir after darunavir/ritonavir 400/100 mg was given twice daily for 5 days.

(c) Fosamprenavir

In a crossover study in healthy subjects the AUC of amprenavir (derived from a single 1.4-g dose of fosamprenavir) was decreased by 18% and the maximum plasma level by 35%, but the minimum level was not significantly altered by the concurrent use of 30 mL of an aluminium/magnesium hydroxide antacid (Maalox TC).

In the same study, ranitidine 300 mg given one hour before fosamprenavir 1.4 g decreased the AUC of amprenavir by 30% and the maximum level by 51% without altering the minimum level.

In contrast, esomeprazole 20 mg once daily had no effect on the steady-state pharmacokinetics of amprenavir after either fosamprenavir 1.4 g
twice daily or fosamprenavir/ritonavir 700/100 mg twice daily in studies in healthy subjects. However, fosamprenavir 1.4 g twice daily increased the esomeprazole AUC by 55%. In this study, the daily dose of esomeprazole was given simultaneously with the first dose of protease inhibitor. Similarly, no pharmacokinetic interaction was apparent in an 8-hour study in a 65-year-old HIV-positive who was given fosamprenavir/ritonavir with esomeprazole.

(d) Indinavir

The manufacturer notes that cimetidine 600 mg twice daily for 6 days had no clinically significant effect on the pharmacokinetics of a single 400-mg dose of indinavir in a study in 12 healthy subjects. In a study in 8 healthy subjects given omeprazole 40 mg daily with a single 800-mg dose of indinavir, half of them had a clinically significant decrease in the plasma levels of indinavir; no significant pharmacokinetic changes occurred in the others. In a review by the same authors, 4 of 9 patients taking omeprazole with indinavir had plasma levels of indinavir lower than expected. In two patients, increasing the indinavir dose from 800 mg to 1 g, three times daily, resulted in acceptable plasma levels. In a later randomised controlled study, omeprazole 40 mg once daily for 7 days reduced the AUC of indinavir 800 mg by 47% in 14 subjects. However, the addition of ritonavir 200 mg to the indinavir negated the effect of the omeprazole.

Note that ‘buffered didanosine tablets’, (p.804), has also been shown to reduce indinavir levels.

(e) Lopinavir/Ritonavir

In a randomised study in healthy subjects, omeprazole 40 mg once daily or ranitidine 150 mg one hour before breakfast had no effect on the relative bioavailability of either lopinavir or ritonavir when lopinavir/ritonavir 800/200 mg once daily was taken 30 minutes after breakfast, or when lopinavir/ritonavir 400/100 mg twice daily (30 minutes after a meal) was given 1.5 hours after the acid-reducing drug. The lopinavir/ritonavir was taken in a tablet form.

In a clinical study of lopinavir/ritonavir once daily (8 study patients, 86 control patients) or twice daily (7 study patients, 45 control patients) in combination with tenofovir and emtricitabine, trough levels of lopinavir were assessed at 4, 8, 16, 24 and 48 weeks: patients taking acid-reducing drugs (proton pump inhibitors 67%, H2-receptor antagonists or antacids) were then compared with control patients not using acid-reducing drugs. There was no significant difference in trough lopinavir levels between the patients taking acid-reducing drugs and the controls, except that at week 24 the trough level of lopinavir was 50% higher, and at week 48 it was 73% higher, in users of acid-reducing drugs taking lopinavir/ritonavir once daily. No difference was seen in the group taking lopinavir/ritonavir twice daily.

(f) Saquinavir

When cimetidine was given with saquinavir the AUC of saquinavir 1.2 g twice daily was 120% greater when it was given with cimetidine 400 mg twice daily, when compared with saquinavir 1.2 g three times daily alone. In a study in 12 healthy subjects, the AUC of saquinavir given with omeprazole 40 mg daily increased the AUC of saquinavir by 82% when saquinavir 1000/100 mg was given twice daily to 18 healthy subjects.

(g) Tipranavir

In a single-dose study in healthy subjects, 20 mL of an aluminium/magnesium hydroxide antacid (Maalox Plus) decreased the AUC, minimum and maximum levels of tipranavir by 25 to 29%, after simultaneous ingestion of tipranavir/ritonavir 500/200 mg.

Mechanism

The UK manufacturer of indinavir states that a normal (acidic) gastric pH may be necessary for optimum absorption of indinavir. Any drug that increases the gastric pH could therefore potentially reduce absorption. Alterted gastric pH may also account for the interaction with atazanavir. Cimetidine probably boosts saquinavir levels by inhibiting the first-pass metabolism of saquinavir. It is not understood why ranitidine and omeprazole increase saquinavir levels.

Importance and management

The marked pharmacokinetic interaction of omeprazole with atazanavir (with or without ritonavir) is established, and lansopraze appears to act similarly. Based on the available data, advice in Europe and the USA is that atazanavir or atazanavir/ritonavir should not be given with omeprazole or other proton pump inhibitors. Modest effects were seen with atazanavir and simultaneous famotidine, whereas ranitidine taken 1.5 hours before atazanavir/ritonavir had a more marked effect. The manufacturer says that no dosage adjustment of atazanavir/ritonavir is required when it is given with an H2-receptor antagonist, all as a single daily dose with food. However, they caution that the magnitude of the interaction may be more pronounced in HIV-positive patients (as the intragastric pH may be higher in this population). To avoid any interaction they suggest that atazanavir/ritonavir should be given once daily with food, 2 hours before and at least 10 hours after the dose of the H2-receptor antagonist. In addition, they recommend atazanavir should be given 2 hours before or 1 hour after buffered medicinal products. This would include didanosine buffered tablets (see ‘NRTIs + Protease inhibitors’, p.804).

Based on the limited data with other protease inhibitors, the manufacturer of amprenavir also recommends it should not be given within 1 hour of an antacid. The decrease in amprenavir levels seen when fosamprenavir is given with an antacid are not considered clinically relevant, and no fosamprenavir dose adjustments are likely to be necessary. Greater decreases were seen with ranitidine, although the minimum levels were unchanged. The UK manufacturer states that no fosamprenavir dose adjustment is needed with ranitidine or other H2-receptor antagonists; however, the US manufacturer says the combination should be used with caution because fosamprenavir may be less effective. However, no interaction occurred with esomeprazole, and this, or other proton pump inhibitors, may be given at the same time as fosamprenavir.

The interaction between omeprazole and indinavir would appear to be established. Omeprazole should probably not be used with indinavir unless ritonavir is used to boost the indinavir levels. This would likely apply to other proton pump inhibitors used with indinavir as well. Antacids modestly decreased tipranavir levels, and administration should be separated by at least 2 hours.

Cimetidine very markedly increases saquinavir levels, and further study is required to discover whether this is clinically useful. Ranitidine and omeprazole cause a fairly marked increase in saquinavir levels, although this is probably not clinically relevant.

Omeprazole and ranitidine do not appear to alter the pharmacokinetics of darunavir/ritonavir or lopinavir/ritonavir.

Protease inhibitors + Food

Food increases the bioavailability of atazanavir, darunavir, lopinavir/ritonavir soft capsules and solution, nelfinavir, saquinavir (all formulations) and tipranavir, but decreases that of indinavir. Food only minimally affects the bioavailability of amprenavir, fosamprenavir, lopinavir/ritonavir tablets and ritonavir. Mixing ritonavir with enteral feeds does not affect the pharmacokinetics of ritonavir.

Clinical evidence, mechanism, importance and management

(a) Absorption decreased

A single 600-mg dose of indinavir was given to 7 HIV-positive subjects immediately after various types of meal. The protein, carbohydrate, fat and high-viscosity meals reduced the AUC of indinavir by 68%, 45%, 34% and 30%, respectively. The fat meal was associated with the largest inter-subject variation in bioavailability. The effect of the protein meal was attributed to the fact that it raised gastric pH and therefore impaired the absorption of indinavir (a weak base). The impairment of indinavir absorption caused by the other meals, which did not alter gastric pH, may have been due to delayed gastric emptying. A similar study comparing a full breakfast with light breakfasts (toast or cereal) on indinavir absorption and reduced its maximum serum levels by 86%, while the light breakfasts high-fat meal by 96% and 43%, respectively. The corresponding increases in the absorption of indinavir/ritonavir soft capsules and oral solution say that it should be taken with food. No clinically significant difference was seen in the bioavailability of lopinavir/ritonavir tablets between fasting and fed subjects, therefore the manufacturers say that it can be taken with or without food. The manufacturers of darunavir note that administration with a light or high-fat meal decreased the wide variation in plasma levels. When given up to 15 minutes after a low-fat meal, the pharmacokinetics (derived from fosamprenavir) when compared with taking the formulation in the fasted state. Fosamprenavir tablets may be taken without regard to food intake.

(b) Absorption increased

1. Atazanavir. The manufacturers of atazanavir note that administration with a light or high-fat meal decreased the wide variation in plasma levels. They recommend that atazanavir should be taken with food to enhance bioavailability and minimise variability. The US information gives examples of a light meal, such as dry toast with jam, juice, and coffee with skimmed milk and sugar, or corn flakes, skimmed milk and sugar.

2. Darunavir with Ritonavir. The manufacturers of darunavir notes that the relative bioavailability of darunavir (with low-dose ritonavir) is 30% lower when it is given without food, compared with intake with food. Therefore, darunavir tablets should be taken with ritonavir and with food. They say that the type of food does not affect exposure to darunavir.

3. Lopinavir/Ritonavir. A moderate-fat meal increased the AUC and maximum level of lopinavir capsules by 48% and 23%, respectively, and a high-fat meal by 96% and 43%, respectively. The corresponding increases for lopinavir solution were 80% and 54% for the moderate-fat meal, and 130% and 56% for the high-fat meal. The manufacturers of lopinavir/ritonavir soft capsules and oral solution say that it should be taken with food. If no clinically significant difference was seen in the bioavailability of lopinavir/ritonavir tablets between fasting and fed subjects, therefore the manufacturers say that it can be taken with or without food. The manufacturers of nelfinavir note that administration with a high-fat meal or a light snack of toast and skimmed milk. A high-fat meal enhanced the AUC by 31%, but had minimal effect on peak plasma levels. The UK manufacturer states that food improves the tolerability of lopinavir/ritonavir. Both manufacturers recommend that lopinavir with ritonavir should be taken with food.

(c) Absorption minimally affected

1. Amprenavir. Food resulted in a 25% reduction in the AUC of amprenavir, but did not change the steady-state trough level. Consequently, the manufacturers say it can be given with or without food, but the US manufacturer notes that it can be given with a high-fat meal. The manufacturers of atazanavir note that administration with a light or high-fat meal decreased the wide variation in plasma levels. When given up to 15 minutes after a low-fat meal, the pharmacokinetics (derived from fosamprenavir) when compared with taking the formulation in the fasted state. Fosamprenavir tablets may be taken without regard to food intake. There is also some evidence that mixing ritonavir with enteral feeds does not affect ritonavir pharmacokinetics. A 600-mg dose of ritonavir oral solution was mixed with 240 mL of enteral feeds (either Adivera or Ensure, chocolate milk or water) within 1 hour of dosing. When given up to 15 minutes after a low-fat meal, the pharmacokinetics of ritonavir in either of the enteral feeds or the milk were almost identical to those when ritonavir was given in water.
A garlic supplement reduced the plasma levels of saquinavir by 50% in one study, but had little effect in another. Another garlic supplement did not significantly affect the pharmacokinetics of a single dose of ritonavir.

Clinical evidence

In a study in 9 healthy subjects garlic reduced the AUC, and maximum and minimum plasma levels of saquinavir by about 50%. The garlic was taken in the form of a dietary supplement (GarlicPure, Maximum Alliin Formul Formula caplets) twice daily for 20 days. Saquinavir 1.2 g three times daily was given for 4-day periods before, during, and after the garlic supplement. Fourteen days after the garlic supplement was stopped the saquinavir pharmacokinetics had still not returned to baseline values. Of the 9 subjects, 6 had a substantial drop in the AUC of saquinavir while taking garlic, then a rise when garlic was stopped. The remaining 3 had no change in the AUC of saquinavir while taking garlic, but had a drop when garlic was stopped. However, in another study, garlic extract (Garlipure) 1.2 g daily for 3 weeks had no significant effect on the pharmacokinetics of a single 1.2-g dose of saquinavir (a slight decrease in AUC in 7 subjects and a slight increase in 3). Gastrointestinal toxicity was noted in 2 patients taking garlic or garlic supplements when they started to take ritonavir-containing regimens. However, in a study in 10 healthy subjects the use of a garlic extract (10 mg, equivalent to 1 g of fresh garlic) twice daily for 4 days did not significantly affect the pharmacokinetics of a single 400 mg dose of ritonavir. There was a non-significant 17% decrease in the AUC of ritonavir. The garlic was given in the form of capsules (Natural Source Odourless Garlic Life Brand).

Mechanism

The mechanism of this interaction is uncertain, but it is thought that garlic reduced the bioavailability of saquinavir by increasing its metabolism in the intestine. Why there was a disparity in the effect of garlic on saquinavir between patients is unclear.

Importance and management

Although information is limited, a reduction in saquinavir plasma levels of the magnitude seen in the first study could diminish its antiviral efficacy. All garlic supplements should probably be avoided in those taking saquinavir as the sole protease inhibitor (no longer generally recommended). While the pharmacokinetic effect on single-dose ritonavir was not clinically important, this requires confirmation in a multiple-dose study.

Gastrointestinal toxicity was noted in 2 patients taking garlic or garlic supplements when they started to take ritonavir-containing regimens. However, in a study in 10 healthy subjects the use of a garlic extract (10 mg, equivalent to 1 g of fresh garlic) twice daily for 4 days did not significantly affect the pharmacokinetics of a single 400 mg dose of ritonavir. There was a non-significant 17% decrease in the AUC of ritonavir. The garlic was given in the form of capsules (Natural Source Odourless Garlic Life Brand).

Clinical evidence, mechanism, importance and management

(a) Amprenavir and Fosamprenavir

The manufacturer of fosamprenavir notes that taking amprenavir with grapefruit juice was not associated with clinically significant changes in plasma amprenavir pharmacokinetics. Note that fosamprenavir is metabolised to amprenavir in the gut.

(b) Indinavir

In a single-dose study in 10 healthy subjects grapefruit juice (8 oz, about 200 mL) reduced the AUC of indinavir 400 mg by 27%, although this was not considered clinically significant. Conversely, in another study in 13 healthy subjects, grapefruit juice or Seville orange juice (both about 200 mL) had no effect on the pharmacokinetics of indinavir. In this study indinavir 800 mg was given every 8 hours for 4 doses; with water, grapefruit juice, or Seville orange juice given with the last 2 doses. Similarly, in 15 HIV-positive subjects, grapefruit juice (about 150 mL of double strength) had no effect on the steady-state pharmacokinetics of indinavir (a non-significant 4.8% increase in AUC was seen).

(c) Saquinavir

In a study of the effects of the concurrent use of grapefruit juice 400 mL and saquinavir (Invirase; hard capsules) 600 mg, grapefruit juice was found to increase the AUC of saquinavir by 50%, possibly by affecting the cytochrome P450 isoenzyme CYP3A4 in the intestine. The manufacturer notes that the increase was 100% when double-strength grapefruit juice was used. The manufacturer says that these increases are unlikely to be clinically relevant, and no dosage adjustment is necessary. Various components of grapefruit juice have been shown to inhibit the metabolism of saquinavir in vitro.
Clinical evidence

(a) Azithromycin
1. Indinavir. A single 1.2-g dose of azithromycin had no effect on the pharmacokinetics of indinavir in healthy subjects who had taken indinavir 800 mg three times daily for 5 days.1
2. Nelfinavir. A single 1.2-g dose of azithromycin was given to 12 healthy subjects who had taken nelfinavir 750 mg every 8 hours for 8 days. The pharmacokinetics of nelfinavir were minimally affected, but the AUC and maximum serum levels of azithromycin were about doubled.2
3. Darunavir. The manufacturer notes that the concurrent use of clarithromycin 500 mg twice daily and darunavir/ritonavir 400/100 mg twice daily increased the AUC of clarithromycin by 57% and increased its minimum level by 174%. The active metabolite 14-hydroxyclarithromycin was not detectable. Darunavir levels were not significantly changed.3,4
4. Indinavir. In 11 healthy subjects clarithromycin 500 mg every 12 hours, given with indinavir 800 mg every 8 hours caused no clinically important alterations in the pharmacokinetics of indinavir (the only significant change was a 52% increase in the trough level). The AUC of clarithromycin was increased by about 50%, and that of 14-hydroxyclarithromycin reduced by about 50%, but neither of these changes were considered clinically important because of the wide safety margin of clarithromycin.5
5. Ritonavir. When ritonavir 200 mg every 8 hours was given with clarithromycin 500 mg every 12 hours there were only minimal changes in ritonavir pharmacokinetics (12.5% increase in AUC and 15.3% increase in maximum plasma level). However, the AUC of clarithromycin increased by 77% with an almost total inhibition of 14-hydroxyclarithromycin formation (99.7% decrease in AUC).6
6. Saquinavir. In a study in healthy subjects the concurrent use of saquinavir soft capsules (Fortovase) [no longer available] 1.2 g three times daily and clarithromycin 500 mg twice daily increased the AUC and maximum serum levels of saquinavir by 177% and 187%, respectively. The AUC and maximum serum levels of clarithromycin were about 40% higher than when it was given alone.7,10 The manufacturer notes that there are no data on the interaction using ritonavir-boosted saquinavir hard capsules or tablets (Invirase).8,10
7. Tipranavir. The manufacturer notes that tipranavir given with low-dose ritonavir increased the AUC and minimum levels of clarithromycin by 19% and 68%, respectively, and decreased the AUC of the 14-hydroxy active metabolite by over 95%. Clarithromycin more than doubled the minimum levels of tipranavir.11,12
(c) Erythromycin
The concurrent use of saquinavir soft capsules (Fortovase) [no longer available] 1.2 g three times daily and erythromycin 250 mg four times daily doubled the AUC and maximum serum levels of saquinavir in HIV-infected subjects.13 The manufacturer notes that there are no data on the interaction using ritonavir-boosted saquinavir hard capsules or tablets (Invirase).8

Mechanism
Ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and consequently markedly inhibits the 14-hydroxylation of clarithromycin by this isoenzyme. Other protease inhibitors would be expected to interact similarly, although to a lesser degree (see also ‘Antivirals’, (p.772)). Clarithromycin is a moderate to weak inhibitor of CYP3A4, and generally has only a small effect on the protease inhibitors, except for saquinavir. The effect of clarithromycin on saquinavir, and nelfinavir on azithromycin may involve inhibition of P-glycoprotein.14,15

Importance and management
The interaction of amprenavir or indinavir with clarithromycin does not appear to be clinically significant. Similarly, although large increases in saquinavir levels have been seen, the manufacturers say that for short courses no dosage adjustment is needed.1,9,10 However, with ritonavir, because the hepatic metabolism of clarithromycin is so strongly inhibited it becomes more dependent on renal clearance, therefore the interaction may be significant in patients with renal failure.8 The manufacturers of ritonavir and clarithromycin suggest that no dosage reductions should be needed in those with normal renal function, but they recommend a 50% reduction in the dose of clarithromycin for those with a creatinine clearance of 30 to 60 mL/minute and a 75% reduction for clearances of less than 30 mL/minute.14,15 Some advice avoiding clarithromycin in dosages exceeding 1 g daily.14,15 Similar clarithromycin dose reductions in renal impairment are recommended for ritonavir-boosted darunavir,16 and ritonavir-boosted tipranavir.11,12 Although there are no formal studies or specific dosage recommendations for other ritonavir-boosted protease inhibitors (fosamprenavir, lopinavir and saquinavir), similar precautions would seem prudent. Atazanavir also reduces the conversion of clarithromycin to its active metabolite, and is usually given with ritonavir. However, the UK manufacturer cautions that reducing the dose of clarithromycin to avoid high levels of the parent drug may result in subtherapeutic levels of the active metabolite. The US manufacturer says that, other than for Mycobacterium avium complex infections, an alternative to clarithromycin should be considered.19 If the combination is used they suggest a 50% dose reduction for the clarithromycin.

The increase in azithromycin levels with nelfinavir is likely to be of clinical significance,2 and, although the outcome is presumed to be positive, this has yet to be assessed in practice. If concurrent use is necessary, monitor for azithromycin adverse effects. Single doses of azithromycin did not affect the pharmacokinetics of nelfinavir or indinavir, and the manufacturers of a combination product of lopinavir/ritonavir do not expect a clinically significant interaction with azithromycin.20,21 Despite the increases in saquinavir levels, the UK manufacturer says that no dose adjustment is needed when saquinavir is given with erythromycin.22 The UK manufacturer of nelfinavir suggests that an interaction with erythromycin is unlikely, although it cannot be excluded.22 The UK manufacturer of ritonavir suggests that because erythromycin levels may rise, due to inhibition of its metabolism by ritonavir, care should be taken if both drugs are given.14 It would seem prudent to monitor for erythromycin adverse effects. A similar warning has been issued by the UK manufacturer of amprenavir about the use of erythromycin.23

Note that clarithromycin and erythromycin have been associated with QT prolongation, and rises in their levels may increase this risk. See ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Protease inhibitors + Mefloquine

Data from individual patients suggest there is no pharmacokinetic interaction between mefloquine and indinavir or nelfinavir. In pharmacokinetic studies in healthy subjects, ritonavir did not alter mefloquine pharmacokinetics, but mefloquine modestly decreased steady-state ritonavir levels.

Clinical evidence

Two HIV-positive patients using HAART, one taking indinavir 800 mg three times daily, the other taking nelfinavir 1.25 g twice daily were given mefloquine 250 mg weekly, before a trip to Africa. Mefloquine achieved therapeutic levels, and its half-life was similar to that found in healthy subjects. In addition, no consistent changes in the plasma levels of the protease inhibitors were found.1

In 12 healthy subjects ritonavir 200 mg twice daily for one week had no significant effect on the pharmacokinetics of mefloquine.2 Conversely, mefloquine (250 mg once daily for 3 days, then 250 mg weekly) significantly reduced the steady-state AUC, and maximum and minimum plasma levels of ritonavir 200 mg twice daily, by 31%, 36%, and 43%, respectively, but had no effect on the pharmacokinetics of single-dose ritonavir.2

Mechanism

Despite being inhibitors of the cytochrome P450 isoenzyme CYP3A4, the protease inhibitors do not appear to alter mefloquine pharmacokinetics.1,2 It was suggested that the decrease in ritonavir levels was due to decreased absorption, perhaps due to mefloquine-induced inhibition of bile acid production or induction of P-glycoprotein.2

Importance and management

The limited evidence suggests that protease inhibitors do not affect mefloquine pharmacokinetics. The data on the effect of mefloquine on ritonavir are less clear. Until further evidence is available, it may be prudent to closely monitor ritonavir levels/efficacy if mefloquine is required.

Protease inhibitors + Miscellaneous

Indinavir levels are raised by interleukin-2, but not affected by influenza vaccine or quinidine. Protease inhibitors are predicted to increase quinidine levels. Nelfinavir does not appear to interact with pancreatic enzyme supplements. In one case report, the combination of ritonavir/saquinavir and fusidic acid raised plasma levels of all three drugs.

Clinical evidence, mechanism, importance and management

(a) Fusidic acid

A 32-year-old HIV-positive man was admitted with suspected fusidic acid toxicity after taking fusidic acid 500 mg three times daily for one week, with his usual treatment of ritonavir 400 mg twice daily, saquinavir 400 mg twice daily and stavudine 40 mg twice daily. His plasma fusidic acid level was found to be twice the expected level, and his ritonavir and saquinavir levels were also elevated. He improved spontaneously, but 4 days later he returned with jaundice, nausea and vomiting. All medications were stopped, but after 6 days his fusidic acid level was still 1.3 times that expected, his saquinavir level was 16.3 micrograms/mL (expected range 1 to 4 micrograms/mL) and his ritonavir level was 43.4 micrograms/mL (expected range 4 to 12 micrograms/mL). He was later able to restart his antiretroviral without problem. It is possible that there was mutual inhibition of drug metabolism. The authors recommend avoiding this drug combination.1 Further study is needed.

(b) Influenza vaccine

Influenza whole virus vaccine was given to 9 patients taking indinavir containing HAART. No significant changes were found in indinavir pharmacokinetics.3

(c) Interleukins

In a pharmacokinetic study in 9 HIV-positive patients, the subjects continued taking their usual antiretrovirals and were given a 4-week course of indinavir 800 mg three times daily followed by 3 to 12 million-unit infusions of interleukin-2 daily for 5 days. The AUC of indinavir increased in 8 of the 9 subjects (average increase 88%). During this time interleukin-6 was also elevated, so it was thought that the increased indinavir concentrations were due to the inhibitory effects of interleukin-6 on the cytochrome P450 isoenzyme CYP3A4. Increased indinavir trough levels were also seen in a further 8 patients not participating in the pharmacokinetic study.3

(d) Pancreatic enzymes

Combined use of pancreatic enzymes (pancrelipase 20,000 USP units, amylase 65,000 USP units and protease 65,000 USP units) and nelfinavir 1.25 g twice daily for 14 days resulted in no significant changes in the pharmacokinetics of nelfinavir in 9 HIV-positive subjects.4

(e) Quinidine

Quinidine sulphate 200 mg was given to 10 healthy subjects, followed 1 hour later by a single 400-mg dose of indinavir. Quinidine had no clinically significant effects on the pharmacokinetics of indinavir.5 However, indinavir is predicted to increase quinidine levels, and the US manufacturer recommends caution and monitoring of quinidine levels.6

Lopinavir/ritonavir is also predicted to increase quinidine levels, and the combination should be monitored.7,8 Similarly, atazanavir/ritonavir, darunavir/ritonavir, amprenavir and fosamprenavir are predicted to increase quinidine levels, and the UK manufacturers contraindicate the combination.9,10 While the US manufacturers recommend monitoring quinidine concentrations,11,12,13 Conversely, for saquinavir/ritonavir, the UK manufacturer recommends caution and monitoring quinidine levels,15 and the US manufacturer contraindicates the combination.16 Both the UK and the US manufacturers contraindicate the use of quinidine with nelfinavir.17,18

ritonavir19,20 or tipranavir/ritonavir.21,22

Various dual combinations of protease inhibitors have been tried, or are used, to boost the levels and consequently the efficacy of one of the protease inhibitors. Ritonavir is the most potent at boosting levels of the other protease inhibitors, and current guidelines recommend the use of low-dose ritonavir in combination with atazanavir, darunavir, fosamprenavir, lopinavir, saquinavir, or tipranavir. Some protease inhibitor combinations may result in additional drug toxicity (indinavir and ritonavir or atazanavir).

Although this monograph summarises the pharmacokinetic interactions and dosing recommendations current guidelines should be consulted when choosing protease inhibitor combinations.

Clinical evidence

A. Amprenavir or Fosamprenavir

(a) Indinavir

The steady-state AUC of amprenavir was 33% higher when amprenavir 750 or 800 mg three times daily was given with indinavir 800 mg three times daily. In this study, the AUC of indinavir was 38% lower than historical control data. Similarly, in a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was reduced by 54% by indinavir. This agrees with in vitro data. It was suggested that the effect of amprenavir on indinavir was due to the lipid-like formulation of amprenavir reducing the absorption of indinavir (analogous to ‘food’, (p.818)). The changes in amprenavir levels were not considered to be clinically relevant.

• No dose adjustment of amprenavir or indinavir needed.
• The appropriate dose of fosamprenavir with indinavir is not established.

(b) Lopinavir/Ritonavir

Preliminary data suggest that the combination of amprenavir 600 mg twice daily with lopinavir/ritonavir 400/100 mg twice daily resulted in amprenavir trough plasma levels that were lower than with the combination of amprenavir/ritonavir at the same doses. Similarly the lopinavir levels were lower than those without amprenavir. Others have reported similar findings, and increasing the dose of ritonavir did not prevent a decrease in amprenavir levels with lopinavir. Similar findings were also reported for fosamprenavir with lopinavir/ritonavir, and further study showed that separation of doses reduced the effect of amprenavir on lopinavir/ritonavir levels, but increased the effect on amprenavir levels.

However, the manufacturer notes that combining lopinavir/ritonavir 400/100 mg with fosamprenavir/ritonavir 700/100 mg, both twice daily, increased the AUC and minimum level of lopinavir by 37% and 52%, respectively, whereas the AUC and minimum level of amprenavir were decreased by 63% and 65%, respectively. In addition, the US manufacturer says that the rate of adverse effects was higher with this combination.

• An optimum dosage for concurrent use has not been established. A dose increase of lopinavir/ritonavir oral solution to 533/133 mg twice daily (dose rounded to 6.5 mL) or 600/150 mg twice daily may be needed if amprenavir is given. Avoid once daily regimens.
• An optimum dosage for concurrent use has not been established. A dose increase of lopinavir/ritonavir tablets to 600/150 mg twice daily may be needed if fosamprenavir is given.

(c) Nelfinavir

The trough concentration of amprenavir 750 or 800 mg three times daily was increased by 189% by nelfinavir 750 mg three times daily, but the AUC and maximum level of amprenavir were not significantly altered. In this study, the pharmacokinetics of nelfinavir were not altered when compared with historical control data. In a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was reduced by about 40% by nelfinavir, which agrees with in vitro data. The increase in amprenavir trough concentration could result in improved antiviral efficacy, but further study is needed.

• No dose adjustment of either drug is needed when amprenavir is given with nelfinavir (UK).
• Appropriate dose of fosamprenavir with nelfinavir is not established.

(d) Ritonavir

The AUC, minimum, and maximum levels of amprenavir 1.2 g twice daily were increased by 131%, 484%, and 33%, respectively, by ritonavir 200 mg twice daily. This agrees with in vitro data. The manufacturer recommends that doses of both protease inhibitors be reduced when they are used together. Based on modelling of pharmacokinetic data, a dose of amprenavir 600 mg with ritonavir 100 mg, both twice daily, has been suggested. This combination has shown good clinical efficacy in at least one study, and resulted in satisfactory amprenavir levels when efavirenz was also used (see also ‘NNRTIs + Protease inhibitors’, p.785). Amprenavir levels with fosamprenavir/ritonavir 700/100 mg twice daily were similar to those achieved with amprenavir/ritonavir 600/100 mg twice daily.

• If ritonavir is given as a pharmacokinetic booster the recommended dose is fosamprenavir/ritonavir 600/100 mg twice daily.
• If ritonavir is given as a pharmacokinetic booster the recommended dose is fosamprenavir/ritonavir 700/100 mg twice daily.

(e) Saquinavir

The steady-state AUC of amprenavir was reduced by 32% when amprenavir 750 or 800 mg three times daily was given with saquinavir (soft gel capsule) 800 mg three times daily, and the maximum plasma level was reduced by 37%. In this study, the pharmacokinetics of saquinavir were not changed when compared with historical control data. In a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was not altered by saquinavir, which agrees with in vitro data. It was suggested that, as amprenavir was given with ‘food’, in the first study, this may have accounted for the reduced amprenavir levels.

• No dose adjustment of amprenavir or saquinavir is needed when they are given together.
• Appropriate dose of fosamprenavir with saquinavir not established.

(f) Tipranavir with Ritonavir

In a clinical study of dual-boosted protease inhibitor combination therapy in multiple-treatment experienced HIV-positive adults there was a 55% reduction in minimum amprenavir levels when tipranavir/ritonavir 500/200 mg twice daily was added to amprenavir/ritonavir 600/100 mg twice daily. Therefore the use of tipranavir/ritonavir with amprenavir/ritonavir is not recommended, as the clinical relevance of the reduction in amprenavir levels has not been established. If the combination is nevertheless considered necessary, a monitoring of the plasma levels of the protease inhibitors is strongly encouraged.

• Combination not recommended.

B. Atazanavir

(a) Darunavir with Ritonavir

The manufacturer notes that combining atazanavir 300 mg once daily with darunavir/ritonavir 400/100 mg twice daily did not significantly alter the AUC and minimum level of darunavir. In addition, the AUC and minimum level of atazanavir were not significantly changed, when compared with atazanavir/ritonavir 300/100 mg once daily alone, although the minimum level was increased by 52%.

• No dose change needed.

(b) Indinavir

There are no pharmacokinetic data on the combination of atazanavir plus indinavir, but it is predicted that there may be an additive risk of hyperbilirubinemia, so the combination is not recommended.

• Combination not recommended.

(c) Ritonavir

The addition of ritonavir 100 mg to atazanavir 300 mg increased the AUC of atazanavir about twofold, and the trough plasma level sevenfold, in healthy subjects. The effect on the trough level was less marked in patients (about a threefold increase). The manufacturer of atazanavir recom-
The addition of atazanavir 400 mg once daily to saquinavir soft capsules 1.2 g once daily increased the AUC of saquinavir about 5.5-fold, and the trough plasma level sevenfold. However, the manufacturer notes that a regimen including this combination did not provide adequate efficacy.

- Not an effective combination

### Indinavir

The manufacturer notes that combining indinavir 800 mg twice daily with darunavir/ritonavir 400/100 mg twice daily increased the AUC and minimum level of darunavir by 24% and 44%, respectively. In addition, the AUC and minimum level of indinavir were increased by 23% and 125%, respectively, when compared with indinavir/ritonavir 800/100 mg twice daily alone. When compared with saquinavir/ritonavir, no further increase of concentrations was noted. Lopinavir twice daily. When saquinavir 1.2 g twice daily was combined with lopinavir/ritonavir 400/100 mg twice daily, the increase in saquinavir AUC was about 30%, 6.6-fold increase in saquinavir AUC relative to saquinavir 1.2 g three times daily alone. Based on historical comparisons, lopinavir levels were similar to those seen without indinavir. 

- No dose change is usually needed. Decreasing the dose of indinavir to 600 mg twice daily may be necessary if the combination is poorly tolerated.

### Lopinavir/Ritonavir

The manufacturer notes that combining lopinavir/ritonavir 400/100 mg with darunavir/ritonavir 300/100 mg, both twice daily, increased the AUC and minimum level of lopinavir by 37% and 72%, respectively, whereas the AUC and minimum level of darunavir were decreased by 53% and 65%, respectively. When an additional 100 mg of ritonavir twice daily was added to the marketed combination, the AUC of lopinavir increased by 33% and the trough concentration by 51% while markedly reducing atazanavir exposure (AUC by 68%, and minimum level by 81%). Consequently, this combination is not recommended.

- Combination not recommended.

### Saquinavir

The manufacturer notes that combining saquinavir hard capsules 1 g twice daily with darunavir/ritonavir 400/100 mg twice daily decreased the AUC and minimum level of darunavir by 26% and 42%, respectively. The levels of saquinavir were not changed when compared with using saquinavir/ritonavir 1000/100 mg twice daily alone.

- Combination not recommended.

### Ritonavir

Ritonavir is used to increase the plasma levels of lopinavir. The marketed dose combination is lopinavir/ritonavir 400/100 mg twice daily. When an additional 100 mg of ritonavir twice daily was added to the marketed combination, the AUC of lopinavir increased by 33% and the trough concentration by 64%. The use of lopinavir with ritonavir as a pharmacokinetic enhancer is established. The dose of additional ritonavir is not established.

### Nelfinavir

The US manufacturer notes that the concurrent use of nelfinavir 1 g twice daily and lopinavir/ritonavir 400/100 mg twice daily resulted in similar nelfinavir pharmacokinetics to nelfinavir 1.25 g twice daily alone, but with markedly increased levels of the M8 metabolite of nelfinavir. Lopinavir levels were modestly reduced (27% decrease in AUC and 38% decrease in minimum level). 

- Dosage decrease of nelfinavir to 1 g twice daily recommended. Avoid once daily regimens. A dose increase of lopinavir/ritonavir oral solution to 533/153 mg twice daily or lopinavir/ritonavir tablets to 600/150 mg twice daily may be needed.

### Tipranavir with Ritonavir

In a clinical study of dual-boosted protease inhibitor combination therapy in multiple-treatment experienced HIV-positive adults there was a 70% reduction in minimum lopinavir levels when tipranavir/ritonavir 500/200 mg twice daily was added to lopinavir/ritonavir 400/100 mg,
twice daily. The clinical relevance of the reduction in lopinavir levels has not been established.

- Combination not recommended, but if it is given monitoring the plasma levels of the protease inhibitors is strongly encouraged.

E. Nelfinavir

(a) Ritonavir

Single-dose data indicate that ritonavir increases the AUC of nelfinavir by 1.8- to 2.5-fold, whereas the AUC of ritonavir is unchanged. In a multiple-dose study in healthy subjects, ritonavir 100 or 200 mg twice daily increased the steady-state AUC of nelfinavir 1.25 g twice daily by 20% and 39%, after morning and evening doses, respectively. The AUC of the M8 metabolite of nelfinavir was increased by 74% and 86%, respectively. There was no difference in the effect of the two doses of ritonavir on nelfinavir AUC. 37

- Appropriate dose of nelfinavir with ritonavir not established. 28

(b) Saquinavir

A single 1.2-g dose of saquinavir (soft gel capsules), given after 3 days of nelfinavir 750 mg every 8 hours had no effect on the pharmacokinetics of nelfinavir, but the nelfinavir caused a fourfold increase in the AUC of saquinavir. 38 Similar two- to twelfefold increases have been found in other studies in HIV-positive subjects. 39-42 A study in which 157 patients received 12 weeks of combined saquinavir/ritonavir treatment (doses unstated) found that the combination was well tolerated. 43 It appears that nelfinavir inhibits the hepatic clearance of saquinavir. 44

- Appropriate dose of nelfinavir with saquinavir not established. 28

F. Ritonavir

G. Saquinavir

A study in 6 patients with advanced HIV disease found that while taking saquinavir 600 mg three times daily the addition of ritonavir 300 mg twice daily increased the maximum saquinavir plasma levels 33-fold, and increased the AUC 58-fold at steady state. 45 A pilot study in HIV-positive patients given both drugs together (saquinavir 800 mg daily, ritonavir 400 to 600 mg daily) found that the ritonavir serum levels were unaffected. However, the saquinavir levels were substantially higher than those achieved with saquinavir alone in daily doses of 3.6 to 7.2 g. 46 A study of a range of ritonavir and saquinavir (Invirase) doses (200 to 600 mg) in 57 healthy subjects found that saquinavir did not affect ritonavir pharmacokinetics, but ritonavir increased the AUC of saquinavir 50 to 132-fold. The authors suggested that giving both drugs in the dosage 400 mg every 12 hours might be optimal. 47 Subsequent study has revealed that the effect of ritonavir on saquinavir is not related to the ritonavir dose in the range 100 to 400 mg twice daily, 48-50 and that the use of a combination with a higher dose of saquinavir and a lower dose of ritonavir may be preferable, as the lower doses of ritonavir are associated with fewer adverse effects. 48 A dose of saquinavir 1 g twice daily with ritonavir 100 mg twice daily is suggested by the manufacturer of saquinavir. 51,52 The UK manufacturer of ritonavir also says that doses of ritonavir higher than 100 mg twice daily should not be used in combination with saquinavir, 53 whereas the US manufacturer of ritonavir gives information solely on the saquinavir/ritonavir 400/400 or 600 mg twice daily regimen. 54 The UK manufacturer of ritonavir notes that higher doses of ritonavir have been associated with an increased incidence of adverse events. Concurrent use of saquinavir and ritonavir has led to severe adverse events, mainly diabetic ketoacidosis and liver disorders, especially in patients with pre-existing liver disease. 55

- When ritonavir is given as a pharmacokinetic booster the recommended dose is saquinavir/ritonavir 1000/100 mg twice daily. Higher ritonavir doses are associated with increased adverse effects. 53

Mechanism

Protease inhibitors are inhibitors and substrates of the cytochrome P450 isoenzyme CYP3A4, with ritonavir being the most potent inhibitor and saquinavir the least (see 'Antivirals', (p.772)). They probably interact by inhibiting each other’s gut (pre-absorption) and hepatic (post-absorption) metabolism, so resulting in increased absorption and decreased elimination. 44,45 A mechanism involving inhibition of P-glycoprotein may also be involved. 44

Importance and management

Ritonavir inhibits the metabolism of amprenavir (and amprenavir derived from fosamprenavir), atazanavir, darunavir, indinavir, lopinavir, nelfinavir, tipranavir, and especially saquinavir. Ritonavir is therefore used in combination with other protease inhibitors to boost their levels, and allow a reduction in the protease inhibitor dose and the frequency of dosing. In US guidelines, the combination of atazanavir with ritonavir, fosamprenavir with ritonavir or lopinavir with ritonavir are currently the protease inhibitors preferred as alternative options to efavirenz for use with dual NRTIs for the treatment of HIV-infection in treatment naïve patients. Ritonavir-boosted saquinavir is considered inferior to the preferred options. In UK guidelines, dual NRTIs plus a boosted protease inhibitor is recommended alternative option to dual NRTIs plus efavirenz. The preferred boosted protease inhibitors are lopinavir with ritonavir and fosamprenavir with ritonavir, with saquinavir plus ritonavir as an alternative regimen, and atazanavir plus ritonavir recommended for specific groups. The newer ritonavir-boosted protease inhibitors, darunavir and tipranavir are not currently recommended as initial therapy, and are used in extensively pre-treated patients with resistance to other protease inhibitors. The US guidelines state that ritonavir-boosted indinavir should be avoided because of a high incidence of nephrolithiasis, and that atazanavir plus indinavir should never be used because of potential additive hyperbilirubinaemia. When considering appropriate protease inhibitor combinations, in addition to pharmacokinetic interactions, cross resistance patterns and adverse effects should also be considered.

Protease inhibitors + Rifamycins

Rifabutin bioavailability is increased by amprenavir, atazanavir, fosamprenavir/ritonavir, indinavir, lopinavir/ritonavir, nelfinavir, tipranavir/ritonavir, and especially ritonavir, with an increased risk of toxicity. Rifabutin modestly decreases the bioavailability of indinavir, nelfinavir, and particularly saquinavir (with an increased risk of therapeutic failure), but has no effect on amprenavir, atazanavir, and ritonavir-boosted fosamprenavir. The combination of rifabutin with protease inhibitors may be used, but dosage adjustments of rifabutin or both drugs are often necessary.

Rifampicin (rifampin) bioavailability is increased by indinavir, but amprenavir has no effect. Rifampicin markedly reduces the bioavailability of amprenavir, atazanavir, fosamprenavir/ritonavir, indinavir, nelfinavir, ritonavir, lopinavir/ritonavir, and saquinavir; it especially reduces that of ritonavir. The effects of rifampicin on lopinavir/ritonavir and saquinavir/ritonavir can be overcome by increasing the protease inhibitor dose, which appears to increase adverse effects (hepatotoxicity).

Clinical evidence

(a) Amprenavir or Fosamprenavir

1. Rifabutin. When amprenavir 1.2 g twice daily was given with rifabutin 300 mg daily to 11 healthy subjects for 10 days there was an almost three-fold increase in the AUC of rifabutin, but the pharmacokinetics of amprenavir were not significantly altered. The combination was poorly tolerated, with 5 of 11 subjects stopping treatment between days 1 and 9 due to adverse events. When reduced doses of rifabutin (150 mg every other day) were given with fosamprenavir/ritonavir 700/100 mg twice daily the rifabutin AUC was unchanged and the maximum level was decreased by 14%, when compared with rifabutin 300 mg once daily given alone. However, the 25-O-desacetyl rifabutin AUC and maximum level were increased 11-fold and sixfold, respectively, which could potentially lead to a increase of rifabutin-related adverse events such as uveitis. Based on historical comparison, rifabutin did not appear to reduce amprenavir exposure from fosamprenavir/ritonavir.2,3

(b) Atazanavir

2. Rifabutin (Rifampin). When 11 healthy subjects were given amprenavir 1.2 g twice daily with rifampicin 600 mg daily for 4 days the pharmacokinetics of rifampicin were not affected, but the AUC of amprenavir was reduced by 82%. The maximum plasma level of amprenavir was also reduced by 70%, from 9.2 to 2.7 micrograms/ml.1 It is expected that concurrent use of fosamprenavir or fosaprenavir/ritonavir with rifampicin will also result in large decreases in plasma concentrations of amprenavir.2,3

(c) Darunavir

1. Rifabutin. The manufacturer notes that atazanavir 400 mg daily given with rifabutin 150 mg once daily for 14 days did not have any important effect on the AUC of atazanavir. However, the AUC of rifabutin 150 mg was 2.3-fold higher than historical data for a standard 300-mg dose.4

2. Rifampicin (Rifampin). When rifampicin 600 mg daily was given with atazanavir/ritonavir 300/100 mg once daily, the AUC and minimum levels of atazanavir were markedly reduced, by 72% and 98%, respectively.5

3. Darunavir

Although there are no data, the manufacturer predicts that rifabutin will decrease ritonavir-boosted darunavir levels, and that darunavir/ritonavir will increase rifabutin levels. They also predict that rifampicin will markedly reduce ritonavir-boosted darunavir levels.6,7

4. Indinavir

1. Indinavir. When 10 healthy subjects were given indinavir 800 mg every 8 hours for 10 days, the indinavir maximum serum levels and AUC were reduced by about three-fold, whereas the indinavir maximum serum levels and AUC were increased two-to
When the same dose of indinavir (800 mg every 8 hours) was given with half the dose of rifabutin (150 mg once daily), the AUC of indinavir was similarly reduced (by 32%), but the increase in the AUC of ritonavir was less (54%). In a further study, the pharmacokinetics of indinavir 1 g every 8 hours (increased dose) and rifabutin 150 mg daily (reduced dose) were investigated in healthy and HIV-positive subjects. The indinavir AUC was the same with this increased dose as with indinavir 800 mg every 8 hours alone. However, despite halving the rifabutin dose, the AUC was still up to 70% higher than with the 300-mg dose alone. When the combination was used in practice, there were no treatment failures in 25 patients being treated with rifabutin while receiving HAART (containing indinavir and/of nelfinavir). The rifabutin was given as 300 mg twice weekly and the indinavir dose was increased from 800 mg to 1.2 g every 8 hours to achieve satisfactory levels.

Rifampicin (Rifampin). A study in 11 AIDS patients given indinavir 800 mg every 8 hours and rifampicin 600 mg daily for 14 days found that the AUC of rifampicin was increased by 73%. In a similar study looking at the effects of the rifampicin on indinavir, the indinavir AUC and maximum serum levels were decreased by 92% and 86%, respectively. In another study, giving rifampicin 300 mg daily for 4 days to 6 HIV-positive patients already receiving ritonavir-boosted indinavir (indinavir/ritonavir 800/100 mg twice daily) decreased the median indinavir plasma levels (measured 12 hours after the last dose) by 87% and the median ritonavir levels by 94%.

Lopinavir

1. Rifabutin. When healthy subjects were given lopinavir/ritonavir 400/100 mg twice daily with rifabutin 150 or 300 mg daily for 10 days the AUC of rifabutin was increased threefold and the AUC of lopinavir was increased by 17%.

2. Rifampicin (Rifampin). Rifaxipicin 600 mg daily for 10 days decreased the AUC of lopinavir (given as lopinavir/ritonavir 400/100 mg twice daily) by 75% in a study in healthy subjects. A dose titration of rifabutin/ritonavir was carried out in healthy subjects to try and overcome the interaction with rifampicin. In 10 evaluable subjects, use of rifampicin 600 mg daily with lopinavir/ritonavir 800/200 mg twice daily decreased the minimum lopinavir level by 57% without affecting the maximum level, when compared with lopinavir/ritonavir 400/100 mg twice daily without rifampicin. In another 9 evaluable subjects, rifampicin 600 mg daily with lopinavir/ritonavir 400/400 mg twice daily did not alter the maximum or minimum level of lopinavir, but markedly increased ritonavir levels, when compared with lopinavir/ritonavir 400/100 mg twice daily without rifampicin. Of 29 subjects who received the adjusted doses of lopinavir/ritonavir with rifampicin, 9 subjects had grade 2 to 3 elevations in liver enzymes, and this was more common in the lopinavir/ritonavir 400/400 mg group than the lopinavir/ritonavir 800/200 mg group.

Nelfinavir

1. Rifabutin. When rifabutin 300 mg daily for 8 days was given with nelfinavir 750 mg every 8 hours for 7 to 8 days, the nelfinavir AUC was reduced by 32% and the rifabutin AUC was increased by 207%. When nelfinavir 750 mg every 8 hours was given with half the dose of rifabutin (150 mg daily), the nelfinavir AUC was reduced by a similar amount (23%), whereas the rifabutin AUC was increased by a lower amount (83%).

2. Rifampicin (Rifampin). Rifampicin 600 mg daily for 7 days decreased the AUC of nelfinavir 750 mg every 8 hours for 6 days by 82%. A 7-month-old infant with HIV and tuberculosis was given a rifampicin-based antimycobacterial regimen with nelfinavir-based HAART. Nelfinavir plasma levels were found to be very low, so rifabutin was added. This improved nelfinavir levels, and also greatly increased those of the principal active metabolite of nelfinavir. The regimen was well tolerated and had a good clinical response.

Ritonavir

1. Rifabutin. In a study in 5 healthy subjects when ritonavir 500 mg twice daily was given with rifabutin 150 mg daily for 8 days, the maximum serum level of rifabutin was increased threefold and the AUC was increased fourfold (and the AUC of its active metabolite, 25-O-desacytelyrifabutin, 35-fold). Seven subjects had to be withdrawn due to adverse events, primarily leucopenia. Retrospective analysis of regimens containing ritonavir found that the average serum level of rifabutin was associated with a higher incidence of rifabutin-related adverse effects including arthralgia, joint stiffness, uveitis and leucopenia.

*Formerly considered contraindicated (rifabutin levels markedly increased with risk of toxicity)*

Continued
Protease inhibitors + St John's wort (Hypericum perforatum)

St John's wort causes a marked reduction in the serum levels of indinavir, which may result in HIV treatment failure. Other protease inhibitors, whether used alone or boosted by ritonavir, are predicted to interact similarly.

Clinical evidence

In a single-drug pharmacokinetic study, 8 healthy subjects were given three 800-mg doses of indinavir on day 1 of 1 to achieve steady-state levels, and then an 800-mg dose on day 2. For the next 14 days they were given St John's wort extract 300 mg three times daily. Starting on day 16, the indinavir dosing was repeated. It was found that the St John's wort reduced the mean AUC of indinavir by 54% and decreased the 8-hour indinavir trough serum level by 81%.

Mechanism

Not fully understood, but it seems highly likely that St John's wort induces the activity of the cytochrome P450 isoenzyme CYP3A4, thereby increasing the metabolism of indinavir and therefore reducing its levels.

Importance and management

Direct information seems to be limited to this study, but the interaction would appear to be established. Such a large reduction in the serum levels of indinavir is likely to result in treatment failures and the development of viral resistance. Therefore St John's wort should be avoided. There seems to be no direct information about other protease inhibitors, but since they are also metabolised by CYP3A4 it is reasonable to expect that they will be similarly affected by St John's wort. The FDA in the US has suggested
that concurrent use of St John’s wort and protease inhibitors is not recommended.\(^2\) Similarly, the CSM in the UK has advised that patients taking protease inhibitors should avoid St John’s wort and that anyone already taking both should stop the St John’s wort and have their HIV RNA viral load measured.\(^3\) The manufacturers of indinavir give similar advice,\(^4,5\) and also note that protease inhibitor levels may increase on stopping St John’s wort, and the dose may need adjusting.\(^6\) They note the inducing effect may persist for up to 2 weeks after stopping treatment with St John’s wort.\(^4\) US and UK manufacturers of all protease inhibitors (amprenavir, atazanavir, darunavir, fosamprenavir, lopinavir/ritonavir, nelfinavir, saquinavir, tipranavir) either contraindicate or advise against the use of St John’s wort.

3. Committee on Safety of Medicines. Message from Professor A Breckenridge (Chairman of CSM) and Fact Sheet for Health Care Professionals, 29th February 2000.

### Protease inhibitors + Tenofovir

Atazanavir/ritonavir, darunavir/ritonavir and lopinavir/ritonavir modestly increased the levels of tenofovir, and there is at least one case report of nephrotoxicity with the combination of tenofovir, didanosine, and lopinavir/ritonavir.

**Saquinavir/ritonavir, tipranavir/ritonavir, and probably also fosamprenavir/ritonavir, have little effect on tenofovir levels.** Tenofovir modestly decreased atazanavir levels, and this was minimised when ritonavir was also given. Tenofovir had no important effect on ritonavir-boosted darunavir, lopinavir, and tipranavir levels, and modestly increased those of ritonavir-boosted saquinavir in one of two studies. Indinavir and nelfinavir do not interact pharmacokinetically with tenofovir.

#### Clinical evidence

**\(\text{Atazanavir} \text{/ ritonavir} \)**

The AUC of atazanavir was decreased by 25%, and the trough level by 40% when atazanavir 400 mg daily was given with tenofovir disoproxil fumarate 300 mg daily, and the AUC of tenofovir was increased by 24%.\(^1,3\) Similar results were seen when administration was separated by 12 hours.\(^3\) When atazanavir 300 mg once daily was given with ritonavir 100 mg once daily (as a pharmacokinetic booster), tenofovir disoproxil fumarate 300 mg once daily reduced the AUC of atazanavir by a similar amount (25%), but had less effect on the trough level (23% reduction), when compared with atazanavir/ritonavir alone.\(^4\) Similarly, the pharmacokinetics of atazanavir/ritonavir did not differ significantly between patients taking tenofovir and those not.\(^2\) Combined use increased the tenofovir AUC by 37% and the minimum level by 29%.\(^2,3\)

**\(\text{Darunavir with Ritonavir} \)**

The manufacturer notes that concurrent use of darunavir/ritonavir 300/100 mg twice daily with tenofovir disoproxil fumarate 300 mg once daily modestly increased the tenofovir AUC and minimum level by 22% and 37%, respectively. Darunavir levels were not significantly changed (minimum level increased by 24%).\(^6,7\)

**\(\text{Fosamprenavir with Ritonavir} \)**

The US manufacturer notes that, in a phase III clinical study plasma amprenavir trough levels (derived from fosamprenavir) were similar in subjects receiving tenofovir with fosamprenavir and ritonavir to those in subjects not receiving tenofovir.\(^4\) Similarly, in a pharmacokinetic study in healthy subjects, tenofovir disoproxil fumarate 300 mg once daily had no significant effect on the pharmacokinetics of amprenavir after fosamprenavir/ritonavir 1400/100 mg once daily or fosamprenavir/ritonavir 1400/200 mg once daily.\(^9\)

**\(\text{Indinavir} \)**

The manufacturer of tenofovir notes that there was no pharmacokinetic interaction between tenofovir disoproxil fumarate 300 mg once daily and indinavir 800 mg three times daily in healthy subjects.\(^1,6\)

(e) **Lopinavir/Ritonavir**

The concurrent use of lopinavir/ritonavir 400/100 mg twice daily and tenofovir resulted in a 30% increase in the AUC and a 50% increase in the trough level of tenofovir, but no change in the pharmacokinetics of lopinavir/ritonavir.\(^1,10\) There is one case report of Fanconi syndrome with nephrogenic diabetes insipidus, which developed in a patient taking lopinavir/ritonavir 800/200 mg daily, tenofovir disoproxil fumarate 300 mg daily, didanosine and lamivudine (for an interaction between tenofovir and didanosine, see ‘NRTIs’, (p.806)). The tenofovir level was 3.7-fold higher than expected and the didanosine level was eightfold higher than it had been before tenofovir was started. Lopinavir levels were unchanged.\(^11\)

(f) **Nelfinavir**

The manufacturer of tenofovir notes that there was no pharmacokinetic interaction between tenofovir disoproxil fumarate 300 mg once daily and nelfinavir 1.25 g twice daily in healthy subjects.\(^1,10\)

(g) **Saquinavir with Ritonavir**

Tenofovir disoproxil fumarate 300 mg once daily modestly increased the saquinavir AUC and minimum level by 29% and 47%, respectively, after administration of saquinavir/ritonavir 1000/100 mg twice daily in healthy subjects. The only change in tenofovir pharmacokinetics was a slight 23% increase in minimum level.\(^10,12\) In another study,\(^13\) mentioned by the manufacturer of saquinavir,\(^14,15\) in 18 HIV-positive patients treated with saquinavir/ritonavir 1000/100 mg twice daily and tenofovir disoproxil fumarate 300 mg once daily, saquinavir AUC and maximum values were just 1% and 7% lower, respectively, than those seen with saquinavir/ritonavir alone.

(h) **Tipranavir with Ritonavir**

Tipranavir/ritonavir 500/100 mg twice daily had no effect on the AUC and minimum level of a single 300-mg dose of tenofovir disoproxil fumarate, but it decreased the tenofovir maximum level by 23%. The tipranavir AUC and minimum level were decreased by 18% and 21%, respectively. With an increased dose of tipranavir/ritonavir 750/200 mg twice daily, the maximum level of tenofovir was reduced by 38% with no change in AUC or minimum level, and the decreases in tipranavir AUC and minimum levels were less (9% AUC and 12% minimum level).\(^16\)

#### Mechanism

It has been suggested that ritonavir increases tenofovir levels via its effect on drug transporter proteins in the renal tubuli.\(^6,11\)

#### Importance and management

The modest increase in tenofovir levels with ritonavir-boosted atazanavir, darunavir and lopinavir is of uncertain clinical relevance. However, it has been suggested that higher tenofovir levels could potentiate tenofovir-associated adverse events, including renal disorders.\(^2,3,17\) For this reason, the UK manufacturer of darunavir says that monitoring of renal function may be indicated when ritonavir-boosted darunavir is given in combination with tenofovir, particularly in patients with underlying systemic or renal disease, or in patients taking nephrotoxic drugs.\(^5\) The US manufacturer of lopinavir/ritonavir also recommends monitoring,\(^18\) and this seems a prudent precaution.

The decrease in atazanavir levels with tenofovir is not of clinical importance if ritonavir is also used, and this combination has been used successfully as part of antiretroviral therapy in clinical studies.\(^1,2\) Unboosted atazanavir should be used with caution\(^6\) or not given\(^1\) with tenofovir because of the potential for reduced efficacy and development of resistance. Ritonavir-boosted darunavir and lopinavir levels were not significantly affected by tenofovir, amprenavir levels were also unaffected following boosted fosamprenavir administration, and the increase in ritonavir-boosted saquinavir levels are not likely to be clinically relevant. The slight interaction between tenofovir and tipranavir/ritonavir is unlikely to be clinically relevant. There is no clinically relevant interaction between nelfinavir or indinavir and tenofovir.

Current UK guidelines give tenofovir as one of the preferred drugs as part of a dual NRTI regimen, to be used with either fosamprenavir/ritonavir or lopinavir/ritonavir, for the treatment of HIV infection in treatment regimens.
naive patients. They say that saquinavir/ritonavir is an alternative, and atazanavir/ritonavir may be used in specific groups. US guidelines are similar. They say that the effect on the trough level could represent a time-dependent effect rather than a drug interaction, since it also occurred in a control group. Further study. US guidelines are similar. Further study as a similar reduction in plasma levels after a similar indinavir regimen was thought to be a time-dependent effect, see ‘milch thistle’.

Further study as a similar reduction in plasma levels after a similar indinavir regimen was thought to be a time-dependent effect, see ‘milch thistle’.

Protease inhibitors; Indinavir + Goldenseal (Hydrastis)

Goldenseal root had no effect on the pharmacokinetics of a single dose of indinavir in one study.

Clinical evidence

In a study in 10 healthy subjects, the peak plasma level and oral clearance of indinavir after a single 800-mg dose was not changed by goldenseal root (Nature’s Way) 1.4 g twice daily for 2 weeks. In addition, there was no change in the indinavir half-life. Eight of the subjects had less than a 20% change in oral clearance, but one subject had a 46% increase and one had a 46% decrease.

Mechanism

Goldenseal (Hydrastis canadensis) was found to be an inhibitor of cytochrome P450 450 isoenzyme CYP3A4 in vitro. This was confirmed in a clinical study using oral midazolam as a probe substrate for CYP3A4, which found a decrease of about 40% in the metabolism of midazolam to hydroxymidazolam. Goldenseal root might therefore be expected to inhibit the metabolism of indinavir.

Importance and management

This study suggests that goldenseal root has no effect on indinavir levels, and may be used without any undue concern in patients on this protease inhibitor, although confirmation may be required in the light of the midazolam probe study, and the two subjects who experienced greater effects. The contrasting results from the indinavir study and the midazolam study might be explained by indinavir having a relatively high oral bioavailability compared with midazolam.

Further study as a similar reduction in plasma levels after a similar indinavir regimen was thought to be a time-dependent effect, see ‘milch thistle’.

Protease inhibitors; Indinavir + Milk thistle

Although some studies have found that milk thistle slightly lowers indinavir levels, it appears that this is a time-dependent effect rather than a drug interaction, since it also occurred in a control group in one study. The balance of evidence suggests that no important pharmacokinetic interaction occurs.

Clinical evidence

Milk thistle (Silybum marianum) 175 mg three times daily (Thisilyn; Nature’s Way, standardised for silymarin content) for 3 weeks caused a 9% reduction in the AUC of indinavir and a 25% reduction in its peak plasma level. Further doses of indinavir 800 mg every 8 hours, but only the value for the trough level reached statistical significance. The authors suggested that the effect on the trough level could represent a time-dependent effect of indinavir pharmacokinetics, since the plasma levels without milk thistle were found to be similarly lowered after a washout phase. In another similar study, in 10 healthy subjects, milk thistle standardised for silymarin 160 mg (General Nutrition Corp.) three times daily for 13 days and then with indinavir 800 mg every 8 hours for 4 doses did not cause any statistically significant changes in the indinavir pharmacokinetics (6% reduction in AUC and 32% reduction in minimum level). In yet another similar study, in 8 healthy subjects, milk thistle extract 456 mg, standardised for silymarins (Kare and Hope Ltd) three times daily for 28 days had no effect on the pharmacokinetics of a single dose of indinavir in one study.
no effect on the pharmacokinetics of indinavir 800 mg every 8 hours for four doses when compared with 6 subjects in a control group not receiving milk thistle extract. Both the control and indinavir group had a lower indinavir AUC after the second and third time of administration compared with the first, and this decline was greater in the control group. A meta-analysis of these 3 studies showed no effect of milk thistle on indinavir levels.

Mechanism

Based on animal data, milk thistle might be expected to increase indinavir levels by inhibiting its metabolism, or to have effects via P-glycoprotein.

Importance and management

The currently available data suggest that milk thistle extract does not have an effect on the pharmacokinetics of indinavir, although it is not totally conclusive. The reduction in indinavir levels appears to be just a time-dependent effect rather than an effect of the milk thistle, and further study is needed with longer exposure to indinavir than just four doses.

Protease inhibitors; Indinavir + Venlafaxine

In a single-dose study, venlafaxine lowered indinavir levels.

Clinical evidence, mechanism, importance and management

In a study, 9 healthy subjects were given a single dose of indinavir before and after 10 days of venlafaxine 150 mg daily in divided doses. Indinavir did not affect the pharmacokinetics of venlafaxine, but venlafaxine reduced the AUC and maximum plasma levels of indinavir by 28% and 36%, respectively. This is possibly enough to reduce the efficacy of indinavir. Quite why this happens is not clear. More study is needed to establish the effects of multiple doses. Until more is known it would seem prudent to monitor closely to ensure that the antiviral effects of indinavir are not compromised.

Protease inhibitors; Nelfinavir + Calcium

Calcium supplements do not affect the plasma levels of nelfinavir.

Clinical evidence, mechanism, importance and management

Calcium supplements had no effect on plasma levels of nelfinavir or its M8 metabolite in 15 patients receiving nelfinavir 1.25 g twice daily as part of a HAART regimen. Calcium was given as calcium carbonate 1350 mg twice daily to 9 patients, and calcium gluconate/calcium carbonate 2950/300 mg twice daily to 6 patients, both for 14 days. Plasma levels of nelfinavir were measured before a dose and 3 hours after a dose. Similar results were reported in another study. No nelfinavir dosage adjustments appear necessary if calcium supplements are given.

Ribavirin + Antacids

The manufacturers of ribavirin note that there was a minor 14% decrease in the AUC of ribavirin 600 mg when it was given with an antacid containing aluminium, magnesium, and simeticone, but this is not considered clinically relevant. No special precautions are needed.

Rimantadine + Aspirin or Paracetamol (Acetaminophen)

Both aspirin and paracetamol slightly reduce the levels of rimantadine, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Aspirin

In a study in healthy subjects, rimantadine 100 mg twice daily was given for 13 days. On day 11, aspirin 650 mg four times daily was started and continued for 8 days. The peak plasma levels and AUC of rimantadine were reduced by about 10% in the presence of aspirin. This reduction is unlikely to be clinically relevant.

(b) Paracetamol

In a study in healthy subjects, rimantadine 100 mg twice daily was given for 13 days. On day 11, paracetamol 650 mg four times daily was started and continued for 8 days. The peak plasma levels and AUC of rimantadine were reduced by about 11% in the presence of paracetamol. This reduction is unlikely to be clinically relevant.

Rimantadine + Cimetidine

Cimetidine causes a small but probably clinicunimportant rise in the plasma levels of rimantadine.

Clinical evidence, mechanism, importance and management

In 23 healthy subjects the AUC of a single 100-mg dose of rimantadine was increased by 20% and the apparent total clearance reduced by 18% when it was taken one hour after the first dose of cimetidine 300 mg four times daily for 6 days. The authors of the study suggest that these changes are likely to have little, if any, clinical consequences. The effects of multiple dose concurrent use are not known.

Telbivudine + Miscellaneous

There appears to be no pharmacokinetic interaction between telbivudine and adefovir, ciclosporin or lamivudine. Peginterferon-alfa 2a and food do not alter telbivudine pharmacokinetics. No interactions mediated by the cytochrome P450 isoenzymes are predicted for telbivudine.

Clinical evidence, mechanism, importance and management

(a) Adefovir

In a study in healthy subjects the concurrent use of telbivudine 600 mg daily and adefovir 10 mg daily for 7 days did not alter the pharmacokinetics of either drug, when compared to their use alone. No dosage adjustments of either drug are anticipated to be needed if they are used together.

(b) Ciclosporin

The manufacturer notes that there was no pharmacokinetic interaction between ciclosporin and telbivudine.
In a study in healthy subjects, when a single 600-mg dose of telbivudine was given immediately after a high-fat/high-calorie meal there was no effect on the pharmacokinetics of telbivudine, when compared with the fasting state. Telbivudine may be taken with or without food.

The manufacturer notes that peginterferon-alfa 2a did not alter the pharmacokinetics of telbivudine. However, no conclusion could be made about the effect of telbivudine on peginterferon-alfa 2a because of high interindividual variability in its levels.

In a study in healthy subjects, when telbivudine 200 mg daily and lamivudine 100 mg daily were given concurrently for 7 days the pharmacokinetics of both drugs were unchanged. No dosage adjustments of either drug are anticipated to be needed if they are used together.

Furthermore, in vitro studies suggest that telbivudine does not inhibit any of the cytochrome P450 isoenzymes commonly responsible for drug metabolism, and is therefore unlikely to interact with drugs that are substrates for these isoenzymes.

The manufacturer notes that telbivudine is not metabolised and is principally excreted by the kidneys. It is therefore unlikely to be affected by drugs that induce or inhibit cytochrome P450 isoenzymes.2

Tenofovir absorption is increased by high-fat food. Caution is recommended with drugs causing renal toxicity. Tenofovir did not alter the pharmacokinetics of ribavirin, and there was no clinically significant pharmacokinetic interaction with rifampicin (rifampin).

**Clinical evidence, mechanism, importance and management**

(a) Cidofovir

Tenofovir is actively secreted by human organic anion transporter 1 (hOAT1) in the kidneys. Therefore, the manufacturers suggest that if it is given with other drugs that are also secreted by this renal transporter, such as cidofovir, increased levels of tenofovir or the other drug could result. In the UK, they specifically recommend that tenofovir and cidofovir are not given together, unless clearly necessary, when renal function should be monitored weekly.

(b) Food

Administration of tenofovir with a high-fat meal increased its AUC by about 40%, and its maximum level by about 14%, when compared with the fasted state, whereas administration with a light meal had no effect. The UK manufacturer recommends that tenofovir is taken with food, whereas the US manufacturer says that it can be taken without regard to food.

(c) Other nephrotoxic drugs

Tenofovir has the potential to cause nephrotoxicity, and the manufacturer recommends monthly monitoring of renal function. Although the concurrent administration of other nephrotoxic drugs has not been studied, the manufacturer suggests that renal function should be monitored more frequently (weekly) if concurrent use is unavoidable. They specifically name aminoglycosides, amphotericin B, cidofovir (see above), foscarnet, ganciclovir, interleukin-2, pentamidine and vancomycin.

(d) Ribavirin

Tenofovir disoproxil fumarate 300 mg daily did not alter the pharmacokinetics of a single 600-mg dose of ribavirin in 22 subjects, and the pharmacokinetics of tenofovir did not appear to be changed by ribavirin when compared with historical data. Note that, there is evidence that HIV-positive patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis and hepatic decompensation when receiving any ‘NRTI’, (p.805), including tenofovir, and increased monitoring is recommended.

(e) Rifampicin (Rifampin)

In 23 subjects when rifampicin 600 mg once daily was given with tenofovir disoproxil fumarate 300 mg once daily the pharmacokinetics of both drugs were not significantly changed (tenofovir compared with historical data). One subject who was withdrawn from the study had raised liver enzyme values.

There is some evidence to suggest that if allopurinol and vidarabine (adenine arabinoside) are given together the toxicity of vidarabine may be increased.

**Clinical evidence**

Two patients with chronic lymphocytic leukaemia taking allopurinol 300 mg daily developed severe neurotoxicity (coarse rhythmic tremors of the extremities and facial muscles, and impaired mental function) 4 days after vidarabine was added for the treatment of viral infections. A retrospective search to find other patients who had taken both drugs for 4 days revealed a total of 17 patients, 5 of whom had experienced adverse reactions including tremors, nausea, pain, itching and anaemia. Another possible case of neurological toxicity has also been reported.

**Mechanism**

Uncertain. One suggestion is that the allopurinol causes hypoxanthine arabinoside, the major metabolite of vidarabine, to accumulate by inhibiting xanthine oxidase. A study with rat liver cytosol found that allopurinol greatly increased the half-life of this metabolite.

**Importance and management**

Information seems to be limited to these reports, and so the general clinical importance of this possible interaction is uncertain, but it would be prudent to exercise particular care if these drugs are used together.

The adrenoceptors of the sympathetic nervous system are of two main types, namely alpha and beta. Drugs that block the beta adrenoceptors (better known as the beta blockers) are therapeutically exploited to reduce, for example, the normal sympathetic stimulation of the heart. The activity of the heart in response to stress and exercise is reduced, its consumption of oxygen is diminished, and in this way exercise-induced angina can be managed. Beta blockers given orally can also be used in the management of cardiac arrhythmias, hypertension, myocardial infarction, and heart failure. They may also be used for some symptoms of anxiety and for migraine prophylaxis. Some beta blockers are used in the form of eye drops for glaucoma and ocular hypertension.

Not all beta receptors are identical but can be further subdivided into two groups, beta_1 and beta_2. The former are found in the heart and the latter in the bronchi. Since one of the unwanted adverse effects of generalised beta blockade can be the loss of the normal noradrenaline-stimulated bronchodilation (leading to bronchospasm), cardioselective beta_1-blocking drugs (e.g. atenolol, metoprolol) were developed, which have less effect on beta_2 receptors. However, it should be emphasised that the selectivity is not absolute because bronchospasm can still occur with these drugs, particularly at high doses. ‘Table 22.1’, (below) includes an indication of the cardioselectivity of commonly used systemic beta blockers. Some beta blockers also have alpha_1-blocking activity, which causes vasodilatation, and this is also indicated in ‘Table 22.1’, (below). Some beta blockers, such as celiprolol and nebivolol, also have vasodilator activity but produce this by mechanisms other than blocking alpha_1 receptors. Other beta blockers also possess intrinsic sympathomimetic activity in that they can activate beta receptors and are therefore partial agonists. Sotalol has additional class III antiarrhythmic activity, and therefore it has a range of interactions not shared by most other beta blockers.

Beta blockers may be lipophilic drugs (such as metoprolol) or hydrophilic (such as atenolol). The lipophilic beta blockers are more likely to be involved in pharmacokinetic interactions than the hydrophilic drugs. Many of the lipophilic beta blockers are principally metabolised by the cytochrome P450 isoenzyme CYP2D6 (see ‘Table 22.1’, (below)), and drugs that are inhibitors or inducers of this isoenzyme (see ‘Table 1.3’, (p.6)) increase or decrease their levels. Propranolol is also metabolised in part by CYP1A2 (see ‘Beta blockers + SSRIs’, p.855).

Beta blockers may also be involved in pharmacodynamic interactions with other drugs that are based on enhancement or antagonism of pharmacological effects (such as additive blood pressure reduction).

This section is generally concerned with those drugs that affect the activity of the beta blockers. Where the beta blocker is the affecting drug, the interaction is dealt with elsewhere.

</table>

ISA*: Intrinsic sympathomimetic activity (partial agonists)
Some antacids and antiarrhythmics may cause a modest reduction in the absorption of atenolol, indenol, propranolol, or sotalol, and possibly a slight increase in the absorption of metoprolol. However, the clinical importance of these interactions is probably minimal.

**Clinical evidence**

(a) Atenolol

**Aluminium hydroxide** 5.6 g given to 6 healthy subjects caused an insignificant 20% fall in the plasma levels of a single 100-mg dose of atenolol, which had no effect on the atenolol-induced reduction in exercising heart rate. Similarly, **aluminium hydroxide** had no significant effect on atenolol pharmacokinetics when both drugs were given together for 6 days. Conversely, in 6 healthy subjects a single 500-mg dose of calcium (as the lactate, gluconate and carbonate) caused a 51% reduction in the peak plasma level of the sotalol was reduced by 26% and its AUC was reduced by 21%. Changes in heart rates reflected these pharmacokinetic changes. A study in patients found that the pharmacokinetic changes seen with single doses of **aluminium** or calcium-containing antacids were not clinically significant. However, there was a trend for any changes during concurrent use. Separating the dosages by 2 hours was shown to avoid the interaction in one study, and would seem a simple way of avoiding problems should they occur.

(b) Indenol

A study in rats found that when indenol was given with either Simeco (aluminium/magnesium hydroxide with simeticone) or Kapectate (kaolin-pectin), the AUC was reduced by 15% and 30%, respectively.

(c) Metoprolol

In 6 healthy subjects, 30 mL of Novaluc forte (an aluminium/magnesium-containing antacid) increased the peak plasma level and AUC of a single 100-mg dose of metoprolol by 37% and 33%, respectively, which was considered to be of possible significance in some patients.

(d) Propranolol

**Aluminium hydroxide gel** 30 mL did not affect the plasma level of a single 40-mg dose of propranolol in 6 healthy subjects: the reduction in exercise heart rate was also unaffected. In contrast, a study in 5 healthy subjects found that 30 mL of an **aluminium hydroxide gel** reduced the levels and AUC of a single 80-mg dose of propranolol by almost 60%. In vitro and animal data suggest that bismuth subsalicylate, kaolin-pectin and magnesium trisilicate can also reduce the absorption of propranolol.

(e) Sotalol

A study in 5 healthy subjects found that single doses of **aluminium hydroxide suspension** (Neutregel) or calcium carbonate suspension, given after an overnight fast, had negligible effects on the pharmacokinetics of a single 160-mg dose of sotalol. In contrast, a single dose of **magnesium hydroxide** slightly reduced the AUC of sotalol by 16%. A further study in 6 healthy subjects found that when 20 mL of Maalox (aluminium/magnesium hydroxide) was given at the same time as 160 mg of sotalol, the maximum plasma level of the sotalol was reduced by 26% and its AUC was reduced by 21%. Changes in heart rates reflected these pharmacokinetic changes. No interaction occurred when the Maalox was given 2 hours after the sotalol.

**Mechanism**

Uncertain. The reduction in absorption could possibly be related to a delay in gastric emptying caused by the antacid, delayed dissolution due to an increase in gastric pH, or to the formation of a complex of the two drugs in the gut, which reduces absorption. However, one in vitro study indicated that sotalol was only subject to minor absorption or complexation interactions. Another study found that 35 to 40% of sotalol was bound by magnesium hydroxide, but this may be reversible under physiological conditions and therefore unlikely to be relevant during long-term clinical use.

**Importance and management**

The documentation is limited, in some instances somewhat contradictory, and largely confined to animal or single-dose studies, which may not be clinically relevant. Some changes in absorption may possibly occur but no study seems to have shown that there is a significant effect on the therapeutic effectiveness of the beta blockers. The one study using atenolol in patients found that the pharmacokinetic changes seen with single doses of **aluminium** or calcium-containing antacids were not clinically significant. However, there was a trend for any changes during concurrent use. Separating the dosages by 2 hours was shown to avoid the interaction in one study, and would seem a simple way of avoiding problems should they occur.

pranlolar 20 mg twice daily, recovering from surgery during which acluromycin had been used, received glycopyrronium and neostigmine without any change in heart rate. However, one hour later he developed severe bradycardia (a fall from 65 to 40 bpm) and hypotension (systolic blood pressure 70 mmHg) when given intravenous physostigmine 2 mg over 5 minutes, for extreme drowsiness attributed to the premedication. His symptoms responded to glycopyrronium. Prolonged bradycardia and hypotension, requiring isoprenaline then adrenaline (epinephrine), were seen in an elderly woman taking atenolol 50 mg daily and nitrates when she was given neostigmine and atropine for the reversal of muscle relaxation at the end of general anaesthesia. Another report similarly describes bradycardia in a patient taking propranolol when intravenous neostigmine was used to reverse pancuronium-induced blockade. This responded to atropine.

However, a study in 8 hypertensive patients taking long-term atenolol or propranolol found no significant changes in heart rate and no serious adverse reactions when they were given low-dose oral pyridostigmine 30 mg three times daily for 2 days.10

Mechanism

It would appear that the bradycardic effects of the beta blockers and the acetylcholine-like effects of these anticholinesterase drugs can be additive. These were inadequately controlled by the use of atropine in some of the instances cited. The myasthenic symptoms may be due to beta blockers exerting a depressant effect on the neuromuscular junction.45

Importance and management

The information available indicates that marked adverse reactions between beta blockers and anticholinesterases after surgery are uncommon, but be aware of the possibility of an interaction if a patient becomes bradycardic or hypotensive shortly after surgery.

Limited information suggests that beta blockers given orally or topically could oppose the efficacy of anticholinesterases in the treatment of myasthenia gravis. However, one study suggests that, in cardiovascular emergencies, propranolol may be given to patients with myasthenia gravis, provided that resuscitation equipment and specific antidotes are available.5 Strictly speaking this is a drug-disease rather than a drug-drug interaction.

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, although some studies have not found the increase to be clinically relevant. In various small studies, indomethacin reduced the antihypertensive effects of the beta blockers. There is some evidence that piroxicam usually interacts similarly. Ibuprofen and naproxen have reduced the effect of beta blockers in some small studies but not others. Two isolated cases of hypertension have been reported with naproxen and ibuprofen in patients treated with propranolol and pindolol, respectively. Celecoxib, but not rofecoxib, inhibits the metabolism of metoprolol. Limited information suggests that normally di-

clofenac, imidazole salicylate, oxaprozin, tenoxicam and probably sulindac do not interact.

Multiple-dose aspirin, both in high and low dose, did not reduce the efficacy of antihypertensives including beta blockers in three studies, but one study using single, high doses showed antagonism of the effect of intravenous beta blockers. Another study suggested aspirin may attenuate the benefit of carvedilol in heart failure.

Clinical evidence

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, and the findings of these are summarised in ‘Table 23.2’, (p.862). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both COX-2 inhibitors and non-selective NSAIDs. In two meta-analyses,12 the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between indomethacin and sulindac in one analysis.1 Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,1 the effect was greatest for piroxicam, indomethacin, and ibuprofen, intermediate for naproxen, and least for sulindac and flurbiprofen. In the other meta-analysis,2 the effect was greatest for indomethacin and naproxen, intermediate for piroxicam, and least for ibuprofen and sulindac. An attempt was also made to evaluate the effect by antihypertensive in one analysis.1 The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual clinical and pharmacological studies that have studied the effects of aspirin or specific NSAIDs on beta blockers are outlined in the subsections below.

(a) Aspirin and other salicylates

A small study in patients taking various antihypertensives (including beta blockers and diuretics) found that aspirin, in both low doses (650 mg daily) and high doses (3.9 g daily) for 3 or 4 weeks, did not cause clinically significant increases in blood pressure.3 Similarly, a study in 11 patients taking a number of antihypertensives (which included a few patients taking propranolol or pindolol) found that aspirin 650 mg three times daily for 7 days did not affect the control of blood pressure.4 In contrast, another study found that 5 g of aspirin given over 24 hours prevented the antihypertensive effect of a single 1-mg intravenous dose of pindolol, and a single 1- to 1.5-g dose of aspirin reduced the antihypertensive effect of a single 5-mg intravenous dose of propranolol.5 Aspirin was reported not to affect the control of hypertension by metipranol.6 A retrospective study of patients with heart failure taking carvedilol found that aspirin did not significantly affect systolic blood pressure or heart rate but did observe that left ventricular ejection fraction improved less in those patients taking aspirin in addition to carvedilol. The effect appeared to be dose-related.7

A single-dose study in 6 healthy subjects found that aspirin 500 mg did not affect the pharmacokinetics of atenolol.8 Another study in 6 healthy subjects found that aspirin did not affect the pharmacokinetics of metoprolol, but the maximum plasma levels of aspirin were increased by metoprolol, although this was not considered to be clinically relevant.9

Sodium salicylate did not affect either the pharmacokinetics of alpenolol or its effects on heart rate and blood pressure during exercise in a single-dose study in healthy subjects.10 Imidazole salicylate did not affect the blood pressure control of patients treated with atenolol.11

(b) Celecoxib or Rofecoxib

In an open, randomised crossover study in 12 healthy subjects, celecoxib 200 mg twice daily for 7 days increased the AUC of a single 50-mg dose of metoprolol by 64%. In contrast, rofecoxib 25 mg daily for 7 days did not significantly affect the pharmacokinetics of metoprolol.

(c) Diclofenac

A study in 16 patients taking atenolol, metoprolol, propranolol or pindolol and/or a diuretic found that diclofenac 50 mg three times daily had no effect on the control of blood pressure.12
(d) Flurbiprofen

A study in 10 patients with hypertension found that flurbiprofen 100 mg daily for 7 days did not affect the pharmacokinetics of single-doses of either propranolol 80 mg or atenolol 100 mg. However, the hypertensive effects of propranolol but not atenolol were reduced by the flurbiprofen.13

(e) Ibuprofen

In a randomised study, ibuprofen 400 mg every 8 hours caused significant increases in blood pressure (mean increases of about 5 to 7 mmHg) in 6 hypertensive patients treated with thiazides and beta blockers.14 The anti-hypertensive effect of pindolol was antagonised by ibuprofen in one patient.15 However, ibuprofen 400 mg four times daily had no effect on the control of blood pressure in patients taking propranolol in one randomised controlled study.16

(f) Indomethacin

A study found that when indomethacin 25 mg three times daily was given to hypertensive patients taking thiazides with or without beta blockers, their blood pressure increased by 8 to 10 mmHg. The diastolic blood pressures of 7 hypertensive patients treated with pindolol 15 mg daily or propranolol 80 to 160 mg daily rose from 82 to 96 mmHg when they were given indomethacin 100 mg daily over a 10-day period. Changes in systolic pressures were not statistically significant.17

In another study, indomethacin 50 mg twice daily raised the systolic/diastolic blood pressures of patients taking propranolol 60 to 320 mg daily by 14/5 mmHg when lying and 16/9 mmHg when standing.18 This interaction has also been seen in other studies in patients taking atenolol, labetalol, metoprolol, propranolol, and pindolol.21 Two women with pre-eclampsia taking propranolol or pindolol became markedly hypertensive (risks in blood pressure from 135/85 to 240/140 mmHg, and from 130/70 to 230/130 mmHg, respectively) within 4 to 5 days of being given indomethacin to inhibit premature contractions.25

(g) Naproxen

A study in hypertensive patients taking timolol and hydrochlorothiazide with amiloride found that naproxen 250 mg twice daily caused a significant 4 mmHg rise in diastolic blood pressure, but did not significantly increase systolic blood pressure.26 Similarly, in another study, naproxen 500 mg twice daily caused an average 4 mmHg rise in systolic blood pressure in patients taking atenolol, but did not significantly increase diastolic blood pressure.27 In contrast, another study found that naproxen caused no changes in hypertension controlled with propranolol,28 and a study in patients taking antihypertensives [drugs not specified] found that naproxen did not cause clinically significant increases in blood pressure.3 A case report describes one patient taking propranolol who had a marked rise in blood pressure when given naproxen.29

(h) Oxpazin

A study in 32 hypertensive arthritic patients found that oxaprazin 1.2 g daily for 4 weeks did not affect the antihypertensive effects of metoprolol 100 mg twice daily, although at 2 weeks there was a significant increase in systolic blood pressure.30

(i) Piroxicam

A double-blind study found that about one-quarter of the patients given piroxicam 20 mg daily and propranolol 80 to 160 mg daily developed diastolic pressure rises of 10 mmHg or more when lying or standing.31,32 Increases in both systolic and diastolic pressures (8.1/5.2 mmHg lying and 8.5/8.9 mmHg standing) were seen in another study in 3 patients.33 In contrast, patients taking propranolol and piroxicam 20 mg daily had blood pressure rises of 5.8/2.4 mmHg when lying and 3.5/0.5 mmHg when standing, after 2 weeks, but these increases were not statistically significant.34 Blood pressure showed a trend towards higher levels in another study in 20 patients given timolol and piroxicam 20 mg daily.35

A study in 6 healthy subjects given atenolol 100 mg daily and piroxicam 20 mg daily for 7 days found no pharmacokinetic interaction. An associated study in another 6 healthy subjects given metoprolol 100 mg twice daily and piroxicam 20 mg daily for 7 days found that metoprolol levels were increased by piroxicam, but not to a statistically significant extent.35

(j) Sulindac

Sulindac 200 mg twice daily had little or no effect on the control of hyper tension in patients taking hydrochlorothiazide with amiloride and atenolol, metoprolol, propranolol or pindolol.12 In another study, diastolic blood pressure was slightly and significantly lower when sulindac was given with timolol.26 No statistically significant rises in blood pressure occurred in other studies in patients taking propranolol or atenolol or unspecified antihypertensives9 given sulindac 200 mg twice daily. In contrast, another study claimed that patients given propranolol with sulindac 200 mg twice daily had blood pressure rises of 10.3/4.8 mmHg when standing and 2.4/7.1 mmHg when lying, after 2 weeks, but only the increase in standing systolic blood pressure statistically significant.34 Similarly, a crossover study in 26 hypertensive patients taking labetalol found that sulindac 200 mg twice daily for 7 days raised the mean systolic blood pressure by 6 mmHg when sitting, and by 9 to 14 mmHg when standing, which was considered potentially clinically significant. Diastolic pressures were not affected.21

(k) Tenoxicam

The control of hypertension in 16 patients taking atenolol was found not to be affected by tenoxicam 40 mg daily.36

Mechanism

Indomethacin alone can raise blood pressure (13 hypertensive patients given indomethacin 150 mg daily for 3 days had a mean systolic blood pressure rise from 118 to 131 mmHg).37 One suggested reason is that indomethacin inhibits the synthesis and release of two prostaglandins (PGA and PGE), which have a potent dilating effect on peripheral arterioles throughout the body. In their absence the blood pressure rises. Thus the hypertensive actions of the beta blockers are opposed by the hypertensive actions of indomethacin. This mechanism has been questioned and it is possible that other physiological and pharmacological mechanisms have a part to play.3,38,39 One study found that although indometacin caused increases in blood pressure in treated hypertensive patients, other inhibitors of prostaglandin synthesis (aspirin, naproxen and sulindac) did not.4 Further, all four drugs caused similar reductions in plasma renin activity and aldosterone concentration, which suggests that the effect of indometacin on blood pressure may not be dependent on such changes.3

Celecoxib, but not rofecoxib, inhibits the metabolism of metoprolol by the cytochrome P450 isoenzyme CYP2D6.40

Importance and management

Overall, the evidence suggests that some patients treated with beta blockers can show a rise in blood pressure when given NSAIDs, but this may not always be clinically relevant. Some consider that the use of NSAIDs should be kept to a minimum in patients on antihypertensives.41 The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with high salt intake.42 However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.43 While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.44 There is insufficient data at present to clearly differentiate between NSAIDs, although there is some evidence that the effects of indometacin are greater and sulindac least. Further study is needed.

For the effects of NSAIDs on other antihypertensive drug classes see ‘ACE inhibitors’, (p.28), ‘calcium-channel blockers’, (p.861) and ‘thiazide diuretics’, (p.956).

A few multiple-dose studies have not found aspirin to alter the antihypertensive effect of beta blockers, even in high doses, but one single-dose high-dose study reported an interaction. Another study suggested that aspirin might ameliorate the benefit of carvedilol in heart failure, but the evidence is currently too slim to warrant a change in practice.

Although celecoxib increased levels of metoprolol, increases in plasma metoprolol levels of this size are unlikely to be clinically relevant.1

The plasma levels and the effects of beta blockers that are mainly metabolised by the liver (e.g. alprenolol, metoprolol, timolol) are reduced by the barbiturates. Alprenolol concentrations are halved, but the other beta blockers are possibly not affected as much. Beta blockers that are mainly excreted unchanged in the urine (e.g. atenolol, sotalol, nadolol) would not be expected to be affected by the barbiturates.

**Mechanism**

Barbiturates are potent liver enzyme inducers that can increase the metabolism and clearance of other drugs from the body. Beta blockers that are removed from the body principally by liver metabolism (e.g. alprenolol, metoprolol, timolol) can therefore possibly be cleared more quickly in the presence of a barbiturate.

**Importance and management**

The interaction between alprenolol and pentobarbital is well documented and likely to be of modest clinical importance when the beta blocker is being used to treat hypertension, and possibly angina. Monitor the effects of alprenolol and increase the dose as necessary. Where possible it may be preferable to replace the barbiturate with a non-interacting alternative, such as one of the ‘benzodiazepines’, (p.723), which only have minor effects on the beta blockers, or consider using an alternative non-interacting beta blocker.

A reduced response is possible with any of the beta blockers that are extensively metabolised (see ‘Table 22.1’, (p.833)), but the effects on the AUCs of metoprolol and timolol appear to be less than the effects on alprenolol. Detailed information about the clinical importance of this interaction is largely lacking, but seems likely to be minor. However, it does occur and can influence the alternative measures suggested for alprenolol, and any possible interaction can almost certainly be avoided by using one of the beta blockers that are primarily excreted unchanged in the urine (see ‘Table 22.1’, (p.833)). Evidence is largely lacking, but all barbiturates would be expected to interact similarly, although the extent of the interaction may vary.

**Beta blockers + Bile-acid binding resins**

Although both colestyramine and colestipol can moderately reduce the absorption of propranolol, this does not seem to reduce its effects. Colesevelam does not appear to affect the absorption of metoprolol.

**Clinical evidence**

(a) Colesevelam

A single-dose study in 33 healthy subjects found that colesevelam 4.5 g did not cause a clinically relevant alteration in the plasma levels of sustained-release metoprolol 100 mg.1

(b) Colestipol

When 6 healthy subjects took a single 120-mg dose of propranolol with a 10-g dose of colestipol the peak plasma propranolol levels were raised by 30%. However, if an additional 10 g dose of colestipol was taken 12 hours before the propranolol the peak plasma levels were decreased by 36% and the AUC was reduced by about 30%. No changes in blood pressure or pulse rates were seen.2

(c) Colestyramine

When 6 healthy subjects took a single 120-mg dose of propranolol with an 8-g dose of colestyramine the peak propranolol plasma levels were reduced by almost 25% and the AUC was reduced by 13%. An additional dose of colestyramine 12 hours before the propranolol reduced the AUC by 43%. However, no changes in blood pressure or pulse rate were seen.2 Preliminary results of another study found that colestyramine (single unit dose) caused no significant changes in the blood levels of propranolol in 5 patients with type II hyperlipidaemia taking propranolol 40 mg four times daily.3

**Mechanism**

Uncertain. It seems probable that both colestyramine and colestipol can bind to propranolol in the gut, thereby reducing its absorption.

**Importance and management**

Information is limited. Even though both colestyramine and colestipol can apparently reduce the absorption of a single dose of propranolol, no changes in its effects were reported, suggesting that the interaction is of minimal clinical importance. There is therefore no obvious reason for avoiding concurrent use. However, note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine, and 1 hour before or 4 hours after colestipol.

---

**Beta blockers + Calcium-channel blockers; Dihydropyridines**

The use of beta blockers with felodipine, isradipine, lacidipine, nicardipine, nimodipine and nisoldipine normally appears to be useful and safe. However, severe hypotension and heart failure have occurred rarely when a beta blocker was given with nifedipine or nisoldipine. Changes in the pharmacokinetics of the beta blockers and calcium-channel blockers may also occur on concurrent use, but they do not appear to be clinically important.

**Clinical evidence**

(a) Felodipine

A double-blind, crossover study in 8 healthy subjects found that over a 5-day period, metoprolol 100 mg twice daily did not affect the pharmacokinetics of felodipine 10 mg twice daily. On the other hand, the bioavailability and peak plasma levels of metoprolol were increased by 31% and 38%, respectively.1 Another study in 10 healthy subjects given felodipine 10 mg with either metoprolol 100 mg, pindolol 5 mg, propranolol 80 mg, or timolol 10 mg found no changes in heart rate, PR interval or blood pressure that might be considered to be harmful to patients with hypertension or angina. However, 7 of the 10 subjects reported some increase in adverse effects.2

(b) Isradipine

A preliminary report of a study in 24 healthy subjects found that propranolol 40 mg twice daily given with isradipine 5 mg twice daily caused some modest changes in the pharmacokinetics of both drugs (peak propranolol plasma levels increased by 17%, peak isradipine plasma levels reduced by 18%), but the AUCs were not significantly altered.3 However, an earlier preliminary report by the same research group in 17 subjects found an increase in the propranolol AUC of 28%, a reduction in the isradipine AUC of 22% and a 59% increase in the peak propranolol levels.4

(c) Lacidipine

Twelve patients with mild to moderate hypertension not satisfactorily controlled by atenolol alone were given lacidipine 4 mg once daily with or without atenolol 100 mg daily for 14 days. There was no evidence of a significant change in drug levels, but there was a significant additive reduction in blood pressure during concurrent use, when compared with the reductions observed with either drug alone.5

Single-dose studies in 24 healthy subjects found that propranolol 160 mg reduced the peak plasma levels and AUC of lacidipine 4 mg by 38% and 42%, respectively, while the peak plasma levels and AUC of the propranolol were increased by 35% and 26%, respectively. There was a modest additive reduction of 4 to 6 mmHg in blood pressure, and the combination reduced the heart rate, but not to an extent greater than propranolol alone. No significant adverse effects were seen.6 However, a further preliminary report of a study by the same authors, in which 12 hypertensive patients were given propranolol 160 mg twice daily and lacidipine 4 mg daily for 2 weeks, found a non-significant 30% increase in systemic availability of lacidipine, and no change in propranolol pharmacokinetics. In addition, no clinically significant alterations in ECG recordings, blood pressure, or pulse rate were seen.7

---

The manufacturers of bupropion have predicted this interaction and recommend that if metoprolol is added to treatment with bupropion, doses at the lower end of the range should be used. If bupropion is added to existing treatment, decreased dosages of metoprolol should be considered.2,3 It seems likely that this interaction could occur with any of the beta blockers metabolised by CYP2D6 (see ‘Table 22.1’, (p.833)).

---

**Beta blockers + Bupropion**

A patient taking metoprolol developed bradycardia and hypotension when bupropion was also given.

**Clinical evidence, mechanism, importance and management**

A 50-year-old man taking metoprolol 75 mg twice daily and diltiazem 240 mg twice daily for hypertension developed fatigue 12 days after starting to take bupropion 150 mg twice daily. He was found to have a pulse rate of 43 bpm, a blood pressure of 102/65 mmHg, and signs of mild heart failure. He recovered within 24 hours of stopping all three drugs.1 It was suggested that these effects had occurred as a result of raised metoprolol levels, which had occurred because bupropion inhibited the metabolism of metoprolol by the cytochrome P450 isoenzyme CYP2D6.
(d) Lercanidipine

The manufacturer notes that when lercanidipine was given with metoprolol, the bioavailability of lercanidipine was reduced by 50% while the bioavailability of metoprolol was not changed. They suggest this may occur with any beta blocker, and that some adjustment of the lercanidipine dose may be needed.8

(e) Nicardipine

Nicardipine 30 mg did not affect the pharmacokinetics or pharmacodynamics of atenolol 100 mg in a single-dose study in healthy subjects.9

In another study, 14 healthy subjects were given nicardipine 50 mg every 12 hours and metoprolol 100 mg every 12 hours, both together and alone, for 11 doses. Metoprolol plasma levels were raised by 28% by the nicardipine in the 7 subjects who were of the extensive CYP2D6 metaboliser phenotype, but had no significant effect in the poor metabolisers. The extent of the beta-blockade was unchanged in all of them.10

Preliminary analysis of another study in healthy subjects found that the pharmacokinetics of both propranolol 80 mg twice daily and nicardipine 30 mg three times daily were unaffected when they were given together for 6 days.11 However, this contrasts with two single-dose studies, which found that nicardipine 30 mg increased the AUC and peak plasma levels of a single 80-mg dose of propranolol by 47% and 80%, respectively,12 and raised the AUC and peak plasma levels of an 80-mg dose of sustained-release propranolol to a lesser extent (17% and 22%, respectively).13 A related single-dose study found that in elderly healthy subjects nicardipine 30 mg increased the maximum plasma levels and AUC of propranolol 40 mg by about 100% and 80%, respectively. Nicardipine caused a further decrease in blood pressure, and attenuated the reduction in heart rate seen with propranolol alone.14

A study in 8 healthy subjects found that the increase in heart rate during exercise associated with a single 40-mg dose of nicardipine was reduced by one drop of timolol 0.5% put into each eye. Systolic blood pressure was also reduced during concurrent use, but nicardipine did not cause any further reduction in the intraocular pressure reduction produced by timolol.15

(f) Nifedipine

Nifedipine 10 mg three times daily did not alter the pharmacokinetics of atenolol 100 mg daily.16,17 Betaxolol,18 metoprolol 100 mg twice daily19 or propranolol 80 mg twice daily.20 A single-dose study also found a probable pharmacokinetic interaction between nifedipine and atenolol.21

However, another study found that nifedipine 10 mg three times daily caused an increase in the peak plasma level and AUC of propranolol 80 mg twice daily of 56% and 23%, respectively.18 Another study found that the absorption of a single dose of propranolol appeared to be faster, leading to higher initial concentrations, when it was given after nifedipine.20 Regardless of the pharmacokinetic changes, none of these studies in healthy subjects found any adverse haemodynamic effects from the combination of nifedipine and these beta blockers.18,19

Similarly, in studies in patients with normal left ventricular function there was no evidence of adverse haemodynamic effects when nifedipine (single-dose sublingual22,23 or intravenously,24 or daily dose orally25) was given with atenolol,23 celiprolol26 or propranolol.21,24

However, there are a few earlier isolated case reports of hypotension and heart failure with the combination. Two patients with angina taking atenolol or propranolol developed heart failure when they were given nifedipine 10 mg three times daily. The signs of heart failure disappeared when the nifedipine was withdrawn.26 One out of 15 patients with hypertension and exertional angina progressively developed hypotension (90/60 mmHg) when given nifedipine 10 mg twice daily in addition to treatment with atenolol 50 mg daily and a diuretic for one month.27 A patient with angina taking propranolol 160 mg four times daily developed severe and prolonged hypotension (blood pressure initially not recordable, then 60 mmHg systolic) 18 days after nifedipine 10 mg three times daily was substituted for ‘isosorbide’, and this may have been a factor that led to fatal myocardial infarction.28 Heart failure is also described in another patient with angina taking atenolol (and various other drugs) when nifedipine 20 mg three times daily was given.29

A patient developed hypotension and severe bradycardia on two occasions after being given her usual antihypertensive medication of labetalol and extended-release nifedipine crushed and given via a nasogastric tube. Crushing the nifedipine tablet altered its release characteristics so that the total dose was released quickly resulting in profound hypotension. The labetalol produced additional hypotensive effects and prevented a compensatory increase in heart rate.29

(g) Nimodipine

In a preliminary report of a study in 12 healthy subjects, nimodipine 30 mg three times daily for 4 days had no significant effect on the changes in heart rate, blood pressure or cardiac output seen with either propranolol 40 mg or atenolol 25 mg three times daily. The pharmacokinetics of the beta blockers were also unaltered.30

(h) Nisoldipine

A single 20-mg dose of nisoldipine increased the steady-state AUC and peak plasma level of propranolol 160 mg daily by 35% and 55%, respectively. After combined treatment for 7 days, the AUC of propranolol was increased by 60% and the peak plasma level was increased by 55%. The combination enhanced blood pressure reduction to a small extent, but nisoldipine did not significantly reduce the effect of propranolol on heart rate.31 Similarly, another study found that a single 20-mg dose of nisoldipine increased the AUC and peak plasma level of a single 40-mg dose of propranolol by 43% and 68%, respectively, and that the AUC and peak plasma level of nisoldipine increased 30% and 57%, respectively. In this study, nisoldipine was reported to enhance beta-blockade.32 However, the same research group later found that the steady-state pharmacokinetics of propranolol 80 mg twice daily and nisoldipine 10 mg twice daily were not affected by concurrent use for 7 days, but nisoldipine attenuated the decrease in forearm blood flow seen with propranolol.33 The manufacturer of nisoldipine notes that severe hypotension can occur when it is given at the same time as beta blockers, and that, in isolated cases, signs of heart failure can also occur.34

Mechanism

Not understood. Where pharmacokinetic changes are seen, a possible reason is that the metabolism of the beta blockers is altered by changes in blood flow through the liver. The pharmacodynamic changes with nifedipine may be explained by the fact that nifedipine reduces the contractility of the heart muscle. This is counteracted by a sympathetic reflex increase in heart rate due to nifedipine-induced peripheral vasodilatation, so that the ventricular output stays the same or is even improved. The presence of a beta blocker may oppose this to some extent by slowing the heart rate, which allows the negative inotropic effects of nifedipine to go unchecked.

Importance and management

The concurrent use of beta blockers and the dihydropyridine calcium-channel blockers is common, and normally valuable. However, isolated cases of severe hypotension and heart failure have been seen in a few patients taking beta blockers and nifedipine or nisoldipine. It has been suggested that those likely to be most at risk are patients with impaired left ventricular function53 (which is a caution for the use of nifedipine anyway) and/or those taking beta blockers in high dosage. Bear this in mind. It should also be noted that the topical use of beta blockers (such as timolol eye drops) may reduce heart rate and blood pressure. Changes in the pharmacokinetics of the beta blockers and calcium-channel blockers may also occur, but these do not appear to be clinically important. It may also be worth noting that all but one of the cases of an adverse reaction with a beta blocker and nifedipine occurred with ‘short-acting’ formulations, which are now considered unsuitable for long-term management of angina or hypertension, since they are associated with larger variations in blood pressure and heart rate. The remaining case was associated with the incorrect use of an extended-release nifedipine preparation.

Ten patients were admitted to an intensive coronary care unit during one year with severe bradycardia (heart rates of 24 to 44 bpm) after taking diltiazem 90 to 360 mg daily with propranolol 30 to 120 mg daily, atenolol 50 to 100 mg daily, or pindolol 90 mg daily. All were relatively elderly and presented with lethargy, dizziness, syncope, chest pain, and in one case pulmonary oedema. The ECG abnormalities were localized in the sinus node, the primary rhythm disorders being junctional escape rhythms, sinus bradycardia and sinus pause. These resolved within 24 hours of withdrawing the drugs, although a temporary pacemaker was needed in 4 patients.

Symptomatic and severe bradycard rhythms of this kind have been described in case reports in 16 other patients taking diltiazem with atenolol,2 carteolol,2,3 metoprolol,2,4 nadolol,6 pindolol,2 propranolol,2,4,6 or sotalol.1,7 AV block with unusual ECG changes (T-wave inversion and ST-segment depression) was found in a 16-year-old girl following an overdose of diltiazem and propranolol.1 In a later prospective study of hospital admissions due to cardiovascular adverse drug reactions, bradycardia, syncope, and worsening heart failure were noted in 21 patients taking beta blockers with diltiazem. The beta blockers involved were propranolol (13 patients), atenolol (5), metoprolol (2) and expre nolol (1).8 Similarly severe sinus bradycardia occurred in 8 of 59 patients in three early clinical studies of the combination of diltiazem and propranolol.1,9-11 One patient developed congestive heart failure.13 In contrast, four other similar clinical trials did not report any adverse effects,1,14 and in a single-dose study, one drop of timolol 0.5% eye drops did not cause an additional reduction in heart rate when it was given to healthy subjects with a 60-mg dose of diltiazem.15

(b) Pharmacokinetics

In healthy subjects, diltiazem increased the AUC of propranolol and metoprolol by 48% and 33%, respectively, and increased the maximum serum levels by 45% and 71%, respectively, but atenolol was not significantly affected.19 Another study found that diltiazem caused a 24% to 27% reduction in propranolol clearance.20

Mechanism

The bradyarrhythmic effects of the beta blockers can be additive with the delay in conduction through the atrioventricular node caused by diltiazem.1 This advantageously increases the antianginal effects in most patients, but in a few these effects may exacerbate existing cardiac abnormalities. Diltiazem apparently also inhibits the metabolism of propranolol and metoprolol, but the exact mechanism for this is not clear.15

Importance and management

Concurrent use is unquestionably valuable and uneventful in many patients, but severe adverse effects can develop. This is well established. A not dissimilar adverse interaction can occur with ‘verapamil’, (p.841). On the basis of 6 reports, the incidence of symptomatic bradycardia was estimated to be about 10 to 15%.1 It can occur with different beta blockers, even with very low doses, and at any time from within a few hours of starting treatment to 2 years of concurrent use.1 The main risk factors seem to be ventricular dysfunction, or sinoatrial or AV nodal conduction abnormalities.1 Note that these are usually contraindications to the use of diltiazem. Patients with normal ventricular function and no evidence of conduction abnormalities are usually not at risk. Concurrent use should be well monitored for evidence of adverse effects. Changes in the pharmacokinetics of the beta blockers may also occur, but these changes are probably not clinically important.

The cardiac depressant effects of verapamil and beta blockers are additive, and although concurrent use can be beneficial, serious cardiodepression (bradycardia, asystole, sinus arrest) sometimes occurs. It has been suggested that the combination should only be given to those who can initially be closely supervised. An adverse interaction can also occur with beta blockers given as eye drops.

Clinical evidence

(a) Adverse interactions

1. Intravenous administration. Ventricular asystole developed in 2 cases when intravenous verapamil was given after the unsuccessful use of intravenous practolol, to treat supraventricular tachycardia in a 70-year-old man and a 6-month-old baby. In a later study, the combination of intravenous verapamil and intravenous practolol produced a marked reduction in cardiac contractility, which was more evident when practolol was given first.

2. Oral administration. In one series, 34 out of 42 patients taking beta blockers (daily dose: atenolol 100 mg (34 patients), atenolol 50 mg (2), propranolol 160 mg (4), pindolol 20 mg (1), or metoprolol 100 mg (1)) with verapamil 360 mg daily experienced a reduction in anginal episodes over a mean period of 6.5 months while taking both drugs. However, 12 patients needed a reduced dosage or withdrawal of one or both drugs. One had non-specific symptoms (drugs withdrawn), 2 had bradyarrhythmias (drugs withdrawn) and 6 experienced dyspnoea (3 withdrawals and 3 dosage reductions), presumed to be secondary to left ventricular failure. Other complications were tiredness (2 patients) and postural hypotension (1 patient), which were dealt with by reducing the dosage. In another study in 15 patients with angina who were taking atenolol with verapamil, 4 experienced profound lethargy, one had left ventricular failure and 4 had bradycardia. Other case reports and studies describe heart failure, dyspnoea, sinus arrest, heart block, hypotension, and bradycardia in patients taking verapamil with alpenrolol, atenolol, metoprolol, propranolol, or pindolol. In two further cases, bradycardia occurred in patients taking verapamil and using timolol eye drops. In another case has been reported, but this was complicated by the presence of ‘flecainide’, (p.844).

(b) Pharmacokinetic interactions

The pharmacokinetics of atenolol were not altered by verapamil in one study in a single patient. In a study in 15 patients the plasma levels of verapamil and atenolol varied greatly during individual and concurrent use but mean concentrations were not significantly changed. In another study in 10 patients the mean AUC of atenolol was not significantly increased by verapamil, but individual patients had atenolol AUC increases of up to 112%. Verapamil raised the metoprolol AUC in 10 patients by 33% and the peak plasma levels by 41%. The minimum pulse rate and systolic blood pressure (1 to 3 hours post dose) were also lower in those taking the combination than with metoprolol alone. Similarly, in a single-dose study in 9 healthy subjects, the AUC and maximum plasma level of metoprolol increased by 35% and 64%, respectively, and the AUC and half-life of verapamil increased by 57% and 29%, respectively, on concurrent use.

In healthy subjects, verapamil reduced the clearance of propranolol by 26 to 32% and increased its AUC by 46 to 58% after 6 days of concurrent use. Similarly, in 5 patients, verapamil increased the peak plasma levels of propranolol by 94%, and its AUC by 66%. Propranolol did not affect the pharmacokinetics of verapamil. However, in another study in healthy subjects no pharmacokinetic interaction was noted between propranolol and verapamil after they were taken together for 6 days.

In a randomised, crossover study, a single 120-mg dose of (R)-verapamil reduced the bioavailability of a single 50-mg dose of talinolol by 25% in 9 healthy subjects.

Mechanism

Both beta blockers and verapamil have negative inotropic effects on the heart, which can be additive. Given together they can cause marked bradycardia and may even depress the contraction of the ventricle completely. Verapamil can also raise the serum levels of beta blockers that are extensively metabolised in the liver (e.g. metoprolol, propranolol), probably by inhibiting their metabolism, although the exact mechanism for this is unclear. It is thought that verapamil affects talinolol bioavailability by modulating intestinal P-glycoprotein.

Importance and management

Well documented and well established interactions. Although concurrent use can be uneventful and successful, the reports cited here amply demonstrate that it may not always be safe. The difficulty is identifying the patients most at risk. In the UK, the BNF says that oral concurrent use should only be considered if myocardial function is well preserved, and that verapamil should not be injected in patients recently given beta blockers because of the risk of hypotension and asystole. They also note that, although 30 months has been suggested as a sufficient interval before giving a beta blocker when a verapamil injection has been given first, the safety of this has not been established. The manufacturers of verapamil contraindicate its intravenous use in those receiving intravenous beta blockers. It has been advised that the initiation of treatment should be restricted to hospital practice, where the dose of each drug can be carefully titrated and side effects monitored. However, others contend that, since the interaction occurs with atenolol (which is largely excreted unchanged in the urine), the pharmacodynamic effects are more important than any pharmacokinetic changes. Note that the latter argument is probably valid, as changes of this size, or even more, in the AUC of beta blockers have proved not to be clinically important.

3. vein.

### Beta blockers + Chloroquine or Hydroxychloroquine

Hydroxychloroquine and possibly chloroquine may increase the blood levels of metoprolol, but this is probably not clinically important.

**Clinical evidence, mechanism, importance and management**

Hydroxychloroquine 400 mg daily for 8 days increased the AUC and peak plasma levels of a single 100-mg dose of metoprolol by 65% and 72%, respectively, in 7 healthy subjects who were of the extensive CYP2D6 metaboliser phenotype, see ‘Genetic factors’, (p.4). Hydroxychloroquine may inhibit the metabolism of metoprolol by the cytochrome P450 isoenzyme CYP2D6. The clinical significance of this interaction is unknown, but changes of this size in the AUC of beta blockers have proved not to be clinically important. Other beta blockers that are extensively metabolised (see ‘Table 22.1’, (p.833).) may behave like metoprolol, but those that are excreted unchanged in the urine would not be expected to interact. In *vivo* study suggests that chloroquine may interact with metoprolol in the same way as hydroxychloroquine. More study is needed.

### Beta blockers + Dextropropoxyphene (Propoxyphene)

A single-dose study has shown that the bioavailability of metoprolol is markedly increased by dextropropoxyphene and a case report supports these findings. The bioavailability of propranolol is also increased, but to a lesser extent.

#### Clinical evidence

A 48-year-old man taking metoprolol 100 mg daily developed dizziness and sweating 3 hours after taking dextropropoxyphene 200 mg and paracetamol (acetaminophen) 1.3 g. He was found to have a heart rate of 30 to 40 bpm and a blood pressure of 98/65 mmHg, which returned to normal over the following 8 hours. Assessment of blood samples showed that his normal metoprolol level was 89 nanograms/mL, but that this had risen to 160 nanograms/mL in the presence of dextropropoxyphene.

Preliminary results of a study suggest that after taking dextropropoxyphene [dose not stated] for a day the bioavailability of a single 100-mg oral dose of metoprolol was increased by almost 260% and the total body clearance was reduced by 18% in healthy subjects. The bioavailability of a single 40-mg oral dose of propranolol was increased by about 70%.

#### Mechanism

Dextropropoxyphene inhibits the metabolism of metoprolol by the cytochrome P450 isozyme CYP2D6, which results in increased levels and therefore increased effects. Propranolol is probably affected to a lesser extent as it is also metabolised by CYP1A2.

#### Importance and management

Evidence is limited, but an interaction seems established. It seems likely that this interaction could occur with any of the beta blockers metabolised by CYP2D6 (see ‘Table 22.1’, (p.833)). Therefore it would be prudent to be alert for evidence of an increased response but so far there seems to be very little evidence to suggest that concurrent use causes problems. No interaction would be expected with those beta blockers that are largely excreted unchanged in the urine (see ‘Table 22.1’, (p.833)).

### Beta blockers + Diphenhydramine

Diphenhydramine inhibits the metabolism of metoprolol, but this is probably not clinically important.

#### Clinical evidence

In a placebo-controlled study, a single 100-mg dose of metoprolol was given to 16 healthy male subjects on day 3 of a 5-day course of diphenhydramine 50 mg three times daily. Diphenhydramine decreased the clearance of metoprolol by 46% and increased its AUC by 61% in the 10 subjects who were of the extensive CYP2D6 metaboliser phenotype, but had no significant effect in the 6 poor metabolisers. However, the metoprolol AUC in the extensive metabolisers taking diphenhydramine was still only about one-third of that in the poor metabolisers taking placebo. The effect of metoprolol on heart rate and systolic blood pressure during exercise was also increased by diphenhydramine in extensive metabolisers. However, as before, it was not as great as the effect of metoprolol alone in poor metabolisers.

Diphenhydramine inhibits the cytochrome P450 isoenzyme CYP2D6, which is responsible, in part, for the metabolism of metoprolol and some other beta blockers. CYP2D6 shows polymorphism, with some individuals lacking significant CYP2D6 activity (poor metabolisers), in whom diphenhydramine would have little or no effect. See ‘Genetic factors’, (p.4), for more on polymorphism.

Importance and management

Information appears to be limited to these studies. Increases in plasma metoprolol levels of this size are unlikely to be clinically relevant. Indeed, despite the likely widespread use of ‘extensively metabolised’ beta blockers (see ‘Table 22.1’, (p.833)) and diphenhydramine, no problems seem to have been reported.

Mechanism

Diphenhydramine inhibits the isoenzyme CYP2D6, which is responsible, in part, for the metabolism of metoprolol and some other beta blockers. CYP2D6 shows polymorphism, with some individuals lacking significant CYP2D6 activity (poor metabolisers), in whom diphenhydramine would have little or no effect. See ‘Genetic factors’, (p.4), for more on polymorphism.

Clinical evidence

A man with recurrent migraine headaches, reasonably well-controlled over a 6-year period with 2 daily suppositories of Cafergot (containing ergotamine tartrate) developed progressively painful and purple feet a short while after starting to take propranolol 30 mg daily. When he eventually resumed taking the Cafergot alone there was no further evidence of peripheral vasoconstriction.1

A similar case has been reported elsewhere, although an interaction is inconclusive in this patient, as neither the ergotamine nor the propranolol were taken alone.2 Another similar case occurred in a woman taking oxprenolol and ergotamine tartrate [dosages unknown] for some considerable time. Arteriography showed severe spasm in a number of arteries, which responded eventually to an intra-arterial infusion of glyceryl trinitrate and heparin.3 Severe pain in the legs and feet occurred in another man after he took methysergide 3 mg and propranolol 120 mg daily for 2 weeks. He did not respond to various therapies, and in 6 days it was necessary to amputate both his legs below the knee because of gangrene.4 A woman taking propranolol for migraine prophylaxis became hypertensive [BP 180/120 mmHg] with a crushing substernal pain immediately after being given oxygen, prochlorperazine 5 mg and intravenous dihydroergotamine 750 micrograms for an acute migraine headache. She recovered uneventfully. She was later found to be hyperthyroid.5

These reports contrast with another stating that the use of propranolol with ergotamine was both effective and uneventful in 50 patients.6

Mechanism

Uncertain. One suggestion is that additive vasoconstriction occurs.1,3 Ergot derivatives cause vasoconstriction, and the beta blockers do the same by blocking the normal (beta-stimulated) sympathetic vasodilatation. The beta blockers also reduce blood flow by reducing cardiac output.

Importance and management

Concurrent use is usually safe and effective, and there are only a handful of reports of adverse interactions. It was suggested that at least one of these could have been due to the ergotamine alone (i.e. ergotism).3 However, it would clearly be prudent to be extra alert for any signs of an adverse response, particularly those suggestive of reduced peripheral circulation (coldness, numbness or tingling of the hands and feet).

Beta blockers + Finasteride

Finasteride 5 mg daily for 10 days caused no change in the pharmacokinetics or pharmacodynamics of a single 80-mg dose of propranolol in healthy subjects.1 Further, the manufacturers say that finasteride was used with beta blockers in clinical studies without any evidence of an interaction.2,3 Similarly, ‘dutasteride’, (p.1257) does not appear to interact with beta blockers.

Beta blockers + Fish oils

The hypotensive effect of propranolol may be enhanced by fish oil.

Beta blockers + Dronedarone

Dronedarone increases the AUC of metoprolol in patients with a CYP2D6 extensive metaboliser phenotype. The increase in negative inotropic effects are modest at the recommended therapeutic dose of dronedarone.

Clinical evidence

In a study, 44 healthy subjects (39 extensive and 5 poor CYP2D6 metabolisers) were given metoprolol 200 mg daily for 13 days. Concurrent dronedarone 800 mg, 1.2 g or 1.6 g daily from day 5 increased the AUC of metoprolol in a dose-dependent manner in the 39 subjects who were extensive metabolisers by 1.63-, 2.08- and 2.53-fold, respectively. In addition, concurrent use resulted in an additive dose-dependent negative inotropic effect. In contrast, metoprolol plasma levels were not affected by dronedarone.1

Mechanism

Dronedarone is structurally related to amiodarone, which is known to inhibit the cytochrome P450 isoenzyme CYP2D6, by which metoprolol is metabolised (see ‘Amiodarone + Beta blockers’, p.246). This study also shows that dronedarone inhibits CYP2D6, effectively making extensive metabolisers into poor metabolisers. For more information on metaboliser status see ‘Genetic factors’, (p.4).

Importance and management

A pharmacokinetic interaction is established, but its clinical relevance is uncertain. The negative inotropic effect of metoprolol was almost doubled by the addition of dronedarone 1.6 g daily, but at the anticipated therapeutic dose of 800 mg the effects were modest. Other beta blockers that are metabolised by CYP2D6 (see ‘Table 22.1’, (p.833)) would be expected to interact similarly.

Beta blockers + Ergot derivatives

The use of beta blockers with ergot derivatives in the management of migraine is not uncommon, but concurrent use has resulted in three cases of severe peripheral vasoconstriction and one of hypertension.

Importance and management

A pharmacokinetic interaction is established, but its clinical relevance is uncertain. The negative inotropic effect of metoprolol was almost doubled by the addition of dronedarone 1.6 g daily, but at the anticipated therapeutic dose of 800 mg the effects were modest. Other beta blockers that are metabolised by CYP2D6 (see ‘Table 22.1’, (p.833)) would be expected to interact similarly.

Beta blockers + Fish oils

The hypotensive effect of propranolol may be enhanced by fish oil.
Clinical evidence, mechanism, importance and management

In a study 36 patients with mild hypertension were given either propranolol 80 mg daily or fish oil 9 g daily (as capsules and equivalent to eicosapentaenoic acid 1.8 g and docosahexaenoic acid 1.1 g daily) for 36 weeks followed by placebo for 4 weeks. A further group of 16 patients were given propranolol 80 mg daily for 12 weeks, propranolol plus fish oil 9 g daily for 12 weeks, propranolol plus fish oil placebo for 12 weeks, and finally propranolol placebo for 4 weeks. Fish oil alone decreased blood pressure to a similar extent to propranolol, and decreases in blood pressure with the combination were greater than with either propranolol or fish oil alone.¹ A further similar study in 14 patients taking a beta blocker found that when they were also given 4 capsules of Omnnor (equivalent to eicosapentaenoic acid 1.9 g and docosahexaenoic acid 1.5 g daily) for 6 weeks their blood pressure decreased by a further 3.3/1.9 mmHg.²

The mechanism is uncertain, but as fish oil seems to have a hypotensive effect of its own, it may enhance the hypotensive effect of any beta blocker.

Beta blockers + Flecainide

The combined use of flecainide and beta blockers may have additive cardiac depressant effects. An isolated case of bradycardia and fatal AV block has been reported during the use of flecainide with sotalol, and bradycardia has been reported in a patient taking flecainide who was given timolol eye drops.

Clinical evidence, mechanism, importance and management

A study on cardiac function and drug clearance in 10 healthy subjects found that when propranolol 80 mg three times daily was given with flecainide 200 mg twice daily for 4 days the AUCs of both drugs were increased by 20 to 30%, and they had some additive negative inotropic effects.¹ A report describes a patient taking flecainide 100 mg twice daily who developed bradycardia and fatal atrioventricular conduction block 3 hours after taking a second dose of sotalol 40 mg.² Another report describes a patient with chronic atrial fibrillation that had been stable for 5 years during treatment with flecainide and verapamil. Within 3 days of starting timolol 0.1% eye drops twice daily, she developed bradycardia with a heart rate of 35 to 40 bpm. The eye drops were stopped and 16 hours after the last dose, her heart rate had increased to 90 to 100 bpm.³ Careful monitoring has therefore been recommended if beta blockers are added to flecainide. Note that serious cardiac depression has been seen following the use of flecainide with other drugs that have negative inotropic effects such as ‘verapamil’, (p.261).

Beta blockers + Food

Food can increase, decrease or not affect the bioavailability of beta blockers, but none of the changes has been shown to be of clinical importance.

Clinical evidence, mechanism, importance and management

Food increased the AUC of propranolol by 50 to 80%,¹ ½ metoprolol by about 40%¹ ¹ and labetalol by about 40%,⁴ possibly by changing the extent of their first pass metabolism through the liver.³ ⁴ Food did not affect the extent of absorption of a sustained-release formulation of propranolol.² Food had very little effect on the absorption of oxprenolol³ or pindolol, whereas the AUC of atenolol was reduced by about 20%.² A later study suggested that atenolol (and possibly other hydrophilic beta blockers, see ‘Table 22.1’, (p.833)) become tightly associated with bile acid micelles, preventing their absorption.⁵ None of these changes have been shown to be of clinical importance, nor is it clear whether it matters if patients take these drugs in a regular pattern in relation to meals. Beta blocker serum levels vary widely between patients (a 20-fold difference in propranolol AUC has been noted between individuals),¹ and individualising the dose is therefore more of an issue than food intake.

Beta blockers + Grapefruit and other fruit juices

The bioavailability of celiprolol is markedly reduced by both grapefruit juice and orange juice, the bioavailability of atenolol is moderately reduced by orange juice, and the bioavailability of talinolol is reduced by grapefruit juice.

Clinical evidence, mechanism, importance and management

(a) Acebutolol

In a randomised, crossover study, 10 healthy subjects were given a 200-mL drink of normal-strength grapefruit juice three times a day for 4 days (total of 11 drinks), with a single 400-mg dose of acebutolol on the morning of day 3. Grapefruit juice decreased the maximum levels and AUC of acebutolol by a modest 19% and 6%, respectively. No significant changes in the heart rate or blood pressure were seen.¹

(b) Atenolol

In a randomised crossover study 10 healthy subjects were given 200 mL of orange juice (from concentrate) three times daily with a single 50-mg dose of atenolol on the third day. Orange juice reduced the AUC and maximum serum levels of atenolol by 40% and 49%, respectively, and also attenuated the atenolol-induced reduction in heart rate. The effect of atenolol on blood pressure was unchanged.² This suggests that orange juice may make atenolol less effective when it is used for rate control, but the clinical significance of this effect is unclear.

(c) Celiprolol

In a study 12 healthy subjects were given grapefruit juice 200 mL three times daily for 2 days. On the third day celiprolol 100 mg was given with the second of four 200 mL volumes of grapefruit juice, and on day 2 further 200 mL volumes of grapefruit juice were given. The AUC and peak plasma levels of celiprolol were reduced by about 87% and 95%, respectively. The half-life of celiprolol was slightly prolonged. However, grapefruit juice did not affect the changes in blood pressure or heart rate caused by celiprolol.³ In a similar study in 10 healthy subjects, 200 mL of ‘normal-strength’ orange juice, given 2 to 4 times daily for 4 days, reduced the AUC and peak plasma levels of a single 100-mg dose of celiprolol given on day 3 by 83% and 89%, respectively. The half-life of celiprolol was prolonged from 4.6 to 10.8 hours and the renal excretion of celiprolol was reduced by 77%. However, orange juice did not alter the effects of celiprolol on blood pressure or heart rate.⁴

The mechanism of this effect is not known, but suggestions include an effect on intraduodenal pH and the lipid solubility of celiprolol, or the formation of a complex between celiprolol and an ingredient of grapefruit or orange juice that interfered with celiprolol absorption. Alternatively, inhibition of uptake transporter proteins in the intestine may have reduced absorption.³ ⁴
Although the clinical relevance of these effects has not been fully assessed, the studies suggest that the effects of cefprozil on blood pressure and heart rate are not affected. Nevertheless the marked reduction in cefprozil bioavailability in the presence of grapefruit or orange juice suggests this interaction may be of clinical significance in some patients.3,4

(d) Talinolol

Grapefruit juice 300 mL decreased the AUC of a single 50-mg dose of talinolol by 44%, increased the maximum level by 42%, and increased the oral clearance by 62%. Similar results were seen after repeated administration of grapefruit juice over 6 days. However, the haemodynamic effects of talinolol were not altered by grapefruit juice.5 Because P-glycoprotein levels did not appear to be affected by grapefruit juice, it was suggested that constituents in the juice might inhibit an uptake process other than P-glycoprotein. [Note that, in contrast, a study in animals found that the bioavailability of talinolol was increased by grapefruit juice.]6 The decreases in talinolol levels are unlikely to be clinically relevant.

(g) Metoprolol

A study in 6 healthy subjects given metoprolol 100 mg twice daily for a week found that the metoprolol 1 g daily in divided doses increased the peak plasma levels of metoprolol by 70% and the AUC by 61%, but this did not increase the effect of metoprolol on the heart rate during exercise.4,6 Metoprolol did not affect cimetidine pharmacokinetics.6 Three other studies confirmed that cimetidine increased metoprolol serum levels after single or multiple doses, but none of the studies found that this interaction resulted in an increase the effect of metoprolol on the heart rate during exercise.16-19 An isolated case describes one patient who complained of a “very irregular heart beat” while taking both drugs, which was much less marked when he took the two drugs separated by as much time as possible.20 In contrast, two other studies found that cimetidine did not affect the serum levels of a single 100-mg dose of metoprolol.7,8

(h) Nadolol

The blood levels and pharmacokinetics of nadolol were unaffected by cimetidine, and the effects of the beta blocker on heart rate and blood pressure were not changed.21

(f) Nebivolol

Cimetidine 400 mg twice daily increased the AUC and peak plasma levels of a single 5-mg dose of nebivolol by 48% and 23%, respectively, but did not alter the effect of nebivolol on blood pressure or heart rate.22

(i) Penbutolol

The blood levels and pharmacokinetics of penbutolol23-25 were unaffected by cimetidine, and the effects of the beta blocker on heart rate and blood pressure were not changed.25

(k) Pindolol

Cimetidine 1 g daily in divided doses increased the AUC and peak plasma levels of pindolol 10 mg twice daily by 30% and 33%, respectively, although these changes were not statistically significant.9 In another study, cimetidine 400 mg twice daily increased the AUC of the pindolol by about 40% and decreased the renal clearance by about 35%.24

(l) Propranolol

Cimetidine 300 mg four times daily for a week was given to 12 healthy subjects with propranolol 80 mg every 12 hours from day 3 onwards. The mean steady-state blood levels and the AUC of propranolol were raised by 47%, and the half-life was prolonged by 17%, but cimetidine did not alter the effect of propranolol on heart rate.25 A number of other single-dose and steady-state studies confirmed that cimetidine caused rises of 35 to 136% in the blood levels, AUC and clearance of propranolol,4,6,10,21,26-32 but this did not increase the effect of the beta blocker on blood pressure,21,27,29 or on heart rate, either at rest or during exercise.21,27,29 In contrast, one study did show a further reduction in heart rate when cimetidine was given with propranolol.33 A letter describes one patient given cimetidine 1 g daily for 6 weeks who had an increase in the serum propranolol level of about threefold and an AUC increase of 340% when a single 80-mg dose of propranolol was given.2 In one study, the increase in the steady-state AUC of propranolol tended to be higher when cimetidine was given simultaneously with propranolol than when they were given separated by 10 hours (41% versus 26%), but the difference was not significant.34 In one study propranolol did not affect cimetidine pharmacokinetics.6

(m) Timolol

A double-blind study in 12 healthy subjects found that cimetidine 400 mg twice daily for 3 days did not modify the effect of a single drop of timolol 0.5%, put into each eye on heart rate or intraocular pressure to either a statistically or clinically relevant extent.35
Mechanism

The blood levels of beta blockers extensively metabolised in the liver by the cytochrome P450 isoenzyme CYP2D6 (e.g. metoprolol, nebivolol and propranolol) are increased because cimetidine reduces their metabolism by inhibiting the activity of the liver enzymes. However, this does not seem to be a complete explanation as cimetidine does not affect carvedilol, which is metabolised by CYP2D6, but affects labetalol, a beta blocker that is not metabolised by CYP2D6.12 Pindolol is partly excreted by an active renal tubular secretion mechanism, and cimetidine increases pindolol blood levels by inhibiting this mechanism.24 Cimetidine may reduce the renal clearance of bisoprolol by a similar mechanism.25 Those beta blockers that are largely excreted unchanged in the urine (e.g. atenolol, nadolol) are not affected by cimetidine.21

Importance and management

Well studied and established interactions but, despite the considerable risks in blood levels that can occur when some beta blockers are given with cimetidine, the effects normally appear to be clinically unimportant. Concurrent use is common, but only one isolated case of profound bradycardia (involving atenolol) appears to have been reported. Marked hypotension also seems to be rare. Combined use need not be avoided. However, it has been suggested that patients with impaired liver function who are given cimetidine with beta blockers that are extensively metabolised in the liver (see ‘Table 22.1’, p.833) might possibly develop grossly elevated blood levels, which could cause adverse effects. It would seem prudent to either monitor this type of patient (for effects such as hypotension) until more is known, or to use a non-interacting H₂-receptor antagonist such as ‘ranitidine’, below).

17. Data on file, database on carvedilol, SmithKline Beecham, quoted by Ruffolo RR, Boyle DA, Kim HS, Koopman WT. The metabolic fate of carvedilol in man. J Pharm Pharmacol (1986) 38, 300 mg daily for 7 days. Nizatidine alone caused a fall in heart rate of 6 bpm. A further fall of 6 bpm occurred when they were also given nizatidine 300 mg daily for 7 days. Nizatidine alone caused a fall in heart rate of about 8 bpm. Thus the effects of nizatidine and atenolol on heart rate appear to be additive. It seems likely that nizatidine would have the same effects in the presence of other beta blockers. The clinical significance of these effects is uncertain, but it might be important in elderly patients.1

Famotidine

Famotidine does not appear to interact with the beta blockers.

Clinical evidence, mechanism, importance and management

A survey of 15 patients taking beta blockers (acebutolol, atenolol, betaxolol, nadolol, pindolol, propranolol or sotalol) for 6 to 8 weeks found no evidence of changes in antihypertensive effects or bradycardia while they were taking famotidine 40 mg daily.1 No interaction would be expected, and no special precautions would seem necessary if famotidine is taken with these or any other beta blocker.

Clinical evidence, mechanism, importance and management

After taking atenolol 100 mg daily for 7 days the mean resting heart rate of 12 healthy subjects fell from about 64 to 53 bpm 3 hours after dosing. A further fall of 6 bpm occurred when they were also given nizatidine 300 mg daily for 7 days. Nizatidine alone caused a fall in heart rate of about 8 bpm. Thus the effects of nizatidine and atenolol on heart rate appear to be additive. It seems likely that nizatidine would have the same effects in the presence of other beta blockers. The clinical significance of these effects is uncertain, but it might be important in elderly patients.1

More study is needed.

Nizatidine

The bradycardic effects of atenolol are increased by nizatidine.

Clinical evidence, mechanism, importance and management

Famotidine

Famotidine does not appear to interact with the beta blockers.

Clinical evidence, mechanism, importance and management

A survey of 15 patients taking beta blockers (acebutolol, atenolol, betaxolol, nadolol, pindolol, propranolol or sotalol) for 6 to 8 weeks found no evidence of changes in antihypertensive effects or bradycardia while they were taking famotidine 40 mg daily.1 No interaction would be expected, and no special precautions would seem necessary if famotidine is taken with these or any other beta blocker.

Clinical evidence, mechanism, importance and management

After taking atenolol 100 mg daily for 7 days the mean resting heart rate of 12 healthy subjects fell from about 64 to 53 bpm 3 hours after dosing. A further fall of 6 bpm occurred when they were also given nizatidine 300 mg daily for 7 days. Nizatidine alone caused a fall in heart rate of about 8 bpm. Thus the effects of nizatidine and atenolol on heart rate appear to be additive. It seems likely that nizatidine would have the same effects in the presence of other beta blockers. The clinical significance of these effects is uncertain, but it might be important in elderly patients.1

another study found that ranitidine increased the AUC and plasma levels of metoprolol 100 mg twice daily by 55 and 34%, respectively.6,9 All of these studies found that ranitidine did not alter the effect of metoprolol on heart rate during exercise.1,2,5,9

Ranitidine 300 mg daily for 6 days did not affect the steady-state plasma levels of propranolol 160 mg daily nor did it alter the effect of propranolol on heart rate or blood pressure in 5 healthy subjects.1 Similarly no changes in plasma propranolol levels were seen in other multiple-dose10 or single-dose studies.11-14

Similarly, in other studies, ranitidine 150 mg twice daily did not significantly alter the pharmacokinetic or pharmacodynamic effects of a single 5-mg dose of nebivolol,15 a single 5-mg dose of tertatolol,16 or atenolol 100 mg daily for 7 days.6,8

**Mechanism**

The rises in metoprolol serum levels caused by ranitidine in the two single-dose metoprolol studies are not understood, nor is it clear why one of four studies found an increase after multiple doses.

### Importance and management

The possible effects of ranitidine on the plasma levels and effects of propranolol and metoprolol have been well studied. Although some studies have shown moderate rises in metoprolol levels, particularly after single-doses, these increases are of a magnitude that is unlikely to be clinically important. Less is known about atenolol, nebivolol and tertatolol, although no clinically relevant interactions have been seen. There is nothing to suggest that the concurrent use of ranitidine and any beta blocker should be avoided, nor that there is any need to take particular precautions.

### Beta blockers + Hormonal contraceptives

The blood levels of metoprolol are increased in women taking oral contraceptives, but the clinical importance of this is probably very small. Acebutolol, oxprenolol and propranolol pharmacokinetics are minimally affected by contraceptive use.

#### Clinical evidence

The peak plasma levels and the AUC of a single 100-mg dose of metoprolol were 36 and 70% higher, respectively, in 12 women taking low-dose combined oral contraceptives, when compared with a similar group not taking contraceptives. The elimination half-life of metoprolol was unaffected.1 In a further study by the same research group, the AUC of metoprolol was 71% higher, the AUC of oxprenolol was 26% higher, the AUC of propranolol was 42% higher, and the AUC of acebutolol was marginally lower in women taking combined oral contraceptives, when compared to those not taking contraceptives, but only the metoprolol difference was statistically significant.2 In another study, the total clearance of a single 80-mg dose of propranolol was increased (although not significantly) in 8 women given ethinylestradiol 50 micrograms daily, and an even smaller increase was seen when they were taking a combined oral contraceptive containing ethinylestradiol and norethisterone.3

#### Mechanism

The reason for the changes appears to be that ethinylestradiol alters the metabolism of these beta blockers. In the case of propranolol its conjugation and oxidation are increased by the ethinylestradiol.3

### Importance and management

The changes seen with propranolol, oxprenolol and acebutolol are almost certainly too small to matter, but with metoprolol the changes are somewhat larger. Even so, changes of this size caused by the interactions of other drugs with beta blockers are not usually clinically relevant. No special precautions are generally necessary if any of these beta blockers are given to women taking oral contraceptives containing ethinylestradiol, or those taking ethinylestradiol alone, although note that the effects of a moderate rise may be more significant in those taking metoprolol for heart failure. Also be aware that some of the indications for beta blockers are cautions for, or preclude the use of, combined oral contraceptives.

increased by hydralazine, but no increase in adverse effects seems to have been reported.

Clinical evidence

(a) Effect of hydralazine on beta blockers

Single 25- and 50-mg doses of hydralazine increased the AUC of a single 40-mg dose of propranolol by 60% and 110%, respectively, and raised the peak plasma levels by 144 and 240%, respectively, in 5 healthy subjects. Similarly, in another single-dose study, hydralazine increased the AUC of propranolol by 62 to 77%. However, a further single-dose study using sustained-release propranolol found that hydralazine had no effect on propranolol pharmacokinetics.

In other studies hydralazine increased the AUC of sustained-release oxprenolol by 41% at steady-state, and of metoprolol by 30% after a single dose, and by 38% at steady-state. In contrast, single-dose studies found that hydralazine did not affect the AUC of acebutolol or nadolol.

(b) Effect of beta blockers on hydralazine

Oxprenolol was found not to have a significant effect on the pharmacokinetics of hydralazine.

Mechanism

Uncertain. Hydralazine appears to increase the bioavailability only of those beta blockers that undergo high hepatic extraction and not those that are largely excreted unchanged in the urine. Hepatic extraction is discussed in more detail under ‘Changes in first-pass metabolism’, (p.4), and ‘Table 22.1’, (p.833), lists the metabolic routes of the commonly used systemic beta blockers. It has been suggested that hydralazine may alter hepatic flow or inhibit hepatic enzymes, although other mechanisms may also be involved.

Importance and management

Moderately well documented and established interactions, but the increased beta blocker serum levels appear to cause no adverse clinical effect. Concurrent use is usually valuable in the treatment of hypertension. No particular precautions seem to be necessary.

Beta blockers + Inotropes and Vasopressors

Effects on blood pressure and heart rate: The hypertensive effects of adrenaline (epinephrine) can be markedly increased in patients taking non-selective beta blockers such as propranolol. A severe and potentially life-threatening hypertensive reaction and/or marked bradycardia can develop. Cardioselective beta blockers such as atenolol and metoprolol interact minimally. An isolated report describes a fatal hypertensive reaction in a patient given propranolol and phenylephrine, but concurrent use normally seems to be uneventful. Paradoxically, marked hypotension occurred in one patient given low-dose carvedilol and dobutamine. Anaphylaxis: Some evidence suggests that anaphylactic shock in patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine).

Clinical evidence

A. Effects on blood pressure and heart rate

(a) Adrenaline (Epinephrine)

An early study in 10 healthy subjects found that intravenous adrenaline (epinephrine) 5 micrograms/minute increased heart rates and caused minimal changes in blood pressure. However, after pretreatment with intravenous propranolol 10 mg, the same dose of adrenaline caused a fall in heart rate of 12 bpm and an increase in arterial pressure of 20/10 mmHg. One case report describes 6 patients taking propranolol 20 to 80 mg daily, undergoing plastic surgery, who experienced marked hypertensive reactions (blood pressures in the range of 190/110 to 260/150 mmHg) and bradycardia when their eyelids and/or faces were infiltrated with 8 to 40 mL of local anaesthetic solutions of lidocaine containing 1:100 000 or 1:200 000 (10 or 5 micrograms/mL) of adrenaline. Cardiac arrest occurred in one patient. Similar marked increases in blood pressure, associated with marked bradycardia, have been described in other studies and case reports involving propranolol. In contrast, only a small blood pressure rise was seen in a comparative study with metoprolol. This was confirmed in another study in which patients given identical infusions of adrenaline developed a hypertensive/bradycardic reaction while taking propranolol but not while taking metoprolol. After pretreatment with a single 5-mg dose of pindolol, only small reductions in blood pressure (4 mmHg) and heart rate (about 5 bpm) were seen with the intra-oral injection of 3.6 mL of 2% lidocaine containing 1:80 000 adrenaline (45 micrograms of adrenaline) in healthy subjects. In 24 healthy subjects given either nadolol, atenolol or placebo for 1 week followed by an infusion of adrenaline, mean arterial pressure and calf vascular resistance rose markedly in the nadolol-treated group but not the atenolol group. Marked bradycardia also occurred in those given nadolol and adrenaline.

In 6 healthy subjects, giving adrenaline after intravenous labetalol 1 mg/kg, resulted in a 13 to 21 mmHg increase in mean arterial pressure and a 23 to 29 bpm reduction in heart rate, compared with adrenaline alone.

(b) Dobutamine

A 54-year-old man with severe heart failure was given carvedilol 3.125 to 6.25 mg twice daily. His symptoms worsened and he was admitted for treatment with intravenous dobutamine; the carvedilol was discontinued and other medications apart from furosemide were withheld short-term. Dobutamine was started at 1 microgram/kg per minute and gradually increased to 5 micrograms/kg per minute. However, with each 1 microgram/kg increment the systolic blood pressure dropped to about 70 mmHg for 5 to 10 minutes and then quickly returned to the baseline level of 80 to 84 mmHg. When the dose of dobutamine reached 5 micrograms/kg per minute, his systolic blood pressure dropped to 56 mmHg and the dobutamine was discontinued. The blood pressure returned to normal over the next 30 minutes. Two months later when the patient was no longer taking carvedilol he was again given intravenous dobutamine and his systolic blood pressure increased, as would be expected.

(c) Phenylephrine

A woman taking propranolol 40 mg four times daily for hypertension was given one drop of a 10% phenylephrine hydrochloride solution in each eye during an ophthalmic examination. About 45 minutes later she complained of a sudden and sharp bi-temporal pain and shortly afterwards became unconscious. She later died of an intracerebral haemorrhage due to the rupture of a berry aneurysm. She had received a similar dose of phenylephrine on a previous occasion in the absence of propranolol without any problems.

However, no change in blood pressure was seen in a study in both normotensive subjects and patients taking metoprolol who were given 0.5 to 4-mg doses of phenylephrine intranasally every hour, to a total of 7.5 to 15 mg (4 to 30 times the usual dose). Similarly, in a placebo-controlled study in 12 hypertensive patients, neither propranolol nor metoprolol significantly altered the dose of intravenous phenylephrine required to cause a 25 mmHg increase in systolic blood pressure.
A patient taking propranolol who suffered an anaphylactic reaction after receiving an allergy injection for desensitisation did not respond to adrenaline (epinephrine) and required intubation. Resistance to adrenaline treatment for anaphylaxis occurred in another patient using timolol eye drops. It has also been proposed that the incidence and severity of anaphylactic reactions may be increased in those taking beta blockers, one idea being that the adrenoceptors concerned with suppressing the release of the mediators of anaphylaxis may be blocked by either beta1 or beta2 antagonists. However, one study failed to find any evidence to support an increased incidence of systemic reactions in patients taking beta blockers receiving allergen immunotherapy. See also 'X-ray contrast media', (p.857), and 'penicillins', (p.850), for other anaphylactic reactions potentially exacerbated by beta blockers.

A beta-agonist bronchodilator (e.g. isoprenaline, salbutamol) may be effective in patients taking beta blockers with anaphylaxis resistant to adrenaline, and glucagon was effective in treating a severe anaphylactoid reaction in one patient taking a beta blocker. Severe hypertension, sometimes with bradycardia, has been described following the use of adrenaline to treat allergic reactions, including presumed anaphylaxis, in patients taking propranolol. These are discussed under A. above.

**Mechanism**

Adrenaline (epinephrine) stimulates alpha- and beta-receptors of the cardiovascular system, the former results in vasoconstriction (mainly alpha1) and the latter in both vasodilatation (mainly beta2) and stimulation of the heart (mainly beta1). The net result is usually a modest increase in heart rate and a small rise in blood pressure. However, if the beta-receptors are blocked by a non-selective beta blocker, such as propranolol or nadolol (see ‘Table 22.1’, (p.833) for a list), the unopposed alpha vasoconstriction causes a marked rise in blood pressure, followed by reflex bradycardia. Cardioselective beta blockers such as atenolol and metoprolol, which are more selective for beta1 receptors, do not prevent the vasodilator action of adrenaline at beta2 receptors to the same extent, and therefore the effect of any interaction is relatively small. Consequently, adrenaline has been used to assess the degree of beta blockade produced by propranolol and other beta blockers. Phenylephrine is largely an alpha stimulator, therefore beta blockers should have a minimal effect on its action.

Dobutamine is a beta2, beta1 and alpha1 adrenergic agonist and cardiodilovol is a non-selective beta blocker, but at low doses it is primarily a selective beta1 adrenergic antagonist and it is also an alpha1 antagonist. It was proposed that the drop in blood pressure was caused by vasodilatation due to vascular beta receptor activation, which was not blocked by low doses of carvedilol.

**Importance and management**

The interaction between propranolol and adrenaline (epinephrine) is established. It may be serious and potentially life-threatening, depending on the dosage of adrenaline used. Marked and serious blood pressure rises and severe bradycardia have occurred in patients given 300 micrograms of adrenaline (0.3 mL of 1:1000) subcutaneously or 40 to 400 micrograms by infiltration of the skin and eyelids during plastic surgery. Adrenaline 15 micrograms given intravenously can cause an almost 40% fall in heart rate. Patients taking non-selective beta blockers such as propranolol (see ‘Table 22.1’, (p.833) for a list) should only be given adrenaline in very reduced dosages because of the marked bradycardia and hypertension that can occur. A less marked effect is likely with the cardioselective beta blockers, such as atenolol and metoprolol (see ‘Table 22.1’, (p.833) for a list). Local anaesthetics used in dental surgery usually contain very low concentrations of adrenaline (e.g. 5 to 20 micrograms/mL, i.e. 1:200 000 to 1:50 000) and only small volumes are usually given, so that an undesirable interaction is unlikely.

No interaction between phenylephrine and the beta blockers would be expected, and apart from the single unexplained case cited above, the literature appears to support this. Concurrent use normally appears to be clinically unimportant, particularly bearing in mind the widespread use of beta blockers and the ready availability of phenylephrine in the form of non-prescription cough-and-cold remedies and nasal decongestants.

Acute hypertensive episodes have been controlled with chlorpromazone or phentolamine (both of which are alpha blockers). Hydralazine, nifedipine and aminophylline have also been used. Reflex bradycardia may be managed with atropine and the pre-emptive use of glycopyrrolate has also been suggested.

The paradoxical case of hypotension with dobutamine and low-dose carvedilol suggests that this combination should be monitored carefully.

**Beta blockers + Itraconazole**

Itraconazole markedly increased the bioavailability of celiprolol and only slightly affected the pharmacokinetics of atenolol, without affecting heart rate or blood pressure. These interactions are not expected to be clinically relevant.

**Clinical evidence, mechanism, importance and management**

(a) Atenolol

In a study in 10 healthy subjects itraconazole 200 mg twice daily for 5 doses had only minor effects on the pharmacokinetics of a single 50-mg dose of atenolol and no effects on heart rate or blood pressure were seen.

(b) Celiprolol

In a study in 12 healthy subjects itraconazole 200 mg twice daily for 5 doses increased the AUC of a single 100-mg dose of celiprolol by 80%, without increasing the half-life. However, itraconazole did not increase the effect of celiprolol on heart rate or blood pressure.

It was suggested that itraconazole probably increases the absorption of celiprolol by inhibiting P-glycoprotein in the intestinal wall. Although the increase in plasma levels was marked, it was suggested that
it is unlikely to be clinically relevant because celiprolol has a wide therapeutic range.\(^2\)

**Beta blockers + Macrolides**

The serum levels of talinolol and possibly nadolol are increased by erythromycin, but the clinical importance of this is uncertain. Telithromycin does not appear to adversely affect sotalol-induced QT prolongation. However, the combined use of sotalol and intravenous erythromycin should generally be avoided because of the possible additive effects on QT interval prolongation.

**Clinical evidence, mechanism and importance and management**

(a) **Nadolol**

A study, in which 7 healthy subjects were given a single 80-mg dose of nadolol after erythromycin 500 mg plus neomycin 500 mg every 6 hours for 2 days, suggested an increase in the rate of beta blocker absorption (reduced to time maximum plasma level, but no effect on AUC). A decrease in the elimination half-life was also seen. More study is needed to determine the clinical significance of these findings.

(b) **Sotalol**

Sotalol prolongs the QT interval and should generally not be given with other drugs that do the same, such as intravenous erythromycin, because of the increased risk of torsade de pointes arrhythmia (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). Telithromycin does not appear to be associated with QT prolongation and a study in 24 healthy women found that a single 800-mg dose of telithromycin had no adverse effect on the QT-prolongation induced by a 160-mg dose of sotalol. The telithromycin slightly reduced the AUC and maximum serum levels of sotalol, which was attributed to a decrease in its absorption, but this is expected to be of little clinical significance.

(c) **Talinolol**

A single-dose study in 8 healthy subjects found that the AUC and serum levels of talinolol 50 mg were increased by 51% and 26%, respectively, by erythromycin 2 g. It was suggested that the increased bioavailability of talinolol was due to increased intestinal absorption caused by the inhibition of P-glycoprotein by erythromycin.\(^3\)

**Beta blockers + Metoclopramide**

A patient with scleroderma suffered a fatal cardiac arrest after receiving postoperative intravenous labetalol and intravenous metoclopramide. Metoclopramide increased the rate of absorption of a conventional formulation of propranolol, but did not affect a sustained-release preparation.

**Clinical evidence, mechanism, importance and management**

(a) **Labetalol**

A 38-year-old patient with scleroderma, hypertension (for which she was taking lisinopril) and gangrene of her left index finger underwent minor hand surgery. While in postoperative care her blood pressure rose to 153/120 mmHg and she was given intravenous labetalol 10 mg. About 15 minutes later she experienced nausea and vomiting, which was treated with intravenous metoclopramide 10 mg. About 5 minutes later her heart rate decreased to 38 bpm and she became unresponsive with no palpable pulse: an ECG showed junctional bradycardia. She was initially resuscitated but died about 13 hours later after a further episode of bradycardia, despite full supportive treatment. It was noted that the bradycardia did not respond well to atropine, and there was persistent hypotension, despite escalating vasopressor use. Scleroderma and lisinopril may have contributed to the failure to resuscitate the patient. However, bradycardia or heart block and hypotension may occur with intravenous metoclopramide. In this patient the use of labetalol may have exacerbated the effects of metoclopramide by causing reductions in ventricular contractility due to its beta-adrenergic effects and limiting vasoconstrictive compensatory mechanisms due to alpha-adrenergic effects. However, it has subsequently been suggested that this reaction may have been due to local anaesthetic toxicity rather than a drug interaction,\(^3\) although this was disputed by the original authors.\(^3\) A study in 11 untreated hypertensive patients found that intravenous metoclopramide (7.5 micrograms/kg per minute for 30 minutes) caused a slight decrease in the responsiveness to labetalol 400 to 600 mg daily. However, metoclopramide only attenuated the systolic blood pressure response to labetalol by 3 mmHg: this effect seems unlikely to be clinically significant in most patients.\(^4\)

**Beta blockers + Morphine**

Morphine may moderately raise the serum levels of esmolol, but this is unlikely to be clinically important. The fatal doses of morphine and propranolol are markedly reduced by concurrent use in animals, but the clinical relevance of this in man is uncertain.

**Clinical evidence, mechanism, importance and management**

In a study in 10 healthy men a 3-mg injection of morphine sulfate increased the steady-state levels of a 300 microgram/kg per minute infusion of esmolol, given over 4 hours. However, the increases were only statistically significant in 2 of the subjects (increase of 46%), and were considered to be of no clinical importance. The pharmacokinetics of morphine were unchanged.\(^1\)

Studies in animals have shown that the median fatal dose of propranolol was reduced two to sevenfold by morphine in mice\(^2\) and the median lethal dose of morphine was reduced fivefold to sixfold by propranolol in rats.\(^3\) The same interaction has also been seen in dogs.\(^4\) There do not appear to be any published reports of synergistic toxicity involving morphine and propranolol, so the clinical relevance of this is uncertain.

**Beta blockers + Penicillins**

Plasma atenolol levels are halved by 1-g doses of ampicillin. The clinical importance of this is uncertain, but probably small. No important interaction occurs if atenolol is given with ampicillin.
250 mg every 6 hours. One brief report suggests that anaphylactic reactions to penicillins may be more severe in patients taking beta blockers.

Clinical evidence
A single 1-g dose of ampicillin reduced the AUC of a single 100-mg dose of atenolol by 40%, and decreased its bioavailability from 60 to 36% in 6 healthy subjects. Similarly, when atenolol 100 mg was given with ampicillin 1 g daily for 6 days, the mean steady-state plasma atenolol level was reduced by 52% (from 199 to 95 nanograms/mL), and the AUC was reduced by 52%. The blood pressure lowering effect of atenolol at rest was not affected, but after exercise a small rise in systolic pressure of up to 17 mmHg occurred, whereas diastolic pressure was unchanged. The effects of atenolol on reducing heart rate during exercise were diminished from 24% to 11% at 12 hours. A similar study showed that when a single 50-mg oral dose of atenolol was given with a single 1-g oral dose of ampicillin the AUC of atenolol was reduced by 51.5%, whereas when ampicillin 250 mg four times daily was given for 24 hours, the AUC was only reduced by 18.2%. A brief report describes 2 patients, one taking nadolol and one taking propranolol, who developed fatal anaphylactic shock after taking phenoxymethylpenicillin. The authors suggested that, as fatal reactions to penicillins are rare, the reaction had been exacerbated by the presence of a non-selective beta blocker.

Mechanism
Uncertain. Ampicillin apparently affects the absorption of atenolol.

Importance and management
Information is limited, but the absorption interaction appears to be established. The clinical importance awaits full evaluation but the modest effects on blood pressure and heart rate suggest that it is of limited importance. Information about other beta blockers and penicillins is lacking. Information on potentiation of anaphylaxis is too limited to make comment, but note that some evidence suggests that anaphylactic shock in patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine), see ‘Beta blockers + Inotropes and Vasopressors’, p.848.

**Beta blockers + Phenothiazines**

The concurrent use of chlorpromazine with propranolol, or thioridazine with pindolol, can result in a marked rise in the plasma levels of both drugs. Propranolol markedly increases plasma thioridazine levels. Both beta blockers and phenothiazines can cause hypotension, and these effects could be additive: a handful of case reports suggest that this could occasionally be serious. The concurrent use of sotalol and phenothiazines that prolong the QT interval should generally be avoided.

Clinical evidence

(a) Chlorpromazine
In 4 healthy subjects and one hypertensive patient the mean steady-state levels of propranolol 80 mg every 8 hours were raised by 70% (from 41.5 to 70.2 nanograms/mL) when they were given chlorpromazine 50 mg every 8 hours. The increase was considerable in some subjects but barely detectable in others. A sixth subject taking propranolol promptly fainted when getting out of bed after the first dose of chlorpromazine. He was found to have a pulse rate of 35 to 40 bpm and a blood pressure of 70/0 mmHg. He rapidly recovered, achieving a pulse rate of 85 bpm and a blood pressure of 120/70 mmHg when given atropine 3 mg. However, it is unclear whether the adverse effect was due to chlorpromazine alone, or to an interaction with propranolol.

Propranolol (mean daily dose 8.1 mg/kg) increased the serum chlorpromazine levels of 7 schizophrenics by about 100 to 500%, and raised the plasma levels of the active metabolites of chlorpromazine by about 50 to 100%. The same or similar work by the same authors is described elsewhere. One of the patients was withdrawn from the study because he suffered a cardiovascular collapse while taking both drugs. It has been suggested that the value of propranolol in the treatment of schizophrenia probably results from the rise in serum chlorpromazine levels.

A report briefly mentions a diabetic girl who had an episode of minor hypotension with chlorpromazine that appeared to have been exacerbated by sotalol. A schizophrenic patient taking chlorpromazine and tiotixene experienced delirium, grand mal seizures and skin photosensitivity, attributed to a rise in the serum levels of the antipsychotic drugs caused by increasing doses of propranolol (up to a total of 1200 mg daily). In 4 healthy subjects and one hypertensive patient the mean steady-state (a) Chlorpromazine

(b) Tioridazine
Serum pindolol levels were 2.5-fold higher in 7 patients taking thioridazine than in 17 patients taking haloperidol, phenytoin, and/or phenobarbital. Furthermore, pindolol 40 mg daily increased serum thioridazine levels by about 50% in 8 patients. Two patients stable taking thioridazine 600 or 800 mg daily had three and fivefold rises in plasma levels, respectively, when given propranolol, in increasing doses up to a total of 800 mg daily, over 26 to 40 days. No signs or symptoms of thioridazine toxicity were seen even though plasma levels had risen into the toxic range. Similarly, in another study thioridazine levels rose by about 55 to 370% in 5 patients taking propranolol 320 to 520 mg daily.

Mechanism
Pharmacokinetic evidence and animal studies suggest that propranolol and chlorpromazine mutually inhibit the liver metabolism of the other drug so that both accumulate within the body. The mechanism of the interaction between propranolol and thioridazine is probably similar. Both beta blockers and phenothiazines can cause hypotension, and these effects could be additive.

Importance and management
The interaction between propranolol and chlorpromazine appears to be established although information is limited. Concurrent use should be well monitored and the dosages reduced if necessary. The same precautions apply with propranolol and thioridazine. There seems to be no information about any interaction between other beta blockers and phenothiazines, but if the mechanism of interaction suggested above is true, it seems possible that other beta blockers that are mainly cleared from the body by liver metabolism might interact similarly with chlorpromazine, whereas those mainly cleared unchanged in the urine are less likely to have a pharmacokinetic interaction, although additive hypotensive effects would still be expected. See ‘Table 22.1’, p.833, for information on the metabolism of the commonly used systemic beta blockers.

Note that sotalol and some phenothiazines, including chlorpromazine and thioridazine prolong the QT interval (see ‘Table 9.2’, p.257 for a more extensive list). Combined use should therefore generally be avoided, because of the increased risk of torsade de points. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

**Beta blockers + Phenylpropanolamine**

A small rise in blood pressure may occur in patients taking beta blockers who take single doses of phenylpropanolamine. A marked rise in blood pressure has been seen in one patient taking...
oxprenolol with methylidopa when phenylpropanolamine was also taken. Propranolol attenuates the blood pressure rise seen with phenylpropanolamine.

Clinical evidence, mechanism, importance and management

(a) Effect on beta blockers

A study in 13 patients taking various antihypertensives including 5 taking unnamed beta blockers found that a single dose of Dimetapp Extentabs (phenylpropanolamine 75 mg with brompheniramine 12 mg) caused a blood pressure rise of 1.7/0.9 mmHg over a 4-hour period, which was not statistically or clinically significant.2 These rises in blood pressure after single doses are small and relatively short-lived, and probably of little clinical importance. Another study in 7 stabilised hypertensive patients taking beta blockers (atenolol 5 patients, metoprolol 1, propranolol 1) found that a single 25-mg dose of rapid-release phenylpropanolamine (Super Odrinex) increased the mean peak blood pressures by about 8.5 mmHg over a 6-hour period.2 A later multiple dose study in the same subjects (only 5 of whom completed the study), taking the same beta blockers, found that on day 1 phenylpropanolamine increased diastolic blood pressure by 9 to 16 mmHg, and on day 7 by 0 to 14 mmHg. The day 1 and day 7 results were not statistically different, which suggests that the increase in blood pressure is not enhanced by multiple dosing.3 Note that a marked rise in blood pressure was seen in one patient taking methylidopa and oxprenolol when phenylpropanolamine was also given, see ‘Methylidopa + Sympathomimetics: Indirectly-acting’, p.898.

(b) Effect on phenylpropanolamine

In a placebo-controlled study in 6 healthy subjects, propranolol given either orally as a pretreatment or intravenously after phenylpropanolamine, was found to antagonise the rise in blood pressure induced by the phenylpropanolamine. Oral phenylpropanolamine 75 mg alone increased blood pressure from 116/63 to 148/83 mmHg; pretreatment with oral propranolol 80 mg every 6 hours reduced the baseline blood pressure to 107/62 mmHg and the increase with phenylpropanolamine was lower, reaching only 119/72 mmHg. Intraavenous propranolol 0.3 mg/kg given across the intesti-

Clinical evidence

(a) Pharmacokinetic effects

A study in 12 healthy subjects found that when sotalol 160 mg was given with hydrochlorothiazide 25 mg the pharmacokinetics of both drugs were unchanged.1

The manufacturers of celiprolol suggest that chlortalidone and hydrochlorothiazide reduce its bioavailability.2 This appears to be based on an in vitro study,3 which found that chlortalidone and hydrochlorothiazide blocked the active transport of celiprolol across the intesti-

Beta blockers + Potassium-depleting drugs

The use of potassium-depleting diuretics such as hydrochlorothiazide and sotalol that results in QT prolongation is established, clinically important and potentially life threatening. Prolongation of the QT interval and the development of torsade de pointes in patients taking sotalol, particularly at high doses (said to be greater than 320 mg daily),6 is a recognised adverse effect, but it can occur even with small doses of sotalol if potassium depletion is allowed to develop. It is clearly very important therefore to ensure that potassium levels are maintained if potassium-depleting drugs are given with sotalol. A list of potassium-depleting diuretics is given in ‘Table 26.1’, (p.944). Other drugs that may cause potassium depletion include corticosteroids, some laxatives, and intravenous amphotericin.

The interactions of chlortalidone and hydrochlorothiazide with celipro- lol are poorly documented and their clinical significance is unclear, although it would be expected to be limited.

(b) QT-prolongation

A 4-year study in cardiac clinics in South Africa identified 13 patients who developed syncope and a prolonged QT interval while taking sotalol 80 to 480 mg daily. Twelve patients were taking a combined preparation (Sota- zide) containing sotalol 160 mg and hydrochlorothiazide 25 mg. Eleven patients were being treated for hypertension, one for ventricular asystole, and one for both. Polymorphous ventricular tachycardia was seen in 12 of the patients, and torsade de pointes were seen in 10 of these 12. Arrhythmias occurred within 72 hours of starting sotalol in 6 patients, and at varying intervals from 10 days to 3 years in the other 6 patients. Definite hypokalaemia (defined by the study as serum potassium of less than 3.5 mmol/L) was detected in 8 of the 13 patients. Four of the patients were also taking other drugs known to prolong the QT interval, namely disopyramide and tricyclic antidepressants. The problems resolved in all of the cases within 12 hours of stopping the sotalol and giving potassium supplements when indicated.4 A further case has also been reported.5

Mechanism

Potassium-depleting drugs may cause hypokalaemia, which increases the potential for torsade de pointes arrhythmia with any drug that prolongs the QT interval, including sotalol.

Importance and management

The interaction between potassium-depleting diuretics such as hydrochlo- rothiazide and sotalol that results in QT prolongation is established, clinically important and potentially life threatening. Prolongation of the QT interval and the development of torsade de pointes in patients taking sotalol, particularly at high doses (said to be greater than 320 mg daily),6 is a recognised adverse effect, but it can occur even with small doses of sotalol if potassium depletion is allowed to develop. It is clearly very important therefore to ensure that potassium levels are maintained if potassium-depleting drugs are given with sotalol. A list of potassium-depleting diuretics is given in ‘Table 26.1’, (p.944). Other drugs that may cause potassium depletion include corticosteroids, some laxatives, and intravenous amphotericin.

The interactions of chlortalidone and hydrochlorothiazide with celipro- lol are poorly documented and their clinical significance is unclear, although it would be expected to be limited.

Plasma metoprolol and propranolol levels can be markedly raised (two to fivefold) by propafenone. Toxicity may develop.

Clinical evidence

Four patients with ventricular arrhythmias taking metoprolol 150 to 200 mg daily had a two to fivefold rise in steady-state metoprolol serum levels when they were given propafenone 150 mg three times daily. One of them developed distressing nightmares, and another had acute left ventricular failure with pulmonary oedema and haemoptysis, which disappeared when the metoprolol dosage was reduced or stopped. In 4 other patients taking metoprolol 50 mg three times daily and propafenone 150 mg three times daily, it was found that stopping metoprolol did not affect propafenone plasma levels.1 Single-dose studies in healthy subjects found a twofold decrease in the clearance of metoprolol and a further 20% reduction in exercise-induced tachycardia at 90 minutes when propafenone was also given.3

A patient developed neurotoxicity (including vivid nightmares, fatigue, headache) when given metoprolol 100 mg daily in divided doses, which

Beta blockers + Propafenone
worsened while it was being withdrawn and replaced by propafenone 300 mg daily. The symptoms disappeared when both drugs were stopped.2

Propafenone 225 mg every 8 hours more than doubled the steady-state levels of propranolol 50 mg every 8 hours in 12 healthy subjects. However, the beta-blocking effects were only modestly increased and the propafenone pharmacokinetics remained unchanged.3

Mechanism
It is suggested that propafenone reduces the metabolism of metoprolol and propranolol by the liver, thereby reducing their clearance and raising serum levels.1,3

Importance and management
Information is limited but the interaction would seem to be established. Concurrent use need not be avoided but anticipate the need to reduce the dosage of metoprolol and propranolol. Monitor closely because some patients may experience adverse effects. If the suggested mechanism of interaction is correct it is possible (but not confirmed) that other beta blockers that undergo liver metabolism will interact similarly but not those largely excreted unchanged in the urine. See ‘Table 22.1’, (p.833) for the metabolism of some commonly used beta blockers. Also note that propafenone and the beta blockers have negative inotropic effects, which could be additive and result in unwanted cardiodepression.

Beta blockers + Proton pump inhibitors
Omeprazole does not interact with metoprolol or propranolol, and lansoprazole does not interact with propranolol.

Clinical evidence, mechanism, importance and management
Omeprazole 20 mg daily for 8 days had no effect on the steady-state plasma levels of propranolol 80 mg twice daily, and no effect on resting and exercised heart rates or blood pressure in 8 healthy subjects.1 Another study found that omeprazole 40 mg daily for 8 days had no effect on the steady-state plasma levels of metoprolol 100 mg daily.2 A double-blind crossover study in 18 healthy subjects found that lansoprazole 60 mg daily for 7 days did not significantly affect the pharmacokinetics of a single 80-mg dose of propranolol.3 No special precautions would seem necessary if these proton pump inhibitors are used with propranolol or metoprolol.

Beta blockers + Quinidine
An isolated report describes a patient taking quinidine who developed marked bradycardia when using timolol eye drops. Other reports describe orthostatic hypotension when quinidine was given with atenolol or propranolol. Quinidine can raise plasma metoprolol, propranolol, and timolol levels, but the clinical relevance of this is uncertain.

Both sotalol and quinidine can prolong the QT interval, which may increase the risk of torsade de points arrhythmia if they are used together.

Clinical evidence
(a) Atenolol
Orthostatic hypotension occurred in a 56-year-old woman taking isosorbide dinitrate, diltiazem and quinidine sulfate 300 mg four times daily, 3 days after she started atenolol 50 mg daily. This resolved within 2 days of stopping the atenolol. Before starting the quinidine, she had previously taken atenolol and the other drugs without problems.1

(b) Metoprolol
A metabolic study in 5 healthy subjects who were extensive CYP2D6 metabolisers found that a single 50-mg dose of quinidine markedly inhibited the metabolism of a single 100-mg dose of metoprolol, which effectively made the subjects into poor metabolisers. The plasma levels of metoprolol were approximately tripled. Quinidine had no effect on metoprolol pharmacokinetics in 5 poor metabolisers.2 Similar results have been found when quinidine 50 mg daily was given with metoprolol 100 mg twice daily for 7 days,3 and when a 20-mg dose of metoprolol was given intravenously following either a single 50-mg dose of quinidine or quinidine slow-release tablets 250 mg twice daily for 3 days. The effect on heart-rate reduction was small given the increase in metoprolol levels.5

(c) Propranolol
A single-dose pharmacokinetic study found that quinidine 200 mg doubled the AUC and the peak plasma levels of a 20-mg dose of propranolol. Maximum heart rates during exercise were suppressed by a further 45%.2 A similar study by the same research group found that the AUC of propranolol was increased by about threefold by quinidine.3 A further study found that quinidine doubled the AUC of propranolol and halved its clearance resulting in increased beta-blockade.7 After a single 200-mg dose of quinidine the peak plasma quinidine levels were over 50% higher and its clearance almost 40% lower in 7 patients taking propranolol 40 to 400 mg daily, when compared with 8 control patients, but the quinidine elimination half-life did not differ.9 However, this interaction was not found in two other studies.9,10

A man taking propranolol 40 mg four times daily developed orthostatic hypotension, with symptoms of dizziness and faintness on standing, when he took quinidine 200 mg four times daily. This resolved when quinidine was withdrawn.11 The same authors subsequently briefly reported another two cases of orthostatic hypotension when quinidine was given with unnamed beta blockers.12

(d) Sotalol
Although one study reports the safe concurrent use of sotalol and quinidine,13 both drugs can prolong the QT interval, which may increase the risk of torsade de points arrhythmia if they are used together. See ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257, for a general review of QT-prolongation and drug interactions.

(e) Timolol
An elderly man taking quinidine sulfate 500 mg three times daily for premature atrial beats was hospitalised with dizziness 12 weeks after starting to use timolol 0.5% eye drops for open-angle glaucoma. He was found to have a sinus bradycardia of 36 bpm. The symptoms abated when the drugs were withdrawn and normal sinus rhythm returned after 24 hours. The same symptoms developed within 30 hours of re-starting both drugs, but disappeared when the quinidine was withdrawn.14 In a later study in healthy subjects, a single 50-mg oral dose of quinidine was given 30 minutes before 2 drops of timolol 0.5% ophthalmic solution, put into each nostril. In 13 extensive CYP2D6 metabolisers, quinidine caused a further decrease in heart rate and increase in plasma timolol levels compared with timolol alone. Giving quinidine with timolol in these extensive metabolisers gave results similar to giving timolol alone in 5 poor metabolisers.15 In another study, quinidine augmented the plasma levels and cardiac effects of intravenous timolol.16

Mechanism
Quinidine appears to increase metoprolol, propranolol and timolol plasma levels by inhibiting the cytochrome P450 isoenzyme CYP2D6, thereby reducing their clearance.4,5,13 As CYP2D6 shows polymorphism, these interrelations would be most apparent in patients with high CYP2D6 activity (extensive metabolisers), effectively making them poor metabolisers. See ‘Genetic factors’, (p.4), for further information on polymorphism.

Importance and management
The pharmacokinetic interaction would seem to be established, but of uncertain clinical importance. Only one isolated case of possible excessive beta-blockade has been reported (with quinidine and timolol eye drops). Concurrent use need not be avoided (and may be beneficial in the treatment of atrial fibrillation), but some care is warranted as both quinidine
and the beta blockers have negative inotropic effects, which could be additive and result in unwanted cardiodepression. The general relevance of the isolated reports of orthostatic hypotension with atenolol or propranolol and quinidine is uncertain.

The general consensus is that the combination of two drugs that prolong the QT interval such as quinidine and sotalol should usually be avoided, or only used with great caution. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Beta blockers + Rifampicin (Rifampin)

Rifampicin increases the clearance of bisoprolol, carvedilol, celiprolol, metoprolol, propranolol, tadalafil and talinolol, and reduces their serum levels. The extent to which this reduces the effects of these beta blockers is uncertain, but it is probably small. Similar effects have been seen when atenolol is given with rifampicin, but a case report suggests that occasionally the effects may be of clinical relevance.

Clinical evidence

(a) Atenolol

A case report describes a man taking atenolol for angina whose exercise threshold before developing angina symptoms appreciably worsened when he was given rifampicin. Rifampicin was stopped, and after a week rifabutin was started. Rifabutin did not cause any change in his baseline exercise tolerance.1 In a randomised, placebo-controlled, crossover study, 9 healthy subjects were given rifampicin 600 mg daily for 5 days, with a single 100-mg dose of atenolol on day 6. Although some pharmacokinetic changes were seen they were variable between subjects and in most cases slight. Heart rate and blood pressure were on average slightly higher in the presence of rifampicin (3.5 bpm and 4.3/3.9 mmHg, respectively), suggesting a modest reduction in the effects of atenolol, which was expected to be of only minor clinical relevance.2

(b) Bisoprolol

The AUC of bisoprolol 10 mg daily was reduced by 34% in healthy subjects given rifampicin 600 mg daily.3

(c) Carvedilol

Rifampicin 600 mg daily for 12 days caused a 60% decrease in the maximum serum levels and the AUC of carvedilol.4

(d) Celiprolol

In a study in healthy subjects, rifampicin 600 mg daily reduced the AUC of a single 200-mg dose of celiprolol by 55%.5

(e) Metoprolol

In a study in healthy subjects, rifampicin 600 mg daily reduced the AUC of a single 100-mg dose of metoprolol by 33%.6

(f) Pranolol

Rifampicin 600 mg daily for 3 weeks increased the oral clearance of propranolol in 6 healthy subjects by almost threefold. Increasing the rifampicin dosage to 900 or 1200 mg daily did not further increase the clearance. Four weeks after withdrawing the rifampicin the blood levels of propranolol had returned to normal.7 In a similar study the oral clearance of propranolol was increased by about fourfold by rifampicin 600 mg daily for 3 weeks in both poor and extensive metabolisers of propranolol.8

(g) Talinolol

Rifampicin 600 mg daily decreased the AUC of a single-dose of talinolol 30 mg intravenously or 100 mg orally by 21 and 35%, respectively, in 8 healthy subjects.9

(h) Tertatolol

Rifampicin 600 mg daily for a week increased the clearance of tertatolol almost threefold and reduced the half-life from 9 to 3.4 hours. A slight reduction in the effects of tertatolol on blood pressure was seen and heart rates were raised from 68 to 74 bpm.10

Mechanism

Rifampicin is a potent liver-enzyme inducer that increases the metabolism and loss of extensively metabolised beta blockers such as propranolol and metoprolol. Rifampicin may also interact by mechanisms other than enzyme induction. Rifampicin increases duodenal P-glycoprotein expres-

Beta blockers + Quinolones

Ciprofloxacin reduces metoprolol clearance, but this is probably clinically unimportant. The concurrent use of sotalol and quinolones that prolong the QT interval should generally be avoided.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

Preliminary evidence from 7 healthy subjects given a single 100-mg dose of metoprolol suggested that pretreatment with 5 doses of ciprofloxacin 500 mg, given every 12 hours, increased the AUC of (−)-metoprolol by 54% and reduced its clearance by 38.5%. The AUC of (−)-metoprolol was increased by 29% and its clearance reduced by 12%.1 It has been suggested that this interaction may occur because ciprofloxacin inhibits the activity of the cytochrome P450 isoenzymes concerned with the metabolism and clearance of metoprolol. However, this is questionable as metoprolol is metabolised, predominantly, by CY2D6 while ciprofloxacin inhibits CYP1A2. Changes of this size, or even more, in the AUC of beta blockers have proved to be clinically important with other enzyme-inhibiting drugs, and it seems probable that this will be the case with ciprofloxacin, but this needs confirmation.

(b) Quinolones that prolong the QT interval

In an analysis of cases of torsade de pointes associated with fluoroquinolones on the FDA Adverse Events Reporting System database, two cases of torsade de pointes were noted in patients taking a fluoroquinolone with sotalol (there were 37 cases identified, and 19 occurred in patients also taking other drugs known to prolong the QT interval).1 Sotalol has class III antiarrhythmic effects and prolongs the QT interval, and this could be additive with the effects of quinolones that prolong the QT interval (e.g. gatifloxacin, moxifloxacin, sparfloxacin, see ‘Table 9.2’, (p.257)). The concurrent use of sotalol and these quinolones should generally be avoided (see ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

1. Waite NM, Rutledge DR, Warbashe LH, Edwards DJ. Disposition of the (−) and (−)−isomers of metoprolol following ciprofloxacin treatment. Pharmacotherapy (1990) 10, 236.
sion, so increased clearance of talinolol (which is not metabolised) may be due to induction of P-glycoprotein excretion. The effects on atenolol, which is not extensively metabolised, are also possibly due to induction of P-glycoprotein, although this needs confirmation.

Importance and management

These interactions are established. Their clinical importance is uncertain but probably small. Nevertheless, they cannot be completely dismissed as the case report with atenolol shows. Considering increasing the dosage of the beta blocker if there is any evidence that the therapeutic response is inadequate. Beta blockers that undergo extensive liver metabolism would be expected to be affected by the enzyme-inducing effects of rifampicin (see ‘Table 22.1’). Those beta blockers mainly lost unchanged in the urine would not be expected to be affected, but it appears that a reaction may occur with non-metabolised drugs, such as talinolol, that are substrates for P-glycoprotein. More study is required.

Beta blockers + Sevelamer

The concurrent use of a single 2.418-g dose of sevelamer did not alter the AUC of a single 100-mg dose of metoprolol in 31 healthy subjects.

Beta blockers + SSRIs

Fluoxetine can increase serum pindolol and carvedilol levels, but the clinical effects of this are minimal. Isolated reports describe lethargy and bradycardia in patients taking metoprolol with fluoxetine and propranolol with fluoxetine or fluvoxamine. Increased pindolol levels may increase the levels of propranolol, but not atenolol. Paroxetine may increase levels of metoprolol when compared with a single 5-mg dose of pindolol. Only mild to moderate effects on pulse rate and blood pressure were seen. Some studies suggested that the antidepressant response to fluoxetine is accelerated by pindolol while other studies in patients with predominantly chronic or recurrent depression did not find an enhanced response. A double-blind crossover study in 10 patients with heart failure, taking carvedilol 25 to 50 mg twice daily, found that the addition of fluoxetine 20 mg daily for 28 days increased the AUC of (R)- and (S)-carvedilol by 77%, and decreased the clearance of both enantiomers by 44 to 56%. However, these pharmacokinetic changes were of little clinical significance, since there were no changes in blood pressure, heart rate, and heart rate variability.

(d) Fluvoxamine

A 79-year-old man who had taken propranolol for prophyaxis of migraine for several years developed fatigue and lightheadness within a few days of starting fluvoxamine. He was admitted to hospital with syncope and bradycardia of 38 bpm but recovered after both drugs were discontinued. Fluvoxamine 100 mg daily raised the plasma levels of propranolol 160 mg daily fivefold in healthy subjects, but the bradycardic effects were only slightly increased (by 3 bpm). The diastolic pressure following exercise was only slightly reduced but the general hypotensive effects remained unaltered. Fluvoxamine did not change the plasma levels of atenolol 100 mg daily, but the heart-slowing effects were slightly increased and the hypotensive effects were slightly decreased.

(f) Paroxetine

A study in 8 healthy subjects found that paroxetine 20 mg daily for 6 days increased the AUCs of (R)- and (S)-metoprolol by eightfold and fivefold, respectively, after a single 100-mg dose of metoprolol. The maximum plasma concentration and elimination half-life were increased about twofold. The beta-blocking effects of metoprolol were more sustained and the reduction in exercise systolic pressure was more pronounced when paroxetine was also taken, when compared with metoprolol alone.

(f) Sertraline

No changes in the beta-blocking effects of atenolol were found in a single-dose study in 10 healthy subjects given sertraline 100 mg five hours before atenolol 50 mg.

Mechanism

Fluoxetine and paroxetine inhibit the cytochrome P450 isoenzyme CYP2D6 thus inhibiting the metabolism of some beta blockers (e.g. propranolol, metoprolol, carvedilol) so that they accumulate, the result being that their effects, such as bradycardia, may be increased. Citalopram and escitalopram may also inhibit CYP2D6. In vitro studies with human liver microsomes found that fluoxetine and paroxetine are potent inhibitors of metoprolol metabolism and fluvoxamine, sertraline and citalopram less potent. However, fluvoxamine also potently inhibits the metabolism of propranolol by CYP1A2 and beta blockers that are not extensively me-
tabolised, such as atenolol and sotalol, would not be expected to be affected.

Pindolol may augment the antidepressant effect of fluoxetine by its antagonistic effects at 5-HT1A receptors.8,17

Importance and management

Pharmacokinetic interactions have been found between fluoxetine, fluvoxamine or paroxetine and some beta blockers, but despite marked pharmacokinetic changes, the clinical effects are not generally significant. However, be aware that there are a few isolated reports of severe bradycardia with beta blockers and fluoxetine or fluvoxamine. If problems arise, the interaction can apparently be avoided by giving a beta blocker (such as atenolol), which is not extensively metabolised. Alternatively, sertraline and citalopram seem to be less likely than the other SSRIs to interact with extensively-metabolised beta blockers.15 However, because metoprolol is considered to have a narrow therapeutic index in the treatment of heart failure, the UK manufacturers of escelorolam say that caution and possible dosage adjustments are warranted on concurrent use.18 Similarly the manufacturers of paroxetine suggest that concurrent use should be avoided if metoprolol is being used for heart failure.19 Remember that fluoxetine and particularly its metabolite have long half-lives so that this interaction may possibly still occur for some days after the fluoxetine has been stopped. Also note that bradycardia occurs rarely with fluoxetine alone and in some cases an interaction may be pharmacodynamic rather than pharmacokinetic, and so swapping the beta blocker could, rarely, be ineffective.

The combination of pindolol with fluoxetine may be advantageous in the treatment of depression in some patients.7,8

Clinical evidence

Oxprenolol 80 mg twice daily was given to 10 hypertensive subjects for 15 days, which reduced their mean supine blood pressure from 161/101 to 149/96 mmHg, and their heart rate from 72 to 66 bpm. When they were additionally given sulfinpyrazone 400 mg twice daily for 15 days, their mean blood pressure rose to about the former level. The reduction in mean heart rate remained unaffected. Sulfinpyrazone attenuated the reduction in cardiac workload seen with oxprenolol alone by about half.1

A study in 9 healthy subjects found that sulfinpyrazone 400 mg twice daily did not affect the pharmacokinetics of metoprolol 100 mg twice daily. No adverse effects were noted in healthy subjects during concurrent use.2

Mechanism

Not understood. One idea is that the sulfinpyrazone inhibits the production of vasodilatory (antihypertensive) prostaglandins by the kidney. This would oppose the actions of the oxprenolol.

Importance and management

Information seems to be limited. If sulfinpyrazone is given to patients taking oxprenolol for hypertension, the effects should be monitored. It seems likely that this interaction could be accommodated by raising the dosage of the oxprenol but this needs confirmation. The effect of this interaction on cardiac workload appears to be less important, but it would still be prudent to monitor concurrent use if oxprenolol is used for angina. Metoprolol may be a suitable alternative to oxprenolol as it does not appear to interact with sulfinpyrazone.

Beta blockers + Tobacco ± Coffee and Tea

Tobacco smoking can reduce the beneficial effects of beta blockers on heart rate and blood pressure. Some increase in the dosage of the beta blocker may be necessary. Drinking tea or coffee may have a similar but smaller effect.

Clinical evidence

(a) Caffeine

Two 150-mL cups of coffee (made from 24 g of coffee) increased the mean blood pressure of 12 healthy subjects taking propranolol 240 mg, metoprolol 300 mg or a placebo. Mean blood pressure rises were 7%/22% with propranolol, 7%/19% with metoprolol and 4%/16% mmHg with placebo. The beta blockers and placebo were given in divided doses over 15 hours before the test.2

(b) Tobacco smoking

A double-blind study in 10 smokers with angina pectoris, taking daily doses of either propranolol 240 mg, atenolol 100 mg or a placebo, found that smoking reduced their plasma propranolol levels by 25% when compared with a non-smoking phase. Plasma atenolol levels were not significantly altered. Both of the beta blockers reduced heart rate at rest and during exercise, but the reductions were less when subjects smoked (effects attenuated by 8 to 14%).2

Other studies found that serum propranolol levels in smokers were about half those in non-smokers.3,4 Smoking caused an increase in blood pressure and heart rate in patients with angina and these effects were still evident, to a reduced extent, during propranolol treatment. In addition smoking abolished the beneficial effects of propranolol on ST-segment depression.5

(c) Tobacco smoking and caffeine

Eight patients with mild hypertension taking propranolol 80 mg twice daily, oxprenolol 80 mg twice daily or atenolol 100 mg daily over a 6-week period had their blood pressure monitored after smoking 2 tipped cigarettes and drinking coffee, containing 200 mg of caffeine.
Mechanism

Smoking tobacco increases heart rate, blood pressure and the severity of myocardial ischaemia, probably as a direct effect of the nicotine and due to the reduced oxygen-carrying capacity of the blood.1,2 The blood pressure rise may be exaggerated in the presence of non-selective beta blockers, which block vasodilatation leaving the alpha vasoconstrictor response unopposed. This will also oppose the actions of the beta blockers.

Importance and management

Established interactions. Smoking tobacco and (to a very much lesser extent) drinking tea or coffee oppose the effects of the beta blockers in the treatment of angina or hypertension. Patients should be encouraged to stop smoking because, quite apart from its other toxic effects, it aggravates myocardial ischaemia, increases heart rate and can impair blood pressure control. If patients continue to smoke, it may be necessary to raise the dosages of the beta blockers. The effects of the caffeine in tea, coffee, cola drinks, etc. are quite small and there seems to be no strong reason to forbid them, but the excessive consumption of large amounts may not be a good idea, particularly in those who also smoke.

Atenolol + Allopurinol

Allopurinol 300 mg daily for 6 days did not affect the steady-state pharmacokinetics of atenolol 100 mg daily in 6 healthy subjects.1 No special precautions would therefore appear to be necessary on concurrent use.

Metoprolol + Acetylcholine

An isolated case describes bronchospasm, which developed in a patient taking metoprolol when intra-ocular acetylcholine was given.

Clinical evidence, mechanism, importance and management

An elderly patient with a history of hypertension, obstructive pulmonary disease and stable angina, taking several drugs including metoprolol, experienced severe bronchospasm and pulmonary oedema immediately following the intra-ocular injection of acetylcholine chloride during cataract surgery. Her blood pressure rapidly increased, and she became tachycardic. She had also received phenylephrine eye drops before surgery. The
As propranolol is partly metabolised by CYP1A2, the US manufacturers suggest that any interaction seems unlikely. However, note that propranolol levels may occur when the manufacturers list ritonavir as an inhibitor of CYP1A2, and this possible interaction may be of greater clinical significance as ritonavir can also inhibit CYP2D6, the other main route of propranolol metabolism. In this case, a large rise in propranolol levels may therefore occur. It would therefore seem prudent to be cautious if ritonavir is given with propranolol.

(c) CYP2C19 substrates or inhibitors

The US manufacturers suggest that raised propranolol levels may occur with fluconazole or tolbutamide, which are inhibitors of CYP2C19 and a substrate for CYP2C19, respectively. However, CYP2C19 only plays a small part in propranolol metabolism. Further, the manufacturers also note that omeprazole and lansoprazole (inhibitors and substrates for CYP2C19) do not interact, and so a clinically significant interaction involving CYP2C19 seems unlikely.

### Propranolol + Dextromoramide

An isolated report describes two patients who developed marked bradycardia and severe hypotension when they were given propranolol and dextromoramide following the induction of anaesthesia.

Clinical evidence, mechanism, importance and management

Two women about to undergo a partial thyroidectomy were given propranolol 30 mg and dextromoramide 1.25 or 4 mg by injection during the pre-operative period, after which anaesthesia was induced with a barbiturate. Each woman developed marked bradycardia and severe hypotension, which responded rapidly to intravenous atropine. The reasons for this response are not understood and the general significance of this interaction is unclear.

### Propranolol + Miscellaneous

The manufacturers predict that propranolol levels will be raised by a number of drugs, but only the possible interaction with ritonavir appears to be of much concern.

Clinical evidence, mechanism, importance and management

(a) CYP2D6 inhibitors

As propranolol is metabolised by CYP2D6 the US manufacturers suggest that inhibitors of this isoenzyme may inhibit propranolol metabolism. Some CYP2D6 inhibitors have been seen to interact (such as ‘quinidine’, (p.853)), but the pharmacokinetic effects seem modest in many cases, probably because propranolol is also metabolised by CYP1A2. An interaction with ritonavir (as predicted by the manufacturers) therefore seems possible, and the effects may be greater than those seen with other CYP2D6 inhibitors (see (b) below).

(b) CYP1A2 substrates or inhibitors

As propranolol is partly metabolised by CYP1A2 the US manufacturers predict that its levels may be raised by substrates or inhibitors of this isoenzyme. However, data for ‘imipramine’, (p.1246), ‘isoniazid’, (p.310), and ‘theophylline’, (p.1175), (substrates of CYP1A2) suggest that in fact propranolol raises the levels of these drugs.

Inhibitors of CYP1A2 raise propranolol levels (as seen with ‘fluvoxamine’, (p.855)) and therefore an interaction with ciprofloxacin (as predicted by the manufacturers) seems possible. However, note that propranolol levels fluctuate greatly between individuals, and propranolol is not exclusively metabolised by CYP1A2, and so any interaction seems likely only to produce moderate clinical effects. Note that the manufacturers of propranolol also list ritonavir as an inhibitor of CYP1A2, and this possible interaction may be of greater clinical significance as ritonavir can also inhibit CYP2D6, the other main route of propranolol metabolism (see (a) above). A large rise in propranolol levels may therefore occur. It would therefore seem prudent to be cautious if ritonavir is given with propranolol.

### Propranolol + Ascorbic acid (Vitamin C)

Vitamin C reduces the bioavailability of propranolol but the extent is too small to be of clinical significance.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects given a single 80-mg dose of propranolol found that a single 2-g dose of vitamin C reduced the maximum plasma levels of propranolol by 28%, reduced the AUC by 37% and reduced its recovery in the urine by 66%. The fall in heart rate was also slightly reduced. The reason for this interaction appears to be that vitamin C reduces both the absorption and the metabolic conjugation of propranolol. However, none of the changes seen would appear to be of clinical relevance.

### Propranolol + Misoprostol

Misoprostol does not significantly alter the pharmacokinetics of propranolol.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects misoprostol 400 micrograms twice daily raised the AUC of propranolol 80 mg twice daily by about 20 to 40%, and this remained raised 7 days after misoprostol was discontinued. However, as these findings were unexpected, the authors conducted a randomised, crossover, placebo-controlled study and ensured that propranolol was at steady state before assessing the effect of misoprostol. No significant effects on the pharmacokinetics of propranolol were found. No special precautions would therefore seem necessary during concurrent use.

### Propranolol + Nefazodone

Nefazodone does not significantly affect the pharmacokinetics of propranolol.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that nefazodone 200 mg every 12 hours reduced the AUC of propranolol 40 mg every 12 hours by 14% and decreased the maximum plasma levels by 29%, but no clinically significant changes in the response to propranolol or relevant adverse responses were seen. The pharmacokinetics of the nefazodone were largely unchanged. No special precautions would therefore seem to be necessary if both drugs are used.

### Propranolol + Sucrose polyesters

There is evidence that sucrose polyesters (e.g. Olestra) do not interact with propranolol.
Clinical evidence, mechanism, importance and management

Eight healthy subjects were given sucrose polyester 18 g and a single un-stated dose of propranolol. Sucrose polyester had no effect on the pharmacokinetics of propranolol. Sucrose polyesters are non-absorbable, non-calorific fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general.

Sotalol + Terfenadine

Episodes of torsade de pointes arrhythmia developed in a woman taking sotalol when terfenadine was added.

Clinical evidence, mechanism, importance and management

A 71-year-old woman with a history of atrial fibrillation was successfully treated with sotalol 80 mg twice daily. She started to take terfenadine 60 mg twice daily, and 8 days later she developed repeated self-limiting episodes of torsade de pointes arrhythmia. On one occasion she required resuscitation. Both drugs were stopped and no further episodes of arrhythmia occurred 72 hours after temporary pacing was discontinued. It seems likely that what happened resulted from the additive effects of both drugs on the QT interval, which can lead to the development of torsade de pointes. This case confirms a previous mention of the possibility of this interaction.

Although this seems to be the first report of this interaction, it is consistent with the known pharmacology of both drugs. Torsade de pointes is potentially life threatening, so the concurrent use of these two drugs should generally be avoided. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Talinolol + Sulfasalazine

Sulfasalazine markedly reduces the absorption of talinolol.

Clinical evidence

The AUC of talinolol 50 mg was reduced by 91% (from 958 to 84 nanograms/mL per hour) in 8 healthy subjects given sulfasalazine 4 g. The maximum serum levels were also markedly reduced, from 112 to 23 nanograms/mL in 3 subjects, and to undetectable levels in the other 5 subjects.

Mechanism

Not known. It is suggested that talinolol is adsorbed onto the sulfasalazine, thereby preventing its absorption.

Importance and management

Information is limited to this study, but it would appear to be an established and probably clinically important interaction. The efficacy of the talinolol would be expected to be markedly reduced, but this does not appear to have been studied. If the mechanism suggested by the authors is true, their advice to separate the dosages by 2 to 3 hours should minimise this interaction. More study is needed to confirm how effective this action is, and whether other beta blockers behave similarly.

Calcium-channel blockers

Calcium-channel blockers in current clinical usage affect the slow L-type channel. They are usually classified by their chemical structure, which determines their selectivity for vascular smooth muscle over myocardium, and hence their potential to slow the heart rate (negative inotropic activity) see ‘Table 23.1’, (below). Interactions due to additive inotropic effects will therefore apply only to the benzothiazepine (diltiazem) and phenylalkylamine-type (verapamil) calcium-channel blockers, and usually not to the dihydropyridine-type (e.g. nifedipine) calcium-channel blockers. All three types of calcium-channel blocker will have additive hypotensive effects with other drugs with blood-pressure lowering activity.

Calcium-channel blockers also undergo interactions due to altered metabolism. Both verapamil and diltiazem are principally metabolised by the cytochrome P450 isoenzyme CYP3A4, and also inhibit this enzyme (see ‘Table 1.4’, (p.6)). They are therefore affected by drugs that induce or inhibit CYP3A4, and also themselves interact with drugs metabolised by CYP3A4.

Many of the dihydropyridine-type calcium-channel blockers are also metabolised by CYP3A4, and are affected by inducers or inhibitors of this isoenzyme. However, they do not generally inhibit CYP3A4, or other isoenzymes to a clinically relevant extent. The exception is perhaps nicardipine, which may cause a clinically relevant inhibition of CYP3A4 (see ‘Table 1.4’, (p.6)).

This section is primarily concerned with those interactions where the activity of the calcium-channel blockers is changed by the presence of another drug. Where the calcium-channel blocker is the affecting agent, the relevant monograph is usually categorised under the heading of the affected drug.

Mibefradil is a calcium-channel blocker that acts on the fast T-type calcium channel. It was withdrawn soon after it was launched because of identification of an increasing number of serious drug interactions caused by its inhibitory effects on CYP3A4 and 2D6. It was thought that the practical problems of implementing all the warnings relating to these interactions were too difficult and risky.

†Nimodipine crosses the blood-brain barrier and therefore affects cerebral blood vessels, and is used for cerebral ischaemia.
An isolated report describes increased adverse effects in two patients when terfenadine was given to patients taking nifedipine or verapamil. Verapamil markedly increased the AUC of a single dose of fexofenadine in one study, but another study found a much more modest effect. However, even a marked increase may not be clinically important.

No pharmacodynamic interaction appears to occur between diltiazem and mizolastine, and mizolastine did not alter diltiazem pharmacokinetics. Nifedipine is predicted to increase the levels of mizolastine.

Clinical evidence, mechanism, importance and management

(a) Fexofenadine

In a study in 12 healthy subjects verapamil 240 mg daily for 6 days increased the AUC of a single 120-mg dose of fexofenadine 2.5-fold and increased the maximum level 2.9-fold with marked interindividual variation. Fexofenadine is not metabolised by the cytochrome P450 system, and it was suggested that verapamil may have increased fexofenadine bioavailability by inhibiting the drug transporters, P-glycoprotein or OATPs. Another study showed a smaller 30% increase in maximum level of fexofenadine when a single 60-mg dose was given to subjects who had taken verapamil 240 mg daily for 10 days. Moreover, after 38 days of verapamil, the maximum level and clearance of fexofenadine was not significantly changed.

Note that marked increases in fexofenadine levels with ‘erythromycin’, (p.589) and ‘ketocazole’, (p.584) did not increase adverse effects and were not associated with any prolongation of the QT interval. This suggests that a clinically relevant interaction between verapamil and fexofenadine is not expected, but some caution may be warranted until further experience is gained.

(b) Mizolastine

A double-blind crossover study in 12 healthy subjects taking diltiazem 60 mg three times daily found that the concurrent use of mizolastine 10 mg daily for 5 days did not alter ECGs or blood pressures. No significant increases in adverse effects were seen and the pharmacokinetics of mizolastine remained unchanged. However, mizolastine pharmacokinetics were not assessed. Some manufacturers of nifedipine and those of mizolastine suggest that concurrent use may raise mizolastine levels by inhibition of the cytochrome P450 isoenzyme CYP3A4, and caution is therefore advised, presumably because mizolastine has a weak potential to prolong the QT interval. If caution is required with nifedipine, then this should be extended to both diltiazem and verapamil, since these are both more potent inhibitors of CYP3A4 than nifedipine. Further study is needed.

(c) Terfenadine

An isolated report describes severe angina in a patient stabilised on nifedipine 10 mg three times daily when she took terfenadine 60 mg for seasonal allergy. A second patient taking verapamil 80 mg three times daily also experienced adverse effects (including severe headache and confusion) when a single 60-mg dose of terfenadine was taken. Verapamil, diltiazem, and to a lesser extent some dihydropyridine calcium-channel blockers (e.g. nicardipine) are inhibitors of CYP3A4, but there appear to be no other reports of interactions with either terfenadine or astemizole (substrates of CYP3A4). Of all the calcium-channel blockers, only the manufacturers of lercanidipine advise caution during the concurrent use of terfenadine and astemizole.

The absorption of verapamil can be modestly reduced by antineoplastic regimens containing cyclophosphamide, vincristine, and procarbazine, or vindesine, doxorubicin, cisplatin.

Clinical evidence, mechanism, importance and management

A study in 9 patients with a variety of malignant diseases found that treatment with antineoplastics reduced the absorption of a single 160-mg oral dose of verapamil. The verapamil AUC in 8 patients was reduced by 40% (range 7 to 58%), and one patient conversely had a 26% increase. Five patients received a modified COPP regimen (cyclophosphamide, vincristine, procarbazine, prednisone) and four received VAC (vindesine, doxorubicin, cisplatin). It is believed that these antineoplastic damage the lining of the upper part of the small intestine, which impairs the absorption of verapamil. The clinical relevance of this reduction does not appear to have been studied. Note that verapamil may affect levels of ‘anthracyclines’, (p.611), ‘etoposide’, (p.631), and possibly ‘docetaxel’, (p.662). In addition, nifedipine may affect the levels of ‘vincristine’, (p.671).

The concurrent use of aprepitant and diltiazem markedly increases the levels of both drugs.
Clinical evidence

A. Antagonism of antihypertensive effects

Various large epidemiological studies and meta-analyses of clinical trials have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, and the findings of these are summarised in ‘Table 23.2’, (below). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both COX-2 inhibitors and non-selective NSAIDs. In two meta-analyses,1,2 the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between indomethacin and sulindac in one analysis.3 Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,1 the effect was greatest for piroxicam, indomethacin, and ibuprofen, intermediate for naproxen, and least for sulindac and flurbiprofen. In the other meta-analysis,2 the effect was greatest for indomethacin and naproxen, intermediate for piroxicam, and least for ibuprofen and sulindac. An attempt was also made to evaluate the effect of antihypertensive drugs in one analysis.1 The mean effect was greatest for beta blockers, intermediate for ACE inhibitors and non-selective NSAIDs. In two meta-analyses,1,2 the effect was greatest for naproxen, and least for sulindac in patients treated with antihypertensives.4,5 The findings of individual clinical and pharmacological studies that have studied the effects of aspirin or specific NSAIDs on specific calcium-channel blockers are outlined in the subsections below.

(a) Aspirin
1. Felodipine. In the Hypertension Optimal Treatment (HOT) study, 18 790 treated hypertensive patients, about 82% of whom received a calcium-channel blocker, usually felodipine alone or in combination, were also given either aspirin 75 mg daily or placebo for an average of 3.8 years. It was found that long-term low-dose aspirin does not interfere with the blood pressure-lowering effects of the antihypertensive drugs studied.3
2. Nifedipine. In a small study in 18 patients, low-dose aspirin 100 mg daily for 2 weeks did not alter the blood pressure lowering effect of nifedipine 30 to 60 mg daily, given as a modified-release preparation.4
3. Nitrendipine. A post-hoc analysis of the Syst-Eur trial of nitrédipine-based antihypertensive treatment found no difference in cardiovascular outcome between 861 patients who were also using long-term aspirin (700 patients) and/or other NSAIDs (161) and 2882 patients who had never taken aspirin or NSAIDs. Patients in this trial were randomised to receive nitrendipine, which could be combined or replaced by enalapril, hydrochlorothiazide, or both.5
4. Unnamed calcium-channel blockers. In a randomised study, the use of low-dose aspirin 100 mg daily for 3 months did not alter blood pressure control in patients taking calcium-channel blockers or ACE inhibitors, when compared with placebo.6

(b) Diclofenac
Hypertensive subjects taking slow-release verapamil 240 mg daily had a 26% reduction in the AUC of verapamil when they took diclofenac 75 mg twice daily.7 The AUC of isradipine 5 mg twice daily for a week was unaffected in 18 healthy subjects by a single 50-mg dose of diclofenac but the maximum serum levels were raised by about 20%. Platelet aggregation

was unaffected and the pharmacokinetics of the diclofenac were unchanged.8
A study in elderly women with hypertension found that diclofenac sodium 25 mg three times daily for one week had no effect on the control of their blood pressure with nifedipine.9

(c) Ibuprofen
Fifty-three hypertensive patients had no changes in their blood pressure control with verapamil 240 or 480 mg daily when they also took ibuprofen 400 mg three times daily for 3 weeks.10 However, another study in 12 patients with mild or moderate essential hypertension controlled with amlo-
dipine 10 mg daily, found that ibuprofen 400 mg three times daily for 3 days increased the mean blood pressure by 7.8/3.9 mmHg.11

(d) Indometacin
Indometacin 100 mg daily for a week did not significantly affect the hypoten-
sive effects of nifedipine 20 mg twice daily in 10 patients with mild to moderate essential hypertension.12 In contrast, in another study, indometacin 100 mg in divided doses over 24 hours was found to raise the mean arterial pressure by 17 to 20 mmHg in 5 out of 8 hypertensive patients taking nifedipine 15 to 40 mg daily.13

Five other studies, two in healthy subjects14,15 and 3 in patients with hypertension16–18 found that indometacin did not alter the blood pressure-lowering effects of amlodipine,16 felodipine,14,16 nicardipine15 or verap-
aml.19 Similarly, the haemodynamic effects of nifedipine 30 mg three times daily were not affected to a clinically relevant extent by indometacin 25 mg twice daily in 24 healthy elderly subjects, although the AUC of ni-
modipine and its maximum plasma levels were slightly increased.15 However, indometacin 25 mg three times daily raised systolic and diastolic blood pressure by a mean of 4 mmHg in 15 patients taking nitrendipine 5 to 20 mg twice daily.20

(e) Naproxen
Naproxen 375 mg twice daily had no effect on the pharmacokinetics of ve-
rapamil in hypertensive subjects.21 Fifty-five hypertensive patients had no changes in their blood pressure control with verapamil 240 to 480 mg daily when they were given naproxen 250 mg twice daily for 3 weeks.22 A placebo-controlled study in 100 patients taking nicardipine 30 mg three times daily found that naproxen 375 mg twice daily caused no clinically relevant changes in the control of their blood pressure.21

(f) Piroxicam
A study in hypertensive patients given up to 440 mg of verapamil daily found that piroxicam 20 mg once daily for 4 weeks did not significantly alter the antihypertensive effects of verapamil.22

(g) Sulindac
A study in elderly women with hypertension found that sulindac 100 mg three times daily for one week had no effect on the control of their blood pressure with nifedipine.9

A study in hypertensive patients given up to 440 mg of verapamil daily found that sulindac 200 mg twice daily for 4 weeks did not significantly alter the antihypertensive effects of verapamil.22

B. Antiplatelet effects and gastrointestinal bleeding
Abnormal bruising and prolonging bleeding times occurred in a woman taking verapamil 80 mg three times daily when she took aspirin 650 mg several times a week for headaches. The bruising ceased when the ver-
apamil was stopped. Her normal bleeding time of 1 minute rose to 4.5 minutes while she was taking verapamil, and to 9 minutes while she was taking verapamil and aspirin. A healthy subject taking the same dose of verapamil and aspirin observed the appearance of new petechiae and her bleeding time rose from a normal 4.5 minutes to more than 15 minutes in the presence of both drugs.22 An 85-year-old man taking enteric-coated aspirin 325 mg daily developed widespread and serious ecchymoses of his arms and legs and a retroperitoneal bleed about 3 weeks after starting verapamil 240 mg daily.24

A prospective cohort study25 in 1636 elderly hypertensive patients and a case-control study26 found that calcium-channel blockers were associated with an increased risk of gastrointestinal bleeding compared with beta blockers; in one of the studies, verapamil had the highest rate of bleeding, followed by diltiazem and nifedipine.23 Two studies indicated that gas-
 trointestinal bleeding was not increased by calcium–channel blockers.27,28

A post-hoc analysis of the Syst-Eur data found that there was no interac-
tion between chronic NSAID intake (81% aspirin) and antihypertensive therapy based on nitrendipine in terms of incidence of gastrointestinal bleeding. Further, the results suggested that chronic NSAID therapy tended to be associated with a lower incidence of bleeding in patients taking nitrendipine-based therapy than those on placebo.25

Mechanism
A. Antagonism of antihypertensive effects
There is some evidence that NSAIDs may increase blood pressure in pa-
tients treated with antihypertensives. Possible explanations for this in-
clude inhibition of vasodilator and natriuretic prostaglandins in the kidney and/or a decrease in vascular or endothelial prostaglandin synthesis result-
ing in salt retention and vasoconstriction.24 In contrast, low-dose aspirin appears not to affect the blood pressure-lowering effects of calcium-chan-
el blocker-based antihyper tension therapy.3

B. Antiplatelet effects and gastrointestinal bleeding
The prolonged bleeding times noted with verapamil24 are probably a result of inhibition of platelet aggregation, because calcium-channel blockers inter-
tere with the movement of calcium ions through cell membranes, which can affect platelet function. This appears to be additive with the effects of other antiplatelet drugs. It was suggested that vasodilatation produced by calcium-channel blockers in conjunction with inhibition of platelet aggre-
gation may increase the risk of bleeding, or at least prevent the normal va-
sorhoconstrictive response to bleeding,25 although a protective effect of beta blockers rather than an adverse effect of calcium-channel blockers may also be the reason.27

Importance and management
Although several studies exist, the evidence for an interaction between the calcium-channel blockers and NSAIDs or aspirin is still somewhat incon-
clusive. Some consider that the use of NSAIDs should be kept to a mini-
um in patients on antihypertensives. The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with high salt intake.30 However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.31 While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inade-
quate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.31 There is insufficient data at present to clearly differentiate between NSAIDs. Further study is needed.

There is some limited evidence that the interaction of NSAIDs with cal-
cium-channel blockers is less than with ACE inhibitors.4,16,18

For the effects of NSAIDs on other antihypertensive drug classes see ‘ACE inhibitors’, (p.28), ‘beta blockers’, (p.835) and ‘thiazide diuretics’, (p.956).

Clinically significant interactions between NSAIDs and calcium-chan-
el blockers that result in bleeding appear rare.

Calcium-channel blockers + Azoles

Itraconazole can markedly raise the serum levels of felodipine, which increases its adverse effects, in particular ankle and leg oedema. A few case reports suggest that isradipine and nifedipine can interact similarly with itraconazole, and that fluconazole can also interact with nifedipine. Ketoconazole can markedly raise the plasma levels of lercanidipine and nisoldipine. Caution is warranted with all calcium-channel blockers when azole antifungals, particularly itraconazole and ketoconazole, are used.

Clinical evidence

(a) Felodipine

When itraconazole 200 mg daily or a placebo was given to 9 healthy subjects for 4 days, followed by a single 5-mg dose of felodipine, it was found that the felodipine AUC was increased sixfold and the maximum plasma levels were increased eightfold. The effects of the felodipine on blood pressure and heart rate were also increased.1

A 52-year-old woman taking felodipine 10 mg daily for hypertension for a year, without problems, developed ankle and leg swelling within 7 days of starting itraconazole 100 mg daily for tinea pedis. The oedema disappeared within 2 to 4 days of stopping the itraconazole.2 Virtually the same reaction occurred in another woman taking both drugs. Later tests found that her AUC of a single 5-mg dose of felodipine was increased at least fourfold (possibly up to tenfold) while taking itraconazole, and ankle swelling was noted.3

(b) Itraconazole

Ankle swelling was noted in a patient taking isradipine 5 mg daily when itraconazole 200 mg twice daily was also taken.2

(c) Lercanidipine

The manufacturer notes that an interaction study found that ketoconazole increased the S-lercanidipine AUC and peak plasma levels 15-fold and eightfold, respectively.3

Mechanism

Ankle swelling due to precapillary vasodilatation is a relatively common adverse effect of the dihydropyridine calcium-channel blockers, and this effect appears to be dose-related. Calcium-channel blockers are metabolised in the gut wall and liver by the cytochrome P450 CYP3A subfamily of isozymes, which are inhibited by itraconazole, ketoconazole, and to a lesser extent by fluconazole, so that in the presence of these antifungals the levels of the calcium-channel blockers are raised and the adverse effects increased.

Importance and management

The interaction between felodipine and itraconazole would appear to be established and clinically important. It also seems that isradipine, lercanidipine, nifedipine and nisoldipine can interact similarly with fluconazole, itraconazole or ketoconazole and, because they are metabolised by CYP3A4, it is likely that other calcium-channel blockers will behave in the same way. If itraconazole, ketoconazole, or fluconazole is given to a patient on established treatment with any calcium-channel blocker be alert for the need to lower the dosage of the calcium-channel blocker. However, some manufacturers (e.g. felodipine, lercanidipine) actually contraindicate concurrent use of itraconazole or ketoconazole, and others (e.g. nisoldipine) additionally contraindicate fluconazole. In the US the guidance differs slightly and only caution is considered necessary with felodipine. The manufacturers of nisoldipine predict that fluconazole, itraconazole and ketoconazole will substantially raise nisoldipine levels. They say that concurrent use should be avoided, but, if this is possible then the patient’s blood pressure should be carefully monitored.11

Calcium-channel blockers + Bile-acid binding resins

Colesevelam slightly reduces the bioavailability of verapamil and celestipol slightly reduces the bioavailability of diltiazem. These interactions are unlikely to be clinically important.
Clinical evidence, mechanism, importance and management

(a) Colesevelam

A study in 31 healthy subjects found that a single 4.5-g dose of colesevelam reduced the peak plasma levels and AUC of a single 240-mg dose of verapamil by about 33% and about 55%, respectively. These changes were not considered to be clinically significant.

(b) Colestipol

A study in 12 healthy subjects found that colestipol reduced the AUC and peak plasma levels of a single 120-mg dose of sustained-release diltiazem by 22% and 36%, respectively, and those of a single 120-mg dose of immediate-release diltiazem by 27% and 33%, respectively. In a further study sustained-release diltiazem 120 mg was given alone, or 1 hour before or 4 hours after multiple doses of colestipol. The AUC of diltiazem was decreased by 17% when it was taken 1 hour before colestipol and by 22% when taken 4 hours after colestipol. This suggests that the effects of colestipol on diltiazem bioavailability are not reduced by separating their administration. However, these small reductions in levels are unlikely to result in reduced diltiazem efficacy, but the authors advise caution if these drugs are used concurrently.

Chenodeoxycholic acid and ursodeoxycholic acid reduce the bioavailability of nitrendipine.

**Clinical evidence, mechanism, importance and management**

In a single-dose study, 6 healthy subjects were given nitrendipine 10 mg with or without either chenodeoxycholic acid 200 mg or 600 mg, or ursodeoxycholic acid 50 mg. Ursodeoxycholic acid reduced the peak plasma level and AUC of nitrendipine by 54% and 75%, respectively. Chenodeoxycholic acid 200 mg decreased the peak plasma level and AUC of nitrendipine by about 20%, but the 600-mg dose reduced the peak plasma level and AUC of nitrendipine by 54% and 68%, respectively. The reduction in bioavailability of nitrendipine was possibly due to the effects of the bile acids on tablet disintegration or more probably on drug solubilisation. The clinical importance of the interaction is not known.

Calcium-channel blockers + Bile acids

Calcium-channel blockers + Calcium-channel blockers

Plasma levels of both nifedipine and diltiazem are increased by concurrent use and blood pressure is reduced accordingly. Verapamil is predicted to interact similarly. There are isolated reports of intestinal occlusion attributed to the concurrent use of nifedipine and diltiazem. Note that if nimodipine is used with another calcium-channel blocker is predicted to interact similarly. There are isolated reports of intestinal occlusion attributed to the concurrent use of nifedipine and diltiazem. Note that if nimodipine is used with another calcium-channel blocker.

Clinical evidence

Pretreatment of 6 healthy subjects with diltiazem 30 or 90 mg three times daily for 3 days was found to increase the AUC of a single 20-mg dose of nifedipine two- and threefold, respectively. Similar and related results are reported elsewhere. In another study it was found that nifedipine 10 mg three times daily for 3 days increased the maximum plasma levels of a single 60-mg dose of diltiazem by 54% and increased its AUC by 49%. A patient taking nifedipine 20 mg twice daily developed abdominal distension and vomiting 2 days after also being given diltiazem 100 mg twice daily. Both calcium-channel blockers were stopped and abdominal X-ray suggested paralytic ileus, which resolved but then-recurred when the drugs were restarted. The excessive relaxation of the intestine was attributed to elevated nifedipine plasma levels, which were said to be caused by diltiazem. Another report describes complete or partial intestinal occlusion in a patient taking diltiazem on three occasions, each time when nifedipine was added.

Mechanism

A reduction in the metabolism of both the nifedipine and diltiazem in the liver seems to be the explanation for the increase in drug levels. An increased relaxant effect on smooth muscle is suggested for the cases of intestinal occlusion.

Importance and management

Established interactions but of uncertain clinical importance. The manufacturers of nifedipine advise caution when it is used with diltiazem because of possible increases in nifedipine levels. They say a reduction in the dose of nifedipine should be considered. Verapamil is predicted to interact similarly. Information about the use of combinations of other calcium-channel blockers appears to be lacking. However, the UK manufacturers of nimodipine advise that if it is used with other antihypertensive drugs, including other calcium-channel blockers such as nifedipine, diltiazem, or verapamil, blood pressure monitoring and careful dose titration of nimodipine should be carried out with possible reduction or discontinuation of the other calcium-channel blocker.

Calcium-channel blockers + Calcium compounds

An isolated report describes antagonism of the antiarrhythmic effects of oral verapamil due to the use of oral calcium and calciferol. Note that intravenous calcium compounds may be used prior to intravenous verapamil where the hypotensive effects of verapamil would be detrimental.

Clinical evidence, mechanism, importance and management

An elderly woman with atrial fibrillation, successfully treated for over a year with verapamil, developed atrial fibrillation within a week of starting to take an oral calcium compound 1.2 g with calciferol (vitamin D) 3000 units daily for diffuse osteoporosis. Her serum calcium levels had risen from 2.45 to 2.7 mmol/L. Normal sinus rhythm was restored by giving 500 mL of saline and repeated doses of furosemide 20 mg and verapamil 5 mg by intravenous injection.

Verapamil acts by inhibiting the passage of calcium ions into cardiac muscle cells and it would appear that in this case the increased concentration of calcium ions outside the cells opposed the effects of the verapamil.

The general importance of this isolated case is uncertain, but bear it in mind in the event of an unexpected reduction in verapamil effects.

Note that intravenous calcium compounds are sometimes given prior to intravenous verapamil for the treatment of ventricular arrhythmias to prevent verapamil-induced hypotension in situations where a reduction in blood pressure could be detrimental. This use does not affect the antiarrhythmic efficacy. Calcium, usually in the form of intravenous calcium gluconate, is used as an antidote in cases of overdose of calcium-channel blockers.

Calcium-channel blockers + Ceftriaxone and Clindamycin

An isolated report describes the development of complete heart block in a man taking verapamil, which was attributed to the use of intravenous ceftriaxone and clindamycin. The validity of this interaction has been questioned.

Clinical evidence, mechanism, importance and management

A 59-year-old man who had been taking sustained-release verapamil 240 mg twice daily for 2 years and phenytoin 300 mg daily for several years, developed complete heart block an hour after being given intravenous ceftriaxone 1 g and clindamycin 900 mg for bilateral pneumonia. He needed cardiopulmonary resuscitation and the insertion of a temporary pacemaker, but spontaneously recovered normal sinus rhythm after 16 hours. He made a full recovery. The reasons for this serious reaction are not known, but the authors of the report postulate that these two antibacterials precipitated acute verapamil toxicity, possibly by displacing it from its plasma protein binding sites. Although both antibacterials are highly protein-bound (93% or more), they are acidic and do not bind to the same sites as the verapamil (a base), so that this mechanism of interaction seems very unlikely. This seems to be the first and only report of this reaction, and the suggestion by the authors that it was due to a drug interaction has been seriously questioned. There seems to be no other evidence that either of these antibacterials interact with verapamil, either given orally or intravenously.

Calcium-channel blockers + Chlorpromazine

A patient taking chlorpromazine who was given nifedipine [dosage not stated] for 2 days before surgery, developed marked hypotension during surgery, which was eventually controlled with noradrenaline (norepinephrine). Other phenothiazines and calcium-channel blockers may interact similarly, see ‘Antihypertensives + Other drugs that affect blood pressure’, p.880.

Calcium-channel blockers + Clonidine

Two hypertensive patients taking verapamil developed an complete heart block when clonidine was added. The hypotensive effects of nifedipine and clonidine were additive in hypertensive patients. Transdermal clonidine has been successfully used with nifedipine or diltiazem in small studies.

Clinical evidence

(a) Diltiazem

In a clinical trial, transdermal clonidine decreased blood pressure in 58 of 60 patients with hypertension inadequately controlled by sustained-release diltiazem 90 mg twice daily. The addition of clonidine did not cause a significant decrease in heart rate.

(b) Nifedipine

Sustained-release clonidine 250 micrograms daily for 2 weeks increased the hypotensive effects of nifedipine 20 mg twice daily by about 5 mmHg (mean blood pressure reduction) in 12 patients. Clonidine did not alter the slight heart rate increase seen with nifedipine. In a clinical trial in 39 patients with hypertension inadequately controlled by nifedipine GITS 30 to 60 mg daily, transdermal clonidine successfully decreased blood pressure in all 35 patients who completed a one-week titration phase then an 8-week maintenance phase.

(c) Verapamil

A 54-year-old woman with refractory hypertension (240/140 mmHg) and hyperaldosteronism, took verapamil 160 mg three times daily and spironolactone 100 mg daily for 10 days, and had a reduction in her blood pressure to 180/100 mmHg. She was additionally given clonidine 150 micrograms twice daily, and after the second dose she became confused and her blood pressure was found to have fallen to 90/70 mmHg, with a heart rate of 50 bpm. She had developed complete AV block, which resolved when all the drugs were stopped. A 65-year-old woman with persistent hypertension did not have a satisfactory reduction in blood pressure with extended-release verapamil 240 mg daily (blood pressure 165/100 mmHg). Clonidine 150 micrograms twice daily was then added, and the next day a routine ECG showed that she had a nodal rhythm of 80 bpm, which developed into complete AV block. Her blood pressure had fallen to 130/80 mmHg.

Mechanism

Not fully understood. Verapamil very occasionally causes AV node disturbances, but both of these patients had normal sinus rhythm before the clonidine was added. Clonidine alone has been associated with AV node dysfunction in hypertensive patients. It would seem therefore that these effects were additive in these two patients.

Importance and management

Information about the interaction between verapamil and clonidine seems to be limited to this report. Its authors say that a review of the literature from 1966 to 1992 revealed no reports of any adverse interactions between these drugs. Nonetheless, they suggest that it would now be prudent to give these two drugs together with caution and good monitoring in any patient, even in those without sinus or AV node dysfunction. There was no adverse effect on heart rate in one trial in patients taking diltiazem and using transdermal clonidine. There seems to be no particular need for additional caution when nifedipine is given with clonidine.

Calcium-channel blockers + Co-trimoxazole

Adverse effects (leg cramps, facial flushing) have been reported in one patient taking nifedipine when co-trimoxazole was also taken. One study found that co-trimoxazole had no effect on the pharmacokinetics and hypotensive action of a single dose of nifedipine.

Clinical evidence, mechanism, importance and management

The observation of a patient taking nifedipine who developed leg cramps and facial flushing (possibly as a result of raised plasma nifedipine levels) when given co-trimoxazole, prompted further study of this possible interaction in 9 healthy subjects. After taking co-trimoxazole 960 mg twice daily for 3 days the pharmacokinetics and hypotensive effects of a single 20-mg dose of nifedipine were found to be unchanged. No special precautions would therefore normally seem to be necessary on concurrent use.

Calcium-channel blockers + Dantrolene

An isolated report describes acute hyperkalaemia and cardiovascular collapse when dantrolene was given to a patient taking verapamil, but not when he was subsequently given nifedipine. Animal studies have found similar effects with the combination of dantrolene and verapamil or diltiazem, but not with nifedipine or amlodipine.
Clinical evidence, mechanism, importance and management

A case report describes a 60-year-old man with insulin-dependent diabetes undergoing a right hemicolectomy. Due to inoperable coronary artery disease, which was causing angina pain he was taking verapamil 80 mg three times daily. On the morning of surgery he was given verapamil 80 mg with his pre-operative sedation and then, 2 hours later at the start of surgery, he was given intravenous dantrolene 220 mg over 30 minutes, because he was known to have previously had malignant hypertension. After surgery, when he was on ITU, it was found that his potassium had risen from 4.6 mmol/L before surgery to 6.1 mmol/L at the end of surgery (about 90 minutes after the dantrolene infusion). He was given 10 units of insulin, but an hour later his potassium was 7.1 mmol/L. He was given more insulin, but then developed metabolic acidosis and some cardiac depression, which resolved when he was given bicarbonate and hetastarch 5%. He received three further doses of dantrolene without incident.1

The authors of the report attributed the effects seen to an interaction between verapamil and dantrolene. They note that hyperkalaemia has been seen following dantrolene infusions, but the case they cite was in response to suxamethonium, and the UK and US manufacturers of dantrolene do not include hyperkalaemia as an adverse effect.2,3 Nevertheless, the overall picture is that hyperkalaemia, of whatever cause, can apparently increase the myocardial depression caused by verapamil.4,5 This case seems to be the only report of an interaction between verapamil, and several factors do not make this a clear-cut case of an interaction. However, hyperkalaemia and cardiovascular collapse have been seen in pigs and dogs given dantrolene and verapamil,6-8 and so an interaction cannot be completely ruled out. The manufacturers of dantrolene contraindicate its use in patients taking verapamil.2,3 One animal study suggests that diltiazem may interact similarly,9 and the combination of diltiazem and dantrolene may also cause ventricular arrhythmias.10 The manufacturers of diltiazem similarly contraindicate concurrent use.10 Studies suggest that amlodipine11 and nifedipine12 do not interact and they may therefore be safer alternatives. In the case above1 the patient later underwent further surgery while taking nifedipine, without any significant adverse effect (although the potassium was moderately raised to 5.4 mmol/L).1

Calcium-channel blockers + Fluoxetine

Two patients taking verapamil and two taking nifedipine developed increased adverse effects (oedema, headaches, nausea, flushing, orthostatic hypotension) due to the concurrent use of fluoxetine. Fluoxetine appears to increase nimodipine levels, whereas nimodipine may decrease fluoxetine levels. Fluoxetine does not appear to alter lercanidipine pharmacokinetics.

Clinical evidence

(a) Lercanidipine

The manufacturer notes that a study in elderly subjects found that fluoxetine had no clinically relevant effects on the pharmacokinetics of lercanidipine. No other details were given.1

(b) Nifedipine

A patient taking nifedipine 60 mg daily developed nausea and flushing after also starting to take fluoxetine 20 mg every other day. The adverse effects gradually disappeared over the next 2 to 3 weeks when the nifedipine dosage was halved.2 An 80-year-old woman taking nifedipine developed tachycardia, hypotension and profound weakness 10 days after starting fluoxetine 20 mg daily. On admission to hospital 8 days later she was unable to stand, her standing blood pressure was 90/50 mmHg and her heart rate was 120 bpm. She fully recovered within a week of stopping the fluoxetine.3

(c) Nimodipine

The manufacturer notes that, in elderly patients, nimodipine 30 mg twice daily given with fluoxetine 20 mg daily resulted in an increase in plasma levels of nimodipine, a reduction in plasma levels of fluoxetine, and a trend towards increased levels of the metabolite norfluoxetine,4 but no specific values were given.

(d) Verapamil

A woman taking verapamil 240 mg daily developed oedema of the feet and ankles, and neck vein distension within 6 weeks of starting fluoxetine 20 mg every other day. The oedema resolved within 2 to 3 weeks of reducing the verapamil dosage to 120 mg daily.5 Another patient taking verapamil 240 mg daily for the prophylaxis of migraine developed morning headaches (believed by the patient not to be migraine) about one week after increasing his fluoxetine dosage from 20 to 40 mg daily. The headaches stopped when the verapamil dosage was reduced and then stopped.2

Mechanism

The calcium-channel blockers are metabolised by the cytochrome P450 isoenzyme CYP3A4, which can be inhibited by fluoxetine. This results in a marked reduction in the metabolism and clearance of the calcium-channel blockers. The reactions reported appear to be the exaggeration of the adverse effects of these calcium-channel blockers, possibly due to an increase in their levels.
Importance and management

Although a pharmacokinetic interaction might be predicted, information on an important clinical interaction appears to be limited to these reports.2,3 This suggests that the incidence is very rare. Bear the possibility of a pharmacokinetic interaction in mind if a patient shows an exaggerated response to a calcium-channel blocker after starting fluoxetine, being alert for the need to reduce the drug dosages. The clinical significance of the interaction between nimodipine and fluoxetine is not known.4 Information about other calcium-channel blockers with fluoxetine or other SSRIs appears to be lacking.

Calcium-channel blockers + Food

Some modified-release preparations of felodipine, nifedipine, and nisoldipine show markedly increased levels when given with food, particularly when high in fat. The bioavailability of lercanidipine is markedly increased by food, and it should therefore be given on an empty stomach. Manidipine should be given with food, as this improves its absorption. Food modestly decreases the rate and extent of absorption of nimodipine capsules. Food had no effect on the absorption of amlodipine, bepridil, diltiazem, isradipine, or verapamil in the studies cited.

Clinical evidence

(a) Amlodipine
There was no difference in rate or extent of absorption of amlodipine capsules between the fed and fasted state in a study in healthy subjects.1

(b) Diltiazem
The rate and extent of absorption of both a slow-release and a conventional tablet of diltiazem were unaffected by food in healthy subjects.2 Similarly, the pharmacokinetic parameters of another sustained-release formulation of diltiazem (Mono-Tildiem LP) showed only minor changes when given with food in a study in healthy subjects.3

(c) Felodipine
The manufacturer of one prolonged-release tablet of felodipine (Vasclalpha) notes that taking it with a high-fat meal markedly increased the maximum level (2 to 2.5-fold) without altering the extent of absorption.4

(d) Isradipine
The pharmacokinetic parameters of isradipine differed by less than 20% when modified-release and nonretard formulations of isradipine were given with a light meal compared with the fasted state.5

(e) Lercanidipine
The manufacturer notes that the oral bioavailability of lercanidipine is increased up to fourfold when it is taken up to 2 hours after a high-fat meal.6

(f) Manidipine
The bioavailability of single 20-mg doses of manidipine was increased by 42% when given to 12 healthy subjects after a standard breakfast rather than in the fasting state. Peak plasma levels were increased by about 25% by food (not significant), and the rate of absorption was unaffected.7

(g) Nifedipine
Some single-dose studies suggested that food might delay the absorption of nifedipine8 and reduce its peak levels,9,10 but a multiple dose study found that food did not have an important effect on the steady-state levels of nifedipine in a ‘biphasic’ formulation.11 A further single-dose study in healthy subjects found that the bioavailability of two modified-release preparations of nifedipine (Adalat OROS or Nifedicon) were not significantly different when they were given in the fasting state, although the maximum plasma levels were 31 and 53 micrograms/L respectively. The bioavailability and maximum plasma level (38 micrograms/L) of Adalat OROS were similar after a high-fat breakfast to those in the fasting state. However, the maximum plasma level of Nifedicon increased 2.4-fold to 128 micrograms/L after a high-fat breakfast. Although the bioavailability of Nifedicon was only modestly increased by food, the increase in plasma levels indicates a loss of modified-release characteristics and suggests that the effect of food on nifedipine may depend on the product formulation.12

Calcium-channel blockers + Grapefruit juice

Grapefruit juice very markedly increases the bioavailability of felodipine and nisoldipine and alters their haemodynamic effects. The bioavailability of nicardipine, nifedipine, nimodipine or ni-trendipine is increased without significantly altering haemodynamic effects, whereas the bioavailability of amlodipine, diltiazem and verapamil is only minimally affected. An isolated report describes peripheral oedema and weight gain in a black man taking nifedipine when also drinking grapefruit juice.

Clinical evidence

(a) Dihydropyridine calcium-channel blockers

1. Grapefruit juice. Drinking 200 to 250 mL of grapefruit juice can increase the bioavailability of felodipine two to threefold in healthy subjects and patients with hypertension. Its effects are proportionately increased. One study found that diastolic pressures were reduced by 20% (11% with water) and heart rates increased by 12% (9% with water) when blood felodipine levels were at their highest after a drink of grapefruit juice. Adverse effects such as headaches, facial flushing and lightheadedness were also increased. The interaction develops after taking the first glass of grapefruit juice and persists for about 4 hours.

The bioavailabilities of nicardipine, nifedipine, nimodipine and nitrendipine have also been found to be increased, even about doubled in some instances, but usually only minor changes in haemodynamic effects (blood pressure and heart rate) were reported in healthy subjects. However, the effect may be more pronounced in some hypertensive patients. An isolated report describes a 54-year-old black African man taking nifedipine retard 60 mg daily, lisinopril 5 mg daily and aspirin 75 mg who presented with peripheral oedema, weight gain, and apparently improved blood pressure control of about 6 months' duration. Over this time he had been drinking about 400 mL of freshly squeezed grapefruit juice every morning as part of a diet regimen. He was advised to stop drinking grapefruit juice, and 2 weeks later the oedema had disappeared, he had lost 2 kg in weight, and his blood pressure was slightly higher (140/85 mmHg) than when he presented (130/80 mmHg).

One study in 8 healthy subjects found that when nisoldipine was given with grapefruit juice it produced significantly larger decreases in blood pressure for 8 hours compared to nisoldipine alone. The effect of grapefruit juice decreased with time but lasted for at least 3 days. However, in a further study in healthy subjects, grapefruit juice increased the maximum nisoldipine plasma levels fivefold, but only minor effects on blood pressure and heart rate were found.

Other studies found that the bioavailability of amlodipine was at most only slightly increased by grapefruit juice.

2. Whole Grapefruit. Some studies have found that grapefruit pulp, segments, or extract may increase the AUCs of nifedipine, nisoldipine and felodipine by 1.3-fold, 1.3-fold and threefold respectively.

(b) Diltiazem

In one study grapefruit juice had no significant effect on the bioavailability of diltiazem, but in another it increased the AUC of diltiazem by about 20% but differences in blood pressure and heart rate were not significant.

(c) Verapamil

A study in 10 hypertensive patients found that a single drink of grapefruit juice had no significant effects on the pharmacokinetics of verapamil.

2 to 4 times daily for 3 to 5 days increased the AUC of verapamil by about 40%. Pharmacodynamic parameters (blood pressure heart rate and PR interval) were not significantly altered by grapefruit juice in one study, but prolongation of PR intervals occurred in the other and were of borderline significance, with increases to above 350 milliseconds in 2 subjects (maximum PR intervals of 200 to 260 milliseconds were usually observed).

Mechanism

Uncertain. It has been suggested that the increases in bioavailability are due to components of the fruit juice including flavonoids such as naringin, hesperetin, hesperidin and naringenin. Other studies have demonstrated that grapefruit juice can induce cytochrome P450 enzymes. It is notable that many of the calcium-channel blockers are substrates for cytochrome P450 enzymes, and that nifedipine is the major substrate for P450 3A4. The interaction may be related to the oral bioavailability of the calcium-channel blocker, but this is possibly because cytochrome P450 3A4, which has a lower bioavailability, is most sensitive to the activity of grapefruit juice. The exception is verapamil, which has low bioavailability and appears to be only slightly affected by grapefruit juice, but this is possibly because cytochrome P450 3A4 enzymes other than CYP3A4 are involved in its metabolism. The variability of the interaction may be related to the oral bioavailability of the calcium-channel blocker.

Thus, diltiazem and diltiazem with high bioavailability are least affected, nifedipine is intermediate, and felodipine, which has a lower bioavailability, is most sensitive to the activity of grapefruit juice. The exception is verapamil, which has low bioavailability and appears to be only slightly affected by grapefruit juice, but this is possibly because cytochrome P450 3A4 enzymes other than CYP3A4 are involved in its metabolism. It is noteworthy that only one probable case report of the interaction appears to have been published. Generally speaking the concurrent use of grapefruit juice and calcium-channel blockers other than felodipine, and possibly nisoldipine or verapamil, need not be avoided. However, it would be worth checking the diet of any patient who complains of increased adverse effects with any of the calcium-channel blockers that are known to interact with grapefruit juice. Any problems can be solved by avoiding grapefruit juice, or possibly by swapping the calcium-channel blocker for a non-interacting one (amlodipine appears not to interact).

Plasma levels of diltiazem, isradipine and nifedipine are increased by higher doses of calcium-channel blockers, including nifedipine and nisoldipine. The manufacturer of isradipine notes that cimétidine increases the bioavailability of isradipine by about 50%.

**Clinical evidence**

**(a) Amlodipine**

A crossover study in 12 healthy subjects found that cimétidine 400 mg twice daily for 14 days had no effect on the pharmacokinetics of amlodipine 10 mg daily.

**(b) Diltiazem**

Cimétidine 300 mg before meals and at bedtime for a week increased the AUC of a single 60-mg oral dose of diltiazem by 50% in 6 healthy subjects and increased peak plasma levels by 57%. Ranitidine 150 mg twice daily for a week increased the AUC of diltiazem by 15%, but this was not statistically significant. In the serum levels and AUC of diltiazem of 40% and 25 to 50%, respectively, were seen in another study using cimétidine.

**(c) Felodipine**

Cimétidine 1 g daily increased the AUC of felodipine 10 mg by 56%, and raised the peak serum level by 54% in 12 subjects. There was a short lasting effect on their heart rates but the clinical effects were minimal.

**(d) Isradipine**

The manufacturer of isradipine notes that cimétidine increases the bioavailability of isradipine by about 50%.

**(e) Lacidipine**

A single 800-mg dose of cimétidine increased the maximum plasma level of a single 4-mg dose of lacidipine by 59% and increased the AUC by 74% in one study in healthy subjects. Pulse rates and blood pressures were unaffected.

**(f) Lercanidipine**

Cimétidine 800 mg daily causes no significant alteration in plasma levels of lercanidipine but the manufacturer says that the bioavailability of lercanidipine and its hypotensive effects may be increased by higher doses of cimétidine.

**(g) Nifedipine**

No adverse interaction was seen in 22 patients given calcium-channel blockers, including nifedipine, with oral famotidine for 6 to 8 weeks. No changes in the pharmacokinetics or pharmacodynamics of a 12-hour intravenous infusion of nifedipine 24 mg were seen in 12 healthy subjects given intravenous cimétidine 300 mg every 6 hours for 48 hours.

**(h) Nifedipine**

Cimétidine 1 g daily for a week increased the AUC of nifedipine 40 mg daily by about 60% and increased the maximum plasma levels by about 90%. Ranitidine 150 mg twice daily for a week caused an insignificant rise of about 25% in maximum nifedipine plasma levels and AUC. Severely hypertensive patients had a fall in mean blood pressure from 127 to 109 mmHg after taking nifedipine 40 mg daily for 4 weeks, and a further fall to 95 mmHg after they also took cimétidine 1 g daily for 3 weeks. When they took ranitidine 300 mg instead of cimétidine, there was an insignificant fall in blood pressure.

Other studies clearly confirm that cimétidine causes a very significant rise in plasma nifedipine levels and an increase in its effects, whereas ranitidine interacts only minimally.

A study found no pharmacokinetic interaction between nifedipine and famotidine, but the famotidine reversed the effects of nifedipine on systolic time intervals and significantly reduced the stroke volume and cardiac output.

No adverse interaction was seen in 22 patients given calcium-channel blockers, including nifedipine, with famotidine for 6 to 8 weeks.

**Other studies** clearly confirm that cimétidine causes a very significant rise in plasma nifedipine levels and an increase in its effects, whereas ranitidine interacts only minimally. A study found no pharmacokinetic interaction between nifedipine and famotidine, but the famotidine reversed the effects of nifedipine on systolic time intervals and significantly reduced the stroke volume and cardiac output. No adverse interaction was seen in 22 patients given calcium-channel blockers, including nifedipine, with famotidine for 6 to 8 weeks.
A study in 8 healthy subjects found that taking cimetidine 1 g in divided doses on the day before the study and then three 200 mg doses every 4 hours on the study day, increased the bioavailability of a single 10-mg dose of nisoldipine by about 50%, but the haemodynamic effects of the nisoldipine were unaltered.22 Ranitidine does not interact with nisoldipine.23

Cimetidine 800 mg given before, and 400 mg in divided doses given after, a single 20-mg dose of nisoldipine was found to increase its bioavailability by 154% but the haemodynamic effects were unchanged.24

Another study found that ranitidine increased the AUC of oral nisoldipine 20 mg daily for 1 week by about 50% and decreased its clearance, but there were no changes in the haemodynamic measurements (systolic time intervals, impedence cardiography).25,26 A further study found that ranitidine increases the AUC of nisoldipine by 89%, but this does not appear to be clinically significant.27

Verapamil

In a study in 8 healthy subjects found that cimetidine 300 mg every 6 hours for 8 days did not affect the pharmacokinetics of a single 10-mg intravenous dose of verapamil, but the bioavailability of a 120-mg oral dose of verapamil was increased from 26 to 49%. A small insignificant change in clearance occurred but no change in AUC. The changes in the PK interval caused by the verapamil were unaltered in the presence of cimetidine.28

Another study found that cimetidine 300 mg four times daily for 5 days reduced the clearance of a single intravenous dose of verapamil by 21% and increased its elimination half-life by 50%.29 Cimetidine 400 mg twice daily for a week increased the bioavailability of verapamil from 35 to 42% and its clearance was reduced by almost 30% in another study.30 A further study found a small increase in the bioavailability of both enantiomers of verapamil.31 In contrast, other studies have found that the pharmacokinetics of verapamil were unaffected by cimetidine.32,33

Mechanism

It is believed that cimetidine increases nifedipine levels by inhibiting its oxidative metabolism by the liver. Like ranitidine, it may also increase the bioavailability of nifedipine by lowering gastric acidity.4,14 The mechanisms of the other interactions are probably similar.

Importance and management

The interactions of cimetidine with diltiazem and nifedipine are established. Concurrent use must not be avoided but the increase in the calcium-channel blocker effects should be taken into account. It has been established that the dosage of diltiazem should be reduced by 50 to 100%.34,35 and that of nifedipine by 40 to 50%.36,37 The interaction between verapamil and cimetidine is not well established, but monitor the effects until more is known. It has been suggested that the verapamil dose may need to be reduced by 50%.35 Monitoring is advised if isradipine is given with cimetidine and a reduction in isradipine dose may be required.36

Similarly, high doses of cimetidine may increase the hypotensive effects of lercanidipine and caution is advised.7 The evidence available suggests that, although cimetidine increases the serum levels of felodipine, lacidipine, nimodipine, and nisoldipine, the haemodynamic changes are unimportant. However, this needs confirmation. The manufacturer of nisoldipine warns that the antihypertensive effect may be potentiated by cimetidine,23 but the study available suggests that this is not significant. Although some studies indicate no interaction between nicardipine and cimetidine, the manufacturer notes that cimetidine increases nicardipine plasma levels and monitoring is recommended.38 Amlodipine and cimetidine do not interact.

Ranitidine does not interact significantly with diltiazem, nimodipine, nisoldipine or nifedipine, and is possibly a non-interacting alternative for cimetidine with other calcium-channel blockers. Note that the nisoldipine AUC was increased by 50% and 89% by ranitidine, although this was not considered clinically relevant.

Famotidine does not have a pharmacokinetic interaction with nifedipine.

Clinical evidence

(a) Diltiazem

A patient who had marked hypotension and bradycardia when erythromycin was added to verapamil and propranolol (see under verapamil, below) had previously taken erythromycin with diltiazem and a beta blocker without any reported adverse effects. 1

In a retrospective cohort study, there was one sudden cardiac death in 106 person-years among patients taking diltiazem with erythromycin. 2 When combined with the two deaths with concurrent verapamil and erythromycin, this represented about a fivefold increase in risk of sudden death when compared with those who used neither CYP3A4 inhibitors (defined as ketoconazole, itraconazole, flucloxacillin, diltiazem, verapamil or troleandomycin) nor erythromycin. 3

(b) Felodipine

Twelve healthy subjects were given felodipine 10 mg before and after taking erythromycin 250 mg four times daily for a day. 4 The felodipine AUC was increased almost threefold by the erythromycin, the maximum plasma levels were more than doubled and the half-life prolonged from 6.9 to 11.1 hours. 5

A hypertensive woman taking felodipine 10 mg daily developed tachycardia, flushing and massive ankle oedema within 2 to 3 days of starting to take erythromycin 250 mg twice daily. Her blood pressure had fallen from 120/90 to 110/70 mmHg. She fully recovered within a few days of stopping the erythromycin. 6

(c) Nifedipine

1. Clarithromycin. A 77-year-old man taking sustained-release nifedipine 60 mg twice daily, captopril and doxazosin, and with slight renal impairment, had persistent systolic hypertension (170 to 180 mmHg). Two days after starting clarithromycin 500 mg twice daily for breathing difficulty and cough, his blood pressure was 140/70 mmHg at a routine appointment, and the doxazosin dose was halved and valsartan substituted for captopril. Later that day, he was admitted with hypotension (80/40 mmHg) and bradycardia (40 bpm). Clarithromycin was replaced with erythromycin and the anti hypertensives stopped. After 3 days his blood pressure was stabilised with nifedipine 60 mg daily and furosemide, and the clarithromycin was restarted. Septic shock was ruled out as a cause of the hypotension. 7

2. Erythromycin. In a retrospective cohort study, there were no sudden deaths from cardiac causes in 114 person-years of the use of oral erythromycin with calcium-channel blockers that do not inhibit CYP3A4 to a clinically relevant extent (stated as nearly all nifedipine). 2 This was in contrast to the increased risk of sudden death with erythromycin and diltiazem (see above) or verapamil (see below).

(d) Verapamil

1. Clarithromycin. A 53-year-old woman on haemodialysis 3 times a week, and a range of medicines including digoxin, was given clarithromycin 250 mg and verapamil 120 mg both twice daily because of an acute exacerbation of chronic obstructive pulmonary disease and a tricuspid valve prolapse. After 24 hours she experienced dizziness and episodes of fainting. A day later her supine blood pressure was 89/39 mmHg and her pulse rate 50 bpm. Verapamil was stopped and she recovered within 2 days, after which verapamil was re-started at a dose of 40 mg before each dialysis session. 8 Another report 9 describes a 77-year-old woman with hypertension, taking propranolol and verapamil, who developed marked bradycardia (37 to 50 bpm), within 4 days of starting a course of clarithromycin 500 mg twice daily. The problem was solved by temporarily reducing the dose of the verapamil from 80 mg to 40 mg twice daily and the propranolol to a half until the clarithromycin course was over. Essentially the same thing happened 2 years later while taking the same drugs when erythromycin was added (see below).

2. Erythromycin. A 79-year-old woman taking verapamil 240 mg twice daily and ramipril was admitted to hospital with extreme fatigue and dizziness one week after starting a course of erythromycin 2 g daily for a respiratory-tract infection. Her blood pressure was 80/60 mmHg and her respiratory rate was 18 breaths per minute. ECG showed complete AV block, escape rhythm of 50 bpm, pattern of left bundle-branch block and QTc interval prolongation (583 milliseconds compared with 436 milliseconds 20 days before admission). Verapamil and erythromycin were stopped and intravenous fluids, dopamine and calcium were given. Her blood pressure increased to 110/70 mmHg and after 4 days the QTc interval prolongation had resolved and her heart rate was 76 bpm. 10 Another patient taking verapamil and propranolol developed marked bradycardia and hypotension 2 days after starting to take erythromycin 333 mg three times daily. 11 Two years previously she had experienced a similar interaction with clarithromycin and verapamil, but not with erythromycin and diltiazem (see above).

In a retrospective cohort study, there were two sudden cardiac deaths in 78 person-years among patients taking verapamil with erythromycin. When combined with the one death with current diltiazem and erythromycin, this represented about a fivefold increase in risk of sudden death when compared with those who used neither CYP3A4 inhibitors (defined as ketoconazole, itraconazole, flucloxacillin, diltiazem, verapamil or troleandomycin) nor erythromycin. 2

3. Telithromycin. A 76-year-old woman taking verapamil 180 mg daily experienced shortness of breath and weakness 2 days after starting telithromycin 800 mg daily for a sinus infection. She was found to have marked hypotension (systolic BP 50 to 60 mmHg) and bradycardia (30 bpm). She required a transvenous pacemaker for 3 days and pressor drugs. 12

Mechanism

Calcium-channel blockers are metabolised in the gut wall and liver by the cytochrome P450 CYP3A4 subfamily of isoenzymes, which are inhibited by erythromycin, clarithromycin, and telithromycin, so that in their presence a normal oral dose becomes in effect an overdose with its attendant adverse effects. 13, 14 Verapamil, erythromycin 15 and possibly clarithromycin are also P-glycoprotein inhibitors, which may contribute to the pharmacokinetic interaction by reducing the elimination of the calcium-channel blocker, 16 or by increasing macroside absorption. 6

Erythromycin has been associated with prolongation of the QT interval; an effect that is likely to be increased by drugs that increase erythromycin levels such as diltiazem and verapamil. 2

Importance and management

Information seems to be limited but the interaction would appear to be established and clinically important, although its incidence is probably low. Anticipate the need to reduce the felodipine or verapamil dosage if erythromycin or clarithromycin, or possibly also telithromycin, is added. Nifedipine may also interact. Other reports suggest that the cardiac toxicity of erythromycin may be increased by verapamil, 2, 5 and diltiazem, 2 and the authors of one of these reports consider that erythromycin should not be used with CYP3A4 inhibitors (that is diltiazem and verapamil). 2 There seem to be no reports of interactions between any of the other calcium-channel blockers and macrolides. However, because of the theoretical possibility of an interaction, many of the manufacturers of calcium-channel blockers warn of the possibility of increased plasma levels and the need to either avoid use with macrolides such as erythromycin, or trolenzyme, or to monitor and reduce doses where necessary.

Calcium-channel blockers + Magnesium compounds

Two pregnant women developed bilateral hand contractures after receiving magnesium sulfate either alone or with nifedipine. Two other pregnant women developed muscular weakness and then paralysis when they were given both nifedipine and intravenous magnesium sulfate. Profound hypotension occurred in two women when nifedipine was added to magnesium sulfate and
methyl dopa. However, a retrospective study found no significant increase in neuromuscular weakness in women treated with both magnesium sulfate and nifedipine compared with magnesium sulfate and no antihypertensive, and the incidence of hypotension was actually lower.

Clinical evidence

(a) Hypotension

Two women with pre-eclampsia, unsuccessfully treated with methyl dopa and magnesium sulfate, experienced severe hypotension when a single 10-mg oral dose of nifedipine was added.¹ In contrast, a study in 10 women with severe pre-eclampsia receiving magnesium sulfate found that oral nifedipine 10 mg followed by 20 mg every 20 minutes, caused a steady decrease in mean arterial pressure and severe hypotension was not observed.² Moreover, in a retrospective study, the incidence of hypotension in 162 women given nifedipine and magnesium sulfate was lower than in 183 receiving magnesium sulfate and no antihypertensive (41.4% versus 53%).³ For further details of this study, see (b) below.

(b) Neuromuscular blockade and hypocalcaemia

A report describes symptomatic hypocalcaemia (serum calcium levels 5.4 mg/dL) in a woman at 33 weeks gestation after she received magnesium sulfate plus nifedipine.⁴ However, this report also describes this effect in a patient taking magnesium sulfate alone. Both women experienced bilateral hand contractures and were successfully treated with calcium gluconate.⁴

A pregnant woman at 32 weeks gestation was effectively treated for premature uterine contractions with nifedipine, 60 mg orally over 3 hours, and later 20 mg every 8 hours. When contractions began again 12 hours later she was given magnesium sulfate 500 mg intravenously. She developed jerky movements of the extremities, complained of difficulty in swallowing, paradoxical respirations and an inability to lift her head from the pillow. The magnesium was stopped and the muscle weakness disappeared over the next 25 minutes.⁵

A woman at 28 weeks gestation with mild pre-eclampsia was started on an infusion of magnesium sulfate 2 g/hour. Her plasma magnesium levels were found to be 2.75 mmol/L. No untoward reactions developed when she took a 20-mg dose of nifedipine, but 30 minutes after taking a second dose [by implication 3 to 4 hours later] she complained of flushing and sweating and had difficulty in lifting her head and limbs. Shortly afterwards almost complete muscular paralysis developed. The magnesium sulfate was stopped and a dramatic improvement followed within 15 minutes of a 1-g intravenous injection of calcium gluconate.⁶

In contrast, a retrospective analysis found no increased risk of serious magnesium-related maternal adverse effects in 162 women with pre-eclampsia who were also treated with nifedipine compared with 32 women receiving another antihypertensive or 183 who received no antihypertensive. The women receiving nifedipine had more severe pre-eclampsia and a longer magnesium sulfate infusion. However, the incidence of neuromuscular weakness was 53.1% in these women compared with 53.1% in those receiving another antihypertensive and 44.8% in those receiving no antihypertensive. These differences were not statistically significant. Moreover, the incidence of maternal hypotension was lower in those receiving nifedipine than in those receiving no antihypertensive (see (a) above).³

Mechanism

The probable reason for neuromuscular effects is that both drugs can seriously reduce the amount of calcium ions needed for normal muscular contraction. Nifedipine inhibits the inflow of extracellular calcium across cell membranes. Magnesium probably acts in the same way, and also reduces intracellular calcium by activating adenyl cyclase and increasing cAMP. In addition magnesium stimulates calcium-dependent ATPase which promotes calcium uptake by the sarcoplasmic reticulum. The result is muscular paralysis, which is reversed by giving large amounts of calcium. Magnesium sulfate is also known to have neuromuscular blocking activity. Both drugs can also cause hypotension, which could be additive.

Importance and management

Direct information on the neuromuscular effects and hypotensive effects of the combination of nifedipine and magnesium seems to be limited. Although a few cases of possible additive effects have been reported, one large retrospective study did not find an increase in risk of neuromuscular effects or of hypotension with combined use. Nevertheless, at least one manufacturer of nifedipine advises particular caution when it is used in combination with intravenous magnesium sulfate in pregnant women.⁷

The same interaction would be expected to occur with other calcium-channel blockers.

Calcium-channel blockers + Nitrates

Enhanced hypotensive effects may occur when calcium-channel blockers are given with nitrates. The manufacturers of amlodipine say that long-acting nitrates and sublingual glyceryl trinitrate have been given safely with amlodipine.¹ Increased hypotensive effects and faintness due to additive vasodilating effects have been noted when diltiazem has been given with nitrate derivatives. In patients treated with calcium-channel blockers, the dosage of concurrent nitrate derivatives should be increased gradually.²

Calcium-channel blockers + Phenobarbital

Limited evidence suggests that phenobarbital greatly reduces the levels and/or increases the clearance of felodipine, nifedipine, nimodipine, and verapamil. Other calcium-channel blockers are expected to be similarly affected.

Clinical evidence

(a) Felodipine

After taking felodipine 10 mg daily for 4 days, 10 epileptics (including one who was taking phenobarbital) had markedly reduced plasma felodipine levels (peak levels of 1.6 nanomol/L compared with 8.9 nanomol/L in 12 control subjects). The felodipine bioavailability was reduced to 6.6%.¹

(b) Nifedipine

After taking phenobarbital 100 mg daily for 2 weeks the clearance of a single 20-mg dose of nifedipine in a `cocktail’ also containing sparteine, mephenytoin and antipyrine was increased almost threefold in 15 healthy subjects. The nifedipine AUC was reduced by about 60%.²

(c) Nimodipine

A study in 8 epileptic patients receiving long-term antiepileptic treatment (including 4 who were taking phenobarbital and 2 who were taking phenobarbital with carbamazepine) found that the AUC of a single 60-mg oral dose of nimodipine was only about 15% of that obtained from a group of healthy subjects.³

(d) Verapamil

A study in 7 healthy subjects found phenobarbital 100 mg daily for 3 weeks increased the clearance of verapamil 80 mg every 6 hours four-fold and reduced the bioavailability five-fold.⁴
**Mechanism**

Phenobarbital is an enzyme inducer which can increase the metabolism of the calcium-channel blockers by the cytochrome P450 isoenzyme CYP3A4 in the liver, resulting in lower serum levels.

**Importance and management**

Phenobarbital markedly reduces felodipine, nifedipine and verapamil levels. A considerable increase in the dosage of these calcium-channel blockers will probably be needed in patients taking phenobarbital. Nimodipine effects are also markedly reduced by phenobarbital and the manufacturer contraindicates concurrent use. There is no direct information of interactions with other calcium-channel blockers, but as they are largely metabolised in the same way (see ‘calcium-channel blockers’, (p.860)) they would all be expected to interact similarly.

### Symptomatic orthostasis occurred in a patient taking nelfinavir or ritonavir/indinavir and nifedipine. Another patient had similar symptoms when nelfinavir was added to felodipine therapy. Atazanavir markedly increased diltiazem bioavailability with an increase in cardiac effects in healthy subjects. Similarly, ritonavir/indinavir caused a modest increase in diltiazem levels, and a 1.9-fold increase in amlopidine levels. Based on this evidence, raised calcium-channel blocker levels are predicted when any calcium-channel blocker is given with a protease inhibitor, especially ritonavir. Caution is required.

### Clinical evidence

**(a) Amlodipine**

**Ritonavir/indinavir**

100/800 mg twice daily given with amlopidine 5 mg daily for 7 days increased the median AUC of amlopidine by 1.9-fold in 13 healthy subjects. Amlodipine had no effect on the steady-state AUCs of the protease inhibitors.1

**(b) Diltiazem**

1. **Atazanavir.** A study in healthy subjects found that atazanavir 400 mg once daily given with diltiazem 180 mg once daily resulted in a two- to threefold increase in the bioavailability of diltiazem and its metabolite desacetyl-diltiazem. The pharmacokinetics of atazanavir were not affected by diltiazem. There was an increase in the maximum PR interval with combined use compared to that found with atazanavir alone.2,3

2. **Ritonavir with Indinavir.** Ritonavir/indinavir 100/800 mg twice daily with diltiazem 120 mg daily for 7 days modestly increased the median AUC of diltiazem by 27% (not statistically significant) in 13 healthy subjects. However, two of the subjects had a fourfold increase in the AUC of diltiazem, and the desacetyl-diltiazem AUC increased by 102%. Diltiazem had no effect on the steady-state AUCs of the protease inhibitors.1

**(c) Felodipine**

A woman taking metoprolol 50 mg daily and felodipine 5 mg daily for hypertension developed bilateral leg oedema, orthostatic hypotension, and other symptoms including dizziness and fatigue, 3 days after starting HAART following a needle-stick injury. The antiretroviral therapy included zidovudine, lamivudine, and nelfinavir 2 g daily. Anti hypertensive treatment was stopped and the adverse effects abated within 3 days. The patient was then successfully switched to a diuretic-based regimen without recurrence of oedema.4

**(d) Nifedipine**

A 51-year-old HIV positive man with coronary artery disease, hypertension and osteoarthritis, and taking atenolol, was started on extended-release nifedipine 60 mg daily. When his blood pressure control improved he was started on zidovudine 300 mg, lamivudine 150 mg, and nelfinavir 1.25 g all twice daily. Within 3 days of starting the antiretroviral therapy he experienced dizziness, weakness and hypotension and developed complete heart block with a junctional escape rhythm. His ECG returned to normal within 24 hours of stopping the antiretroviral therapy, but he developed orthostatic symptoms within 2 days of restarting nelfinavir. He later tolerated a regimen consisting of stavudine, didanosine and efavirenz without any episodes of dizziness, hypotension or bradycardia. However, when he was given zidovudine, abacavir, ritonavir, and indinavir, he experienced hypotension, decreased heart rate, weakness and fatigue. His symptoms were controlled by modifying his antihypertensive therapy, including discontinuation of atenolol and reduction of the dose of nifedipine to 30 mg daily.5

### Mechanism

**Protease inhibitors, particularly ritonavir** (see ‘Antivirals’, (p.772)), are potent inhibitors of cytochrome P450 isoenzyme CYP3A4, by which all the calcium-channel blockers are extensively metabolised. It appears that some protease inhibitors can cause a clinically relevant increase in calcium-channel blocker levels. In addition, verapamil, diltiazem and nifedipine can also inhibit CYP3A4, and might therefore theoretically reduce the metabolism of the protease inhibitors. However, the effect might depend on which is the more potent inhibitor, since, in the studies above, diltiazem did not affect atazanavir, indinavir or ritonavir levels.

### Importance and management

Although information is limited, these pharmacokinetic interactions are predictable, and potentially serious. To date, clinically relevant increases in calcium-channel blocker levels or effects have been shown for nelfinavir with nifedipine or felodipine, indinavir/ritonavir with amlopidine, diltiazem or nifedipine, and atazanavir with diltiazem. Caution would be required with any of these combinations, anticipating the need to use lower doses of the calcium-channel blocker. The manufacturers specifically recommend that if diltiazem is given with atazanavir the initial dose of diltiazem should be reduced by 50% with subsequent dose titration and ECG monitoring.2,3 They also note that verapamil levels may be raised and therefore advise caution.2,3 Similarly, the manufacturers of nifedipine say that blood pressure monitoring is required and a reduction in nifedipine dose may be necessary if it is given with HIV-protease inhibitors.6,7 However, some UK manufacturers (e.g. felodipine, lercanidipine, nimodipine) recommend avoiding the concurrent use of ritonavir and other protease inhibitors if possible.

Until more is known, caution is warranted with any combination of a calcium-channel blocker and a protease inhibitor.

### Calcium-channel blockers + Proton pump inhibitors

The clearance of both nifedipine and omeprazole is modestly reduced by their concurrent use, but these changes seem unlikely to be of clinical importance. Pantoprazole does not affect the pharmacokinetics of nifedipine.

### Clinical evidence, mechanism, importance and management

**(a) Omeprazole**

After taking omeprazole 20 mg daily for 7 days the clearance of nifedipine was reduced 21% in 10 healthy subjects. The same subjects had a

Calcium-channel blockers + Quinupristin/Dalfopristin

Quinupristin/dalfopristin modestly increased the AUC of nifedipine. Other calcium-channel blockers are predicted to be similarly affected.

Clinical evidence, mechanism, importance and management

The manufacturers note that the AUC of repeated-dose nifedipine was increased 1.4-fold by quinupristin/dalfopristin, and the maximum level was increased by 1.18-fold.1 This is probably because quinupristin/dalfopristin inhibits the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of nifedipine.2 Although the clinical relevance of these increases have not been assessed, the manufacturers advise blood pressure monitoring and, if necessary, a reduction of nifedipine dosage during concurrent use.2,11 It is predicted that other calcium-channel blockers (e.g., verapamil, diltiazem) will also have their levels raised by quinupristin/dalfopristin.2

Calcium-channel blockers + Rifampicin (Rifampin)

Rifampicin markedly reduces the plasma levels of diltiazem, nifedipine, nilvadipine, verapamil and possibly reduces those of barnidipine, isradipine, lercanidipine, manidipine, nicardipine, nimodipine, and nisoldipine. They may become therapeutically raised. Rifapentine and rifabutin would also be expected to reduce the levels of the calcium-channel blockers.

Clinical evidence

(a) Barnidipine and Manidipine

A brief report states that elderly patients with hypertension well-controlled with calcium-channel blockers including barnidipine or manidipine had blood pressure rises when rifampicin was added.6 Increased dosages or additional antihypertensives were needed to control the blood pressures, and reduced doses were required when the rifampicin was withdrawn.1

(b) Diltiazem

A study in 12 subjects found that the peak serum level following a single 120-mg oral dose of diltiazem alone was 186 nanograms/mL, but after taking rifampicin 600 mg daily for 8 days maximum serum diltiazem levels were less than 8 nanograms/mL.2 One patient with angina controlled with diltiazem 120 mg daily began to feel chest pain at rest one month after starting rifampicin and isoniazid. Nifedipine was also not effective in this man while he was taking rifampicin.3

(c) Nifedipine

A woman with hypertension well controlled with nifedipine 40 mg twice daily, had a blood pressure rise from under 160/90 mmHg to 200/110 mmHg within 2 weeks of starting to take antitubercular treatment, which included rifampicin 450 mg daily. When the rifampicin was stopped and then restarted, the blood pressure fell and then rose again. The peak nifedipine plasma levels and the AUC fell by about 60% in the presence of rifampicin.4 Another patient had anginal attacks refractory to both diltiazem and nifedipine while taking rifampicin, but which were controlled by nifedipine when the rifampicin was stopped. Restarting rifampicin reduced nifedipine levels (peak plasma levels and AUC’s roughly halved) and increased the number of anginal attacks.5 Yet another patient taking nifedipine had a loss of blood pressure control when given rifampicin.5

Six healthy subjects were given nifedipine 20 micrograms/kg intravenously and nifedipine 20 mg orally on separate days before and after taking rifampicin 600 mg daily for 7 days. The pharmacokinetics of the intravenous nifedipine were not significantly changed by the rifampicin, but the oral clearance increased from 1.5 to 20.9 L/minute and the bioavailability fell from 41.2 to 5.3%.6 A pharmacokinetic study in 6 healthy subjects found that when a single 10-mg oral dose of nifedipine was taken 8 hours after a single 1.2-g dose of rifampicin its bioavailability was reduced to 36%, its half-life was more than halved and its clearance increased threefold.7

(d) Nilvadipine

A study in 5 healthy normotensive subjects found that rifampicin 450 mg daily for 6 days reduced the peak plasma level and AUC of a single 4-mg dose of nilvadipine by about 20-fold and 30-fold, respectively. The hypotensive effect and reflex tachycardia associated with nilvadipine alone in these subjects was also abolished by rifampicin.6

(e) Nisoldipine

There is some evidence that nisoldipine is ineffective in reducing blood pressure in the presence of rifampicin.14

(f) Verapamil

The observation that a patient whose raised blood pressure was not reduced by verapamil while on antitubercular drugs, prompted a study in 4 other patients.8 No verapamil could be detected in the plasma of 3 patients who took a single 40-mg dose of verapamil with rifampicin 450 to 600 mg daily, isoniazid 5 mg/kg daily, and ethambutol 15 mg/kg daily. A maximum verapamil level of 20 nanograms/mL was found in the fourth patient. Six other subjects not taking antitubercular drugs had a maximum verapamil plasma concentration of 35 nanograms/mL.9 Similar results have been reported by the same authors in another study.10 Supraventricular tachycardia was inadequately controlled in a patient taking rifampicin 600 mg daily and isoniazid 300 mg daily, despite a verapamil dose of 480 mg every 6 hours. Substitution of the rifampicin by ethambutol resulted in a fourfold rise in serum verapamil levels.11 Later study in 6 healthy subjects found that after taking rifampicin 600 mg daily for 2 weeks the oral bioavailability of verapamil was reduced from 26 to 2%, and the effects of verapamil on the ECG were abolished.12 Yet another study in elderly patients similarly found that rifampicin 600 mg daily markedly increased the clearance of verapamil 120 mg twice daily. The effects of verapamil on AV conduction were almost abolished.13

Mechanism

Rifampicin reduces the effectiveness of nifedipine and verapamil to a greater extent after oral than after intravenous use. The evidence suggests that rifampicin increases the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of calcium-channel blockers in the gastrointestinal wall6,12,13 thereby reducing their oral bioavailability. Rifabutin and rifapentine are also inducers of CYP3A4, although to a lesser extent than rifampicin, and would therefore also be expected to reduce the levels of the calcium-channel blockers.

Importance and management

The interactions between diltiazem, nifedipine, or verapamil and rifampicin are established and of clinical importance. There is some evidence that barnidipine, manidipine, nilvadipine, and nisoldipine interact with rifampicin and the manufacturers of a number of other calcium-chan-
Calcium-channel blockers + Sulfonpyrazone

The clearance of verapamil is markedly increased by sulfonpyrazone.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that sulfonpyrazone 80 mg daily for a week increased the clearance of a single oral dose of verapamil by about threefold, possibly due to an increase in its liver metabolism. The clinical importance of this is uncertain, but be alert for reduced verapamil effects. It seems probable that the dosage may need to be increased.

Calcium-channel blockers + Terbinafine

A study in 12 healthy subjects found that terbinafine 250 mg did not alter the pharmacokinetics of nifedipine 30 mg (as Procardia XL).

Calcium-channel blockers + Valproate

Nimodipine and possibly nifedipine levels are raised by valproate.

Clinical evidence, mechanism, importance and management

Eight epileptic patients who had been taking valproate alone for at least 4 months were given a single 60-mg dose of nimodipine. The AUC of nimodipine was about 50% higher than in the control group. The nimodipine dosage may need to be reduced if it is given with valproate.

One of the UK manufacturers of nimodipine notes that there is a theoretical possibility that levels of nimodipine may be increased in the presence of valproate. The US manufacturer recommends blood pressure monitoring during concurrent use and also suggests that a reduction in the dose of nimodipine should be considered.

Calcium-channel blockers + St John’s wort

St John’s wort significantly reduces the bioavailability of verapamil.

St John’s wort decreases the bioavailability of both R- and S-verapamil by inducing their metabolism by the cytochrome P450 isoenzyme CYP3A4 in the gut. An effect on P-glycoprotein-mediated transport is not likely, as intestinal permeability was not significantly altered. The clinical importance of this interaction is not known but it may be prudent to avoid concurrent use. There appears to be no information about other calcium-channel blockers, but as they are also affected by other CYP3A4 enzyme inducers, it would seem prudent to monitor concurrent use carefully. More study is required.

Calcium-channel blockers + Vinca

An isolated case report suggests that the hypotensive effects of the rapid infusion of vinca may occur more readily in those who are already vasodilated with nifedipine, but it seems likely that the effects seen were due to the rapid infusion alone.

Clinical evidence, mechanism, importance and management

A man with severe systemic sclerosis was hospitalised for Raynaud’s phenomenon and dental extraction. After being started on nifedipine 40 mg daily, he was given intravenous vinca 1 g in 200 mL of dextrose 5% over 30 minutes. After 20 minutes he experienced a severe headache and was found to have a marked macular erythema on the upper trunk, head, neck and arms. His blood pressure fell to 100/60 mmHg and his pulse rate was 90 bpm. He recovered spontaneously. The authors of the report acknowledge the possibility of ‘red-man syndrome’ caused by the vinca, and suggest that it may occur more readily in those already vasodilated with nifedipine. However, given that this is an isolated report, and the vinca was given over 3 times faster than the recommended rate, it seems likely that this is purely an adverse effect of vinca.
Calcium-channel blockers + X-ray contrast media

The hypotensive effects of an intravenous bolus of an ionic X-ray contrast medium can be increased by the presence of calcium-channel blockers. No interaction or only a small interaction appears to occur with non-ionic contrast media.

Clinical evidence, mechanism, importance and management

It is well recognised that ionic X-ray contrast media used for ventriculography reduce the systemic blood pressure due to peripheral vasodilation. They also have a direct depressant effect on the heart muscle. A comparative study of the haemodynamic response of 65 patients found that the hypotensive effect of a bolus dose of an ionic agent (0.5 mL/kg of meglumine amidotrizoate and sodium amidotrizoate with edetate sodium or disodium) was increased by the concurrent use of nifedipine or diltiazem. Haemodynamic effects occurred earlier (3.1 seconds instead of 12.9 seconds), were more profound (a fall in systolic pressure of 48.4 instead of 36.9 mmHg) and more prolonged (62 seconds instead of 36 seconds).1 A similar interaction was seen in dogs given verapamil.2 No interaction or only a minimal interaction was seen in the patients and dogs when non-ionic contrast media (iopamidol or iohexol) were used instead.1,2 The clinical relevance of these findings is uncertain. Note that calcium-channel blockers have been tried to prevent the nephrotoxicity of contrast media.

Calcium-channel blockers + Zidovudine

Animal studies suggest that nimodipine may increase the bioavailability of zidovudine.

Clinical evidence, mechanism, importance and management

Studies in animals have shown that the AUC of zidovudine is increased and its volume of distribution and clearance rate decreased when it is given with nimodipine.1 The clinical relevance of the interaction is not known, but as the adverse effects of zidovudine are dose related, the manufacturer of nimodipine suggests that the possibility of this interaction should be borne in mind in patients given both drugs.2

Cardiovascular drugs, miscellaneous

The drugs dealt with in this section include the centrally acting drugs (clonidine, methyldopa), inotropes and vasopressors (adrenaline, phenylephrine), adrenergic neurone blockers (guanethidine), some vasodilator antihypertensives (hydralazine, diazoxide), nitrates (glyceryl trinitrate), potassium channel activators (nicorandil), peripheral vasodilators (pentoxifylline), calcium sensitisers (levosimendan), endothelin antagonists (bosentan) and newer drugs used in the management of angina (ivabradine and ranolazine).

(a) Miscellaneous antihypertensives

The combination of two antihypertensive drugs often results in an increased antihypertensive action, likewise the combination of drugs which may have hypotension as an adverse effect, can lead to an unexpected increase in hypotension. Examples of this type of interaction are discussed in the monograph ‘Antihypertensives + Other drugs that affect blood pressure’, p.880. Some drugs are known to antagonise the effect of antihypertensives, and these are also generally discussed in this monograph.

(b) Sympathomimetics

Many of the inotropes and vasopressors have actions on the sympathetic nervous system. Noradrenaline (norepinephrine) is the principal neurotransmitter involved in the final link between nerve endings of the sympathetic nervous system and the adrenergic receptors of the organs or tissues innervated. The effects of stimulating this system can be reproduced or mimicked by exogenous noradrenaline and by a number of other drugs that also stimulate these receptors. The drugs that behave in this way are described as ‘sympathomimetics’ and act either directly, like noradrenaline, on the adrenergic receptors, or indirectly by releasing stored noradrenaline from the nerve endings. Some drugs do both. This is very simply illustrated in ‘Figure 24.1’, (below).

The adrenergic receptors of the sympathetic system are not identical but can be subdivided into two main types, namely alpha and beta receptors, which can then be further subdivided. The sympathomimetics are categorised in ‘Table 24.1’, (p.879), and a brief summary of the principal effects of stimulation of these receptors is listed below:

- **Alpha_{1}** (vasoconstriction, increased blood pressure and sometimes reflex bradycardia; contraction of smooth muscle; mydriasis in the eye)
- **Alpha_{2}** (role in feedback inhibition of neurotransmitter release; inhibition of insulin release)
- **Beta_{1}** (increased rate and force of contraction or the heart)
- **Beta_{2}** (vasodilatation and bronchodilation; uterine relaxation and decreased gastrointestinal motility; release of insulin)

A third distinct group of receptors, which occur primarily within the CNS and may be affected by some sympathomimetics, are the dopamine receptors.

It is therefore possible to broadly categorise the sympathomimetics into groups according to their activity.

Given these wide ranging actions on a number of different receptors the group ‘sympathomimetics’ is clearly a very diverse collection of drugs with a wide range of uses. One should not, therefore, extrapolate the interactions seen with one drug to any other without fully taking into account their differences. For this reason, where possible, this term has been avoided and drugs have been grouped by therapeutic use. This section is generally concerned with the interactions of sympathomimetics that have predominately cardiovascular actions (mainly through stimulation of alpha_{1} and/or beta_{1} receptors). Those used as decongestants (through stimulation of alpha receptors with or without beta activity) are mainly discussed in the Miscellaneous drugs section but some of these drugs are also given intravenously for their pressor actions, in which case their interactions are discussed here. Interactions involving beta agonists, such as salbutamol, which selectively stimulate the beta_{2} receptors in bronchi causing bronchodilation, are mainly covered in ‘Respiratory drugs’, (p.1158) and interactions involving dopaminergics, such as levodopa, are dealt with in ‘Antiparkinsonian and related drugs’, (p.672).

---

</table>
**Antihypertensives + Hormonal contraceptives**

Combined oral contraceptives are associated with increased blood pressure and may antagonise the efficacy of antihypertensive drugs. However, the effects are far greater with the high-dose contraceptives that were used historically, and the risks appear to be smaller with the newer low-dose contraceptives.

**Clinical evidence, mechanism, importance and management**

Early after the introduction of combined oral contraceptives it was realised that they can cause increases in blood pressure and clinical hypertension.\(^1\,\^2\) One study,\(^3\) from the 1970s, in 83 women found that the average rise in blood pressure was 9.2/5 mmHg, and that it was about twice as likely to occur as in those not on the pill. Additionally, cases were noted where a rise in blood pressure was 9.2/5 mmHg, and that it was about twice as likely to occur in women with hypertension on combined oral contraceptives.\(^2\,\^6\) Although modern combined oral contraceptives are lower dose, they are still associated with a small increased risk of elevated blood pressure.\(^5\) A UK study found that combined oral contraceptives were associated with a 2.6/1.8 mmHg rise in blood pressure, whereas progesterone-only oral contraceptives did not affect blood pressure.\(^2\) Further, in a study in 24 postmenopausal women with hypertension taking enalapril 10 mg twice daily the use of enalapril with drospirenone/estradiol 3/1 mg (12 women) produced a significant decrease in blood pressure of 9/5 mmHg after 14 days of treatment, when compared with the placebo group (12 patients). No serious adverse effects were reported.\(^6\) Note that drospirenone is an analogue of spironolactone, and shares some of its effects, including its blood-pressure-lowering effects.

This is only a very brief review of this subject, but the risks of hypertension with combined hormonal contraceptives appear to be modest. Nevertheless, they need to be considered in the context of other possible cardiovascular risk factors. Where possible, blood pressure should be monitored before and during contraceptive use.

---

---

**Antihypertensives + Other drugs that affect blood pressure**

The hypotensive effect of antihypertensives can be enhanced by other antihypertensives, as would be expected. Although ‘first-dose hypotension’ (dizziness, lightheadedness, fainting) can occur with some combinations, the additive effects are usually clinically useful. Perhaps more of concern is the use of antihypertensives with drugs that have hypotension as an adverse effect, where the effects may not be anticipated. Some drugs antagonise the blood pressure-lowering effects of the antihypertensives and should therefore be used with caution.

**Clinical evidence, mechanism, importance and management**

(a) **Antihypertensive drugs**

Enhanced hypotensive effects should be expected when using two antihypertensives together and it is now widely acknowledged that most people require more than one antihypertensive to control blood pressure.\(^1\) In the US, more than two-thirds of patients receive two or more antihypertensives in order to reach the desired target blood pressure. Not only does this improve blood pressure control, but adverse effects can also be reduced as lower doses of each drug can be used.\(^2\)

Therefore many antihypertensive combinations produce additive effects that are exploited clinically. ‘Calcium-channel blockers and diuretics’, (p.867) are often used together for additional blood pressure lowering in patients with hypertension. Although there are only a few reports describing these additive interactions, they are highly probable, and caution is advised when using two antihypertensives together. The most common symptoms seen in hypotensive patients are dizziness, fatigue, headache, nausea, confusion, general weakness, lightheadedness, faintness and possible loss of consciousness.

However, in some cases combining two or more antihypertensives has led to severe, first-dose hypotension, see ‘Alpha blockers + ACE inhibitors’, p.84. Further, life-threatening bradyarrhythmia, asystole and sinus arrest can occur when antihypertensives that cause cardiodepression are given together (see ‘beta blockers and diltiazem’, p.840).

In contrast, a sharp and serious rise in blood pressure (rebound hypertension) can occur following the sudden withdrawal of clonidine, and this can be exacerbated in the presence of a beta blocker (see ‘clonidine’, p.882). In some cases fatalities have occurred. ‘Table 24.2’, (p.881) lists antihypertensive combinations that have been implicated in adverse events.

(b) **Drugs with significant hypotensive adverse effects**

Caution must also be used when combining two or more drugs that, although not primarily indicated for hypertension, may have hypotensive adverse effects. In fact, it is these drugs, rather than drugs commonly given for their hypotensive effects that may cause more of a problem, as the effects are less likely to be deliberately sought. These drugs are listed in ‘Table 24.3’, (p.881) with cross-references to the individual monographs that discuss the reports of adverse effects from these combinations.

(c) **Drugs that antagonise hypotensive effects**

When using antihypertensive drugs it is important to consider the implications of using drugs that antagonise their effects. The NSAIDs are the prime example of this. Drugs that are thought to antagonise the effects of antihypertensives are listed in ‘Table 24.4’, (p.881), with cross-references to the individual monographs that discuss the reports of adverse effects from these combinations.

---

---

**Antihypertensives + Phenylpropanolamine**

A single dose of a sustained-release preparation of phenylpropanolamine and brompheniramine was found to cause a minor and clinically insignificant rise in the blood pressures of patients on various antihypertensives.

**Clinical evidence, mechanism, importance and management**

A randomised, double-blind, crossover study in 13 patients with hypertension controlled with unnamed diuretics (7), ACE inhibitors (6), beta blockers (5), calcium-channel blockers (1) and a centrally acting alpha-agonist (1) found that a single dose of Dimetapp Extendtabs (phenylpropanolamine 75 mg with brompheniramine 12 mg) caused only a minor rise in blood pressure of 1.7/0.9 mmHg over 4 hours.\(^1\) This sustained-release preparation in this dosage has therefore no clinically important effect on blood pressure, but (as the authors point out), these results do not necessarily apply to different doses and immediate-release preparations. A marked rise in blood pressure was seen in one patient taking methyldopa and oxprenolol when given phenylpropanolamine, see ‘Methyldopa + Sympathomimetics; Indirectly-acting’, p.898. Consider also ‘Beta blockers + Phenylpropanolamine’, p.851.

Ketoconazole increases bosentan levels by twofold: fluconazole is predicted to have a greater effect.

Clinical evidence, mechanism, importance and management

In a randomised crossover study, 10 healthy subjects were given bosentan 62.5 mg twice daily for 11 doses, either alone, or with ketoconazole 200 mg daily. The maximum plasma level of bosentan was increased 2.1-fold, and the AUC was increased 2.3-fold (range 1.4- to 4-fold) by ketoconazole. This interaction probably occurs because bosentan is metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a known, potent inhibitor.1

Other potent CYP3A4 inhibitors (e.g. itraconazole) are expected to interact similarly to ketoconazole.2 However, because fluconazole (a moderate inhibitor of CYP3A4) also inhibits CYP2C9, another enzyme involved in the metabolism of bosentan, it is anticipated that it could cause even larger increases in bosentan levels.

The clinical significance of raised the bosentan levels is unclear. Bosentan has been tolerated in single-doses of up to 2.4 g in healthy subjects, although elevations in liver transaminases have been seen during long-term, even larger increases in bosentan levels.

The hypotensive adverse effects of the phenothiazines, and possibly haloperidol may be additive with the antihypertensive effects of clonidine. Patients may feel faint and dizzy if they stand up quickly.

Clinical evidence

One report describes a patient who experienced dizziness and hypotension (systolic blood pressure 76 mmHg) about an hour after being given chlorpromazine 100 mg, clonidine 100 micrograms and furosemide 40 mg. Another patient also experienced hypotension 2 hours after being given clonidine 100 micrograms and a 1-mg intramuscular dose of haloperidol.1

There is also an isolated and unexplained case of a psychotic patient taking fluphenazine decanoate who began to exhibit delirium, agitation, disorientation, short-term memory loss, confusion and clouded consciousness within 10 days of starting to take clonidine 200 micrograms daily. These symptoms disappeared when the clonidine was stopped and returned when it was re-started. He had previously uneventfully taken haloperidol with clonidine.2

Mechanism

Simple addition of the hypotensive effects of both drugs seems to be the explanation for the increased hypotension and orthostasis. However, note that in contrast to the case report above, animal studies have shown that chlorpromazine reduces the antihypertensive effect of clonidine.3

Importance and management

The increased hypotension and orthostasis that can occur if phenothiazines are used with antihypertensive drugs such as clonidine is established. Note that, of the phenothiazines, levomepromazine is particularly associated with postural hypotension. One report suggests that haloperidol may interact similarly. Monitor, particularly during the initial stages of concurrent use, and warn patients that if they feel faint and dizzy they should lie down, and that they should remain lying down until symptoms abate completely. Dosage adjustment may be necessary.

The manufacturers of clonidine note that a reduced antihypertensive effect may occur with antipsychotics with alpha-blocking properties (e.g. chlorpromazine), as well as mentioning the risk of orthostatic hypotension. Consider also ‘Clonidine + Tricyclic and related antidepressants’, p.884. Although antagonism of the antihypertensive effect of clonidine has been seen in animals given chlorpromazine, there appear to be no clinical reports.

The use of clonidine with beta blockers can be therapeutically valuable, but a sharp and serious rise in blood pressure (‘rebound hypertension’) can follow the sudden withdrawal of clonidine, which may be worsened by the presence of a beta blocker. Isolated cases of marked bradycardia and hypotension have been seen in patients given clonidine with esmolol. There are also two reports describing paradoxical hypertension with the combination of clonidine and beta blockers.

Clinical evidence

(a) Exacerbation of the clonidine-withdrawal hypertensive rebound

A woman with a blood pressure of 180/140 mmHg was taking clonidine and timolol. When the clonidine was stopped in error, she developed a violent throbbing headache and became progressively confused, ataxic and...
Clonidine and atenolol (a cardio-selective beta blocker) have additive hypotensive effects and smaller doses of clonidine can be given, which decreases its troublesome adverse effects (sedation and dry mouth). In contrast, limited evidence suggests that propranolol or nadolol (non-selective beta blockers) the blood pressure reductions were the same as with either drug alone, although this has not been confirmed in other studies. The weight of evidence suggests that paradoxical hypertension is rare.12,13

### Clonidine + Bupropion

Bupropion 100 mg three times daily for 9 days did not reduce the hypotensive effect of a single 300-microgram dose of oral clonidine in 8 healthy subjects.1

### Clonidine and related drugs + CNS depressants

Increased sedation may occur if alcohol or other CNS depressants are taken with clonidine, guanfacine or guanabenz.

#### Clinical evidence, mechanism, importance and management

Sedation is a common adverse effect of clonidine and other central alpha-adrenoceptor agonists such as guanfacine and guanabenz, particularly during the initial stages of treatment.13 Patients starting treatment with these drugs should be warned that their tolerance to alcohol and other CNS depressant drugs may be diminished. Patients who are affected should not drive or operate machinery. Consider also ‘Moxonidine + Miscellaneous’, p.899.

### Clonidine + Hormonal contraceptives

The sedative effects of intravenous clonidine have been increased by a combined oral contraceptive.
Clinical evidence, mechanism, importance and management

A study in a group of 10 women found that the sedative effects of a single 1.3-microgram/kg dose of intravenous clonidine were increased by a combined oral contraceptive (ethinylestradiol/levonorgestrel 30 micrograms/150 or 250 micrograms). The clinical importance of this is uncertain. Consider also ‘Antihypertensives + Hormonal contraceptives’, p.880.

Clonidine + Naloxone

A study in animals suggesting naloxone blocked the antihypertensive effects of clonidine prompted a placebo-controlled study in 6 patients with hypertension. Each patient received a single oral dose of clonidine 300 micrograms during an infusion of either naloxone 6 micrograms/kg per hour for 8 hours. Supine and standing blood pressure and heart rate were monitored. Naloxone was not found to affect the hypertensive or bradycardic effect of clonidine.1

Clonidine + Prazosin

There is some evidence to suggest that prazosin can reduce the antihypertensive effects of clonidine, whereas some other evidence suggests that this does not occur.

Clinical evidence, mechanism, importance and management

The hypertensive effect of a 150-microgram intravenous dose of clonidine was reduced by 47% in 18 patients with essential hypertension after they took prazosin (mean dose 11 mg three times daily for 4 days).1 A later crossover study by the same research group in 17 patients with essential hypertension (mean blood pressures 170/103 mmHg) found that clonidine 300 micrograms daily for 4 days reduced the mean blood pressure by 38/18 mmHg and prazosin 6 mg daily for 3 days reduced the mean blood pressure by 10/4 mmHg. However, when prazosin and clonidine were given together the mean blood pressure was only reduced to a similar extent as prazosin alone (12/6 mmHg).2 Similarly, some earlier studies had suggested that the combination of clonidine and prazosin produced only a modest,1 or no additive antihypertensive effect.4 Conversely, other studies using the combination have not reported a reduced antihypertensive effect.2,5 In the presence of prazosin the rebound hypertension following clonidine withdrawal was said to be moderate (a rise from 145/85 to 169/104 mmHg).6

Clonidine is an alpha, agonist, whereas prazosin is an alpha, blocker. Consequently, it has been postulated that the drugs may be partially antagonistic when given together, and the authors of the first study cite a number of animal studies to support this.1 Although not conclusive, it seems possible that concurrent use may not always be favourable. Monitor the effects.

Clonidine + Rifampicin (Rifampin)

Rifampicin does not interact with clonidine.

Clinical evidence, mechanism, importance and management

In 6 subjects taking clonidine 200 micrograms twice daily the use of rifampicin 600 mg twice daily for 7 days did not affect the elimination kinetics of clonidine, or its effects on pulse rate or blood pressure.1 No special precautions would seem necessary on concurrent use.

Clonidine + Tricyclic and related antidepressants

The tricyclic antidepressants, clomipramine, desipramine and imipramine, reduce or abolish the antihypertensive effects of clonidine. Other tricyclics are expected to behave similarly. A hypertensive crisis developed in a woman taking clonidine who was also given imipramine, and severe pain occurred in a man taking amitriptyline and diamorphine when he was given intrathecal clonidine. Conversely, the tetracyclics, maprotiline and mianserin do not appear to alter the antihypertensive effects of clonidine. An isolated case report describes a hypertensive crisis in a patient taking mirtazapine and clonidine. Hypotension occurred in a boy taking clonidine and trazodone.

Clinical evidence

(a) Tetracyclic and related antidepressants

Maprotiline 100 mg in 4 divided doses over 22 hours did not alter the effect of a single dose of clonidine on blood pressure or heart rate in 8 healthy subjects.1 Mianserin 20 mg three times daily for 2 weeks had no effect on the control of blood pressure in 5 patients receiving clonidine.2,3 Similarly, mianserin pretreatment did not significantly alter the hypertensive action of a single dose of clonidine in healthy subjects.2,4 In contrast, an isolated report describes hypertensive urgency in a man with end-stage renal disease taking clonidine, metaboloprol and losartan when mirtazapine (a mianserin analogue) was added for depression.5

(b) Trazodone

A 12-year-old boy taking clonidine 100 micrograms three times daily and dexamfetamine 15 mg twice daily was prescribed trazodone 50 mg at bedtime. After a few weeks his trazodone dosage was increased to 100 mg at bedtime. Within 45 minutes of taking his first increased dose he had a hypotensive episode with bradycardia and sedation. The trazodone dose was reduced back to 50 mg, but the drug was discontinued 2 weeks later because of low blood pressure.6

(c) Tricyclic antidepressants

Desipramine 75 mg daily for 2 weeks caused the lying and standing blood pressures of 4 out of 5 hypertensive patients taking clonidine 600 to 1800 micrograms daily (with chlortalidone or hydrochlorothiazide) to rise by 22/15 mmHg and 12/10 mmHg respectively.7 This interaction has been seen in other patients taking clomipramine, desipramine and imipramine.8–11 In one study, the antihypertensive effects of a single intravenous dose of clonidine were reduced by about 50% in 6 patients given desipramine for 3 weeks.12 Similarly the blood pressure lowering effect of a single 300-microgram dose of clonidine was reduced by 40 to 50% in 8 healthy subjects when it was given on day 9 of treatment with imipramine 25 mg three times daily.13 An elderly woman taking clonidine 200 micrograms daily developed severe frontal headache, dizziness, chest and neck pain and tachycardia of 120 bpm with hypertension (230/124–130 mmHg) on the second day of taking clonidine and trazodone. Hypotension occurred in a boy taking clonidine and trazodone.

Mechanism

Not understood. One idea is that the tricyclics desensitise or block central alpha2-receptors.17 This would explain the interaction with mirtazapine (a
mianserin (analpha-blocker) did not interact.2 Another idea is that tricyclics block noradrenaline uptake. However, mepatrolpine, which also blocks noradrenaline uptake, did not interact.3 Trazodone, which also has alpha-blocking properties was predicted to inhibit the effect of clonidine based on a study in animals where it antagonised the hypotensive effect of clonidine when given centrally (note this effect was not seen when it was administered intravenously).15 The case of hypotension described could be explained by the hypotensive effect of trazodone alone, but may have been compounded by the hypotensive effect of clonidine.

**Importance and management**

The interaction between clonidine and the tricyclics is established and clinically important. The incidence is uncertain but it is not seen in all patients.7 Avoid concurrent use unless the effects can be monitored. Increasing the dosage of clonidine may possibly be effective. The clonidine dosage was apparently successfully titrated in 10 out of 11 hypertensive patients already on amitriptyline or imipramine.19 Only clomipramine, desipramine and imipramine have been implicated so far, but other tricyclic antidepressants maprotiline and mianserin do not generally appear to interact with clonidine. The isolated case of hypotension with trazodone is of unknown general importance.

ing pregnancy. Available in the Cochrane Database of Systematic Reviews; Issue 3. Chiches-

**Importance and management**

The concurrent use of intravenous diazoxide and hydralazine should be undertaken extremely cautiously with thorough monitoring. Note that the doses of diazoxide used in the above reports were frequently higher than those currently recommended for hypertensive crises.7 In addition, there are now many more options available for the treatment of very severe hyper-
tension, and the BNF in the UK considers intravenous diazoxide to be one of the less suitable choices.5 Moreover, diazoxide was frequently as-

Other cases of severe hypotension in patients given high doses of intravenous diazoxide and intravenous or oral hydralazine are described in this1 and other studies and reports.2–4 In some instances the patients had also received other antihypertensives such as methylpsepina or reserpine.1,4 At least three of the cases had a fatal outcome.4

**Mechanism**

Not fully understood. The (vasodilatory) hypotensive effects of the two drugs are additive, and it would seem that in some instances the normal compensatory responses of the cardiovascular system to maintain an adequate blood pressure reach their limit. This can occur with intravenous di-

**Diazoxide + Other drugs with hyperglycaemic activity**

The risk of hyperglycaemia is increased if diazoxide is given with other drugs with hyperglycaemic activity (e.g. the thiazides, chloro-
pramone, corticosteroids, combined oral contraceptives).

**Clinical evidence, mechanism, importance and management**

An isolated report1 describes a child receiving long-term treatment for hy-
poglycaemia with diazoxide 8 mg/kg daily in divided doses and bend-
rufomethiazide 1.25 mg daily, who developed a diabetic pre-coma and severe hyperglycaemia after taking a single 30-mg dose of chlor-
pramone. The reason for this reaction is not understood but one idea is that all three drugs had additive hyperglycaemic effects. Enhanced hyper-
glycaemia has been seen in other patients given diazoxide with trichlorme-
thiazide.5 Caution is clearly needed to ensure that the hyperglycaemic effects do not become excessive. The manufacturers of diazoxide also mention that the risk of hyperglycaemia may be increased by corticoster-
oids or oestrogen-progestogen combinations (e.g. combined oral con-
traceptives).3

**Diazoxide + Hydralazine**

Severe hypotension, in some cases fatal, has followed the use of high doses of intravenous diazoxide, given before or after hy-
drazone.

**Clinical evidence**

A previously normotensive 25-year-old woman had a blood pressure of 250/150 mmHg during the 34th week of pregnancy, which failed to re-

**Glycerin trinitrate (Nitroglycerin) + Antimuscarinics**

Drugs with antimuscarinic effects, such as the tricyclic antide-
presssants and disopyramide, depress salivation and many pa-
tients complain of having a dry mouth. In theory sublingual 
glycerin tritrate tablets will dissolve less readily under the 
tongue in these patients, thereby reducing their absorption and
effects. However, no formal studies seem to have been done to confirm that this actually happens. ‘Table 18.1’, (p.672), and ‘Table 18.2’, (p.674) list drugs that have antimuscarnicotinic effects. A possible alternative is to use a glyceryl trinitrate spray in patients who suffer from dry mouth.

Glyceryl trinitrate (Nitroglycerin) + Aspirin

Some limited evidence suggests that analgesic doses of aspirin can increase the serum levels of glyceryl trinitrate given sublingually, possibly resulting in an increase in its adverse effects such as hypotension and headache. Paradoxically, long-term aspirin use appears to reduce the effects of intravenous glyceryl trinitrate used for vasodilatation in patients following coronary artery bypass surgery.

Clinical evidence

(a) Glyceryl trinitrate (sublingual) effects increased

When aspirin 1 g was given to 7 healthy subjects followed one hour later by 800 micrograms of glyceryl trinitrate sublingual spray, the mean plasma glyceryl trinitrate levels 30 minutes after administration were increased by 54% (from 0.24 to 0.37 nanograms/mL). The haemodynamic effects of the glyceryl trinitrate (including heart rate and reduced diastolic blood pressure) were enhanced. Some changes were seen when aspirin 500 mg was given every 2 days (described as an anti-aggregant dose) but the effects were not statistically significant.1,2

(b) Glyceryl trinitrate (sublingual) effects unchanged

A study in 40 healthy subjects who were given 650 mg aspirin or placebo, followed after 1 to 2 hours by sublingual glyceryl trinitrate 432 micrograms found no significant alterations in the peak haemodynamic response, nor the area under the time-pressure and time-pulse curves. There was a transient pressor response, which occurred 1 minute after glyceryl trinitrate was given: this was blunted by aspirin. Taken alone, this change was significant, but when the overall pattern of changes during the 30 minute study was considered, the differences were not significant.3

(c) Glyceryl trinitrate (intravenous) effects reduced

A study in patients following coronary artery bypass surgery found that those who had been taking aspirin 150 or 300 mg daily (33 patients) for at least 3 months, needed more glyceryl trinitrate to control blood pressure during the recovery period than those who had not taken aspirin (33 patients). To achieve the blood pressure criteria required, the aspirin-group needed an 8.2 microgram/minute infusion of glyceryl trinitrate. The dose remained relatively high at 3.3 micrograms/minute even after 8 hours, whereas the non-aspirin group needed only 5.5 micrograms/minute, which was reduced to 1.9 micrograms/minute after 8 hours.4

Mechanism

Not understood. Prostaglandin-synthetase inhibitors such as aspirin can, to some extent, suppress the vasodilator effects of glyceryl trinitrate by blocking prostaglandin release. However, it seems that a much greater pharmacodynamic interaction also occurs, in which aspirin reduces the flow of blood through the liver, so that the metabolism of the glyceryl trinitrate is reduced, thus increasing its levels, and therefore its effects.

Importance and management

A confusing and unexplained situation. It seems possible that patients taking sublingual glyceryl trinitrate may experience an exaggeration of its adverse effects such as hypotension and headaches if they are taking analgesic doses of aspirin. Also be aware that long-term aspirin use may reduce the vasodilatory effects of intravenous glyceryl trinitrate. The antiplatelet effects of aspirin and glyceryl trinitrate appear to be additive.5

Clinical evidence

The effect of sublingual glyceryl trinitrate was not altered by pretreatment with nifedipine in two studies. Nifedipine and intravenous glyceryl trinitrate had additive vasodilator effects in one study, but the preliminary results of another study found that patients undergoing coronary artery bypass surgery and taking nifedipine 20 mg twice daily required more intravenous glyceryl trinitrate than those taking nifedipine 10 mg twice daily or those not taking nifedipine.

Clinical evidence, mechanism, importance and management

(a) Sublingual glyceryl trinitrate

In 9 patients with stable chronic angina, there was no significant haemodynamic interaction between sublingual glyceryl trinitrate and a single-dose of nifedipine, or nifedipine three times daily for 5 days.1 In another study in healthy subjects, the venodilatory effect of sublingual glyceryl trinitrate was not altered by pretreatment with nifedipine 10 mg.2 No special precautions are required during concurrent use.

(b) Intravenous glyceryl trinitrate

In 7 patients with severe congestive heart failure, a single-dose of oral nifedipine increased stroke volume, with a peak effect at 30 minutes. The addition of intravenous glyceryl trinitrate at 2 hours further increased stroke volume and increased the cardiac index.3 Therefore the addition of glyceryl trinitrate enhanced the vasodilator action of nifedipine. Conversely, in the preliminary findings of a comparative study of 3 groups of patients undergoing coronary bypass graft surgery, those taking nifedipine 20 mg twice daily needed initial doses of intravenous glyceryl trinitrate (to reduce cardiac workload, maintain graft patency and control blood pressure) that were about 40% higher than those in the other 2 groups; one taking nifedipine 10 mg twice daily for hypertension, and the other a control group of normotensive patients. Moreover, these higher doses had little effect on the initial mean systolic blood pressure of half of the group taking nifedipine 20 mg twice daily, and they needed an additional infusion of nitropusside.4 It was suggested that since glyceryl trinitrate is converted to nitric oxide to elicit its vasodilator effect, it is possible that the nifedipine inhibits the enzymic production of the nitrous oxide. This appears to be the only study to suggest a negative interaction, and the clinical relevance of its findings is unclear. Note that this study was non-randomised, and there may have been other important differences between the patients in each group that would account for the effects seen.

Guanethidine + Amphetamines and related drugs

The antihypertensive effects of guanethidine can be reduced or abolished by drugs including dexamfetamine, ephedrine, metamphetamine and methyldopa. The blood pressure may even rise higher than before treatment with the antihypertensive.

Clinical evidence

When 16 hypertensive patients taking guanethidine 25 to 35 mg daily were given single-doses of dexamfetamine 10 mg orally, ephedrine 90 mg orally, metamphetamine 30 mg intramuscularly or methyldopa 20 mg orally, the hypotensive effects of the guanethidine were com-
pletely abolished, and in some instances the blood pressures rose higher than before treatment with the guanethidine. Another report describes the same interaction between guanethidine and dexamfetamine.

### Mechanism

These drugs are all indirectly-acting sympathomimetic amines, which not only prevent guanethidine-like drugs from entering the adrenergic neurons of the sympathetic nervous system, but also displace the antihypertensive drug already there. As a result the blood pressure lowering effects are lost. In addition these amines release noradrenaline (norepinephrine) from the neurons, which raises the blood pressure. Thus the antihypertensive effects are not only opposed, but the pressure may even be raised higher than before treatment.

### Importance and management

Well documented, well established, and clinically important interactions. Other drugs, such as phenylpropanolamine, which is also an indirectly-acting sympathomimetic, are likely to interact similarly. Patients taking guanethidine should avoid indirectly-acting sympathomimetics, see “Table 24.1”, (p.879) for a list. Warn them against the temptation to use proprietary non-prescription nasal decongestants containing any of these amines to relieve the nasal stuffiness commonly associated with the use of guanethidine and related drugs. The same precautions apply to the sympathomimetics used as appetite suppressants. However, one brief report stated that diethylpropion has been used with guanethidine without any adverse events. Note that guanethidine increases the hypertensive effects of ‘directly-acting sympathomimetics’, (p.891).

### Guanethidine + Antipsychotics

Large doses of chlorpromazine may reduce or even abolish the antihypertensive effects of guanethidine, although in some patients the inherent hypotensive effects of the chlorpromazine may possibly predominate. Case reports suggest that haloperidol and tiotixene may interact similarly. Molindone is reported not to interact with guanethidine, but it would be wise to confirm that excessive hypotension does not develop.

### Clinical evidence

Two severely hypertensive patients, with stable blood pressure while taking guanethidine 80 mg daily, were given chlorpropramide 200 to 300 mg daily. The diastolic blood pressure of one rose over 10 days from 94 to 112 mmHg and continued to rise to 116 mmHg, even when the chlorpropramide was withdrawn. The diastolic pressure of the other rose from 105 to 127 mmHg, and then to 150 mmHg, again, even after the chlorpropramide had been withdrawn. Other reports similarly describe marked rises in blood pressure in patients taking guanethidine with chlorpromazine 100 to 400 mg daily.

Three hypertensive patients taking guanethidine 60 to 150 mg daily had increases in their blood pressure when haloperidol 6 to 9 mg daily was added. The blood pressure rose from 132/95 to 149/99 mmHg in the first patient; from 125/84 to 148/100 mmHg in the second patient; and from 138/91 to 154/100 mmHg in the third patient. Tiotixene 60 mg daily was later given to one of these patients and the blood pressure rose from 126/87 to 156/110 mmHg. These results have been reported elsewhere.

However, a single 25-mg dose of prochlorperazine did not significantly antagonise the effect of guanethidine 15 to 20 mg daily in 5 patients. In another study in 7 patients taking guanethidine 50 to 95 mg daily, the addition of molindone 30 to 120 mg daily had no effect on blood pressure.

### Mechanism

Chlorpromazine prevents the entry of guanethidine into the adrenergic neurons of the sympathetic nervous system resulting in a loss of its blood pressure-lowering effects. The other interacting antipsychotics probably have similar effects. This is essentially the same mechanism of interaction as that seen with the ‘tricyclic antidepressants’, (p.888).

### Guanethidine + Levodopa

When two patients taking guanethidine were given levodopa it was possible to reduce the guanethidine dosage in one and to stop adjunctive diuretics in the other.

### Clinical evidence, mechanism, importance and management

A brief report describes a patient taking guanethidine and a diuretic who, when given levodopa (dose not stated), required a reduction in his daily dose of guanethidine, from 60 to 20 mg. Another patient similarly treated was able to discontinue the diuretic. The suggested reason is that the hypertensive adverse effects of the levodopa are additive with the effects of the guanethidine. Direct interaction seems to be limited to this report but it would be wise to confirm that excessive hypotension does not develop if levodopa is added to treatment with guanethidine.

### Guanethidine + MAOIs

The antihypertensive effects of guanethidine can be reduced by nialamide, and probably therefore other similar MAOIs.

### Clinical evidence, mechanism, importance and management

Four out of 5 hypertensive patients taking guanethidine 25 to 35 mg daily had a rise in blood pressure from 140/85 to 165/100 mmHg six hours after being given a single 50-mg dose of nialamide. The reason is not understood but one idea is that MAOIs possibly oppose the guanethidine-induced loss of noradrenaline from sympathetic neurons. In animal studies, effective antagonism of guanethidine was shown by those MAOIs that also possess sympathomimetic effects (phenelzine and tranylcypromine).
promine), but not by iproniazid or nialamide, and the antagonism was weaker than that seen with some other sympathomimetics.

Direct clinical information seems to be limited to the single dose study, but it would be prudent to monitor the effects if any MAOI is given to patients taking any guanethidine-like drug. The manufacturers of guanethidine actually contraindicate the use of MAOIs because of the possibility of the release of large quantities of catecholamines and the risk of hypertensive crisis. They recommend that at least 14 days should elapse between stopping an MAOI and starting guanethidine.

Guanethidine + NSAIDs

Phenylbutazone and kebuzone reduce the antihypertensive effects of guanethidine.

Clinical evidence, mechanism, importance and management

When 20 patients taking guanethidine 75 mg daily were given phenylbutazone or kebuzone 750 mg daily the mean systolic blood pressure rose by 20 mmHg (from 169 to 189 mmHg). This rise represents about a 35% reduction in the antihypertensive effect of guanethidine. The mechanism of this interaction is uncertain but it is probably due to salt and water retention caused by these pyrazolone compounds. Direct evidence seems to be limited to this report. Patients taking guanethidine should be monitored if phenylbutazone or kebuzone is given concurrently. There does not appear to be any information on guanethidine and other NSAIDs, but indometacin in particular is well known to reduce the efficacy of other classes of antihypertensives, see for example ‘ACE inhibitors + NSAIDs’.

Guanethidine + Tricyclic and related antidepressants

The antihypertensive effects of guanethidine are reduced or abolished by amitriptyline, desipramine, imipramine, nortriptyline and protriptyline. Doxepin in doses of 300 mg or more daily interacts similarly, but in smaller doses appears not to do so, although one case is reported with doxepin 100 mg daily. A few case reports suggest that maprotiline and mianserin do not interact with guanethidine.

Clinical evidence

(a) Tricyclic antidepressants

Five hypertensive patients taking guanethidine sulfate 50 to 150 mg daily had a mean arterial blood pressure rise of 27 mmHg when they were also given desipramine 50 or 75 mg or protriptyline 20 mg daily for 1 to 9 days. The full antihypertensive effects of the guanethidine were not re-established until 5 days after the antidepressants were withdrawn.

The same interaction has been described in other reports, with guanethidine and desipramine, imipramine, amitriptyline or nortriptyline. The interaction may take several days to develop fully and can last an average of 5 days after discontinuation of the tricyclic. Some studies, and clinical experience suggests that doxepin does not begin to interact until doses of about 200 to 250 mg daily are used, then at 300 mg or more daily it interacts to the same extent as other tricyclics.

However, in one case excessive hypertension occurred in a man taking guanethidine and doxepin 100 mg daily.

(b) Tetracyclic antidepressants

Maprotiline 25 mg three times daily caused no appreciable change in blood pressure in two patients taking guanethidine. Similarly, in a study in two patients, mianserin 20 mg three times daily for 2 days did not alter the antihypertensive efficacy of guanethidine.

Mechanism

The guanethidine-like drugs exert their hypotensive actions by entering the adrenergic nerve endings associated with blood vessels using the noradrenaline uptake mechanism. The tricyclics successfully compete for the same mechanism so that the antihypertensives fail to reach their site of action, and as a result, the blood pressure rises once again. The differences in the rate of development, duration and extent of the interactions reflect the pharmacokinetic differences between the various tricyclics, as well as individual differences between patients.

Importance and management

A very well documented and well established interaction of clinical importance. Not every combination of guanethidine and tricyclic antidepressant has been studied but all are expected to interact similarly. Concurrent use should be avoided unless the effects are very closely monitored and the interaction balanced by raising the dosage of the antihypertensive. Note that the use of guanethidine and related adrenergic neuron blockers has largely been superseded by other antihypertensive drug classes.

Guanfacine + Phenobarbital or Phenytoin

In two patients, the concurrent use of phenobarbital or phenytoin increased the metabolism of guanfacine.

Clinical evidence, mechanism, importance and management

When a hypertensive patient with chronic renal failure who was taking guanfacine 4 mg daily, was given phenobarbital 10 mg daily the antihypertensive effects of guanfacine were noted to be reduced and its dose was progressively raised over about 18 months to 12 mg daily. Phenobarbital was eventually stopped. Single measurements of the pharmacokinetics of guanfacine, both when the patient was taking phenobarbital, and 2 months after cessation of phenobarbital, showed that the half-life of guanfacine increased fourfold when the phenobarbital was stopped. The manufacturer also reports a similar case with phenytoin and guanfacine. Phenobarbital and phenytoin probably induce the metabolism of guanfacine. Patients taking these drugs are likely to need more frequent doses of guanfacine.

A single report describes a reduced antihypertensive response to guanfacine in a patient given amitriptyline and later imipramine. The sedative effects of guanfacine and tricyclics are predicted to be additive.

**Clinical evidence**

A 38-year-old woman with stable hypertension, taking guanfacine 2 mg daily, had a rise in her mean blood pressure from 138/89 mmHg to 150/100 mmHg while taking amitriptyline 75 mg daily for 14 days. The pressure fell again when the amitriptyline was stopped. A month later her blood pressure rose to 142/98 mmHg after she had taken imipramine 50 mg daily for two days, and fell again when it was stopped.

**Mechanism**

Uncertain. A possible reason is that, like clonidine (another alpha-2 agonist), the uptake of guanfacine into neurones within the brain is blocked by tricyclic antidepressants, thereby reducing its effects.

**Importance and management**

Direct information is limited to this report, but it is supported by animal studies and consistent with the way another alpha-2 agonist interacts with tricyclic antidepressants (see ‘Clonidine + Tricyclic and related antidepressants’, p.884). Be alert for this interaction in any patient given guanfacine and any tricyclic antidepressant. Guanabenz is another alpha-2 agonist that might interact similarly, but as yet there is no direct clinical evidence that it does so. Note that the sedative effects of guanfacine or guanabenz and tricyclics would be predicted to be additive.

**Hydralazine + Food**

The manufacturers note that patients taking hydralazine who develop hypotension while undergoing surgery should not be treated with adrenaline (epinephrine). This is because hydralazine frequently causes tachycardia, and adrenaline would enhance this.

**Hydralazine + NSAIDs**

Oral indometacin abolished the hypotensive effects of intravenous hydralazine in one study, but no effect was found in another. In patients with pulmonary hypertension, intravenous indometacin reduced the effects of intravenous hydralazine, and in patients with hypertension, intravenous diclofenac reduced the effects of intravenous dihydralazine.

**Clinical evidence, mechanism, importance and management**

In 9 healthy subjects, oral indometacin 50 mg every 6 hours for 4 doses abolished the hypotensive response to intravenous hydralazine 150 micrograms/kg, and the subjects only responded when given another dose of hydralazine 30 minutes later. A study in 7 patients with pulmonary hypertension given indometacin 50 mg and hydralazine 350 micrograms/kg, both intravenously, either alone, or concurrently, also found that the effects of hydralazine (reduction in systemic arterial pressure, heart rate, cardiac index) were reduced by indometacin. In contrast, another study in 9 healthy subjects found that oral indometacin 25 mg four times daily for 2.5 days did not affect the hypotensive response to a single 200-microgram/kg intravenous dose of hydralazine.

Thus it is not clear if indometacin interacts with intravenous hydralazine, and it is uncertain if an interaction occurs when hydralazine is given orally. On the other hand, a single-dose study in 4 hypertensive subjects found that the actions of intravenous dihydralazine (effects on blood pressure, urinary excretion, heart rate and sodium clearance) were reduced by intravenous diclofenac.

NSAIDs can cause increases in blood pressure due to their effects on sodium and water retention. Various NSAIDs have been reported to reduce the efficacy of other antihypertensive drug classes, for example see ‘ACE inhibitors + NSAIDs’, p.28. It would therefore be prudent to monitor concurrent use of hydralazine and NSAIDs.

**Inotropes and Vasopressors + Antimuscarinics**

The hypertensive and other serious adverse effects of intravenous phenylephrine and phenylephrine absorbed from eye drops can be markedly increased by intravenous or intramuscular atropine.
Clinical evidence

A brief report describes 7 cases of pseudo-phaeochromocytoma, with severe rises in blood pressure and tachycardia, which occurred in young adults and children when they underwent eye operations and were given phenylephrine 10% eye drops and atropine. Only two of them had any pre-existing cardiovascular illness (moderate hypertension). All were under general anaesthesia with propofol, phenoperidine and vecuronium, and premedicated with intramuscular atropine, and some were later given more intravenous atropine to control the bradycardia, which occurred as a result of stretching the oculomotor muscles. The total atropine doses were less than 10 micrograms/kg in adults and 20 micrograms/kg in children. At least 0.4 mL of phenylephrine 10% was used. In three cases left ventricular failure and pulmonary oedema occurred, which needed monitoring in intensive care. The authors say that no further cardiovascular adverse events were observed during similar procedures when steps were taken to reduce the amount of phenylephrine used and absorbed (see Importance and Management, below).1 Prior to this case report, a number of cases of cardiovascular adverse effects (severe hypertension, cardiac arrhythmias, myocardial infarction) had been reported for phenylephrine eye drops (usually 10%), or as a subconjunctival injection, and many of these patients had also received antimuscarinics (atropine, cyclopentolate, homatropine, tropicamide),2-6 although the contribution, if any, of these antimuscarinics to the adverse effects is unknown.

In a study, 6 healthy subjects were given an intravenous phenylephrine infusion at incremental rates before and after being given three intravenous doses of atropine (20, 10, and 10 micrograms/kg) at 90, 120 and 150 minutes. It was found that phenylephrine 420 nanograms/kg per minute raised the diastolic and systolic blood pressures by 4 mmHg before using atropine, and 17 mmHg after atropine was given. For safety reasons the increases in blood pressure were limited to 30 mmHg above the baseline.7

Mechanism

Phenylephrine causes vasoconstriction, which can raise the blood pressure. Normally this would be limited by a baroreflex mediated by the vagus nerve, but if this cholinergic mechanism is blocked by atropine or other antimuscarinics, the rise in blood pressure is largely uncontrolled. Severe hypertension may occur, and other adverse cardiac events such as acute cardiac failure may follow.

Importance and management

A surprisingly large amount of phenylephrine can be absorbed from eye drops, and the potential cardiovascular adverse effects of this are well documented. The reports cited here suggest that these risks are clearly increased by the systemic use of atropine. The authors of one of the reports1 found that the systemic absorption of phenylephrine can be reduced by using lower concentrations of phenylephrine, swabbing to minimise the amount that drains into the nasolachrymal duct to the nasal mucosa where rapid absorption occurs, and reducing the drop size by using a thin-walled cannula. Others have demonstrated that a cannula reduced the dose of phenylephrine given by two-thirds without loss of efficacy.3 Other suggestions for reducing systemic absorption of phenylephrine are punctal plugging, nasolachrymal duct compression, and lid closure after instillation of the eye drop.5 Note that phenylephrine eye drops are contraindicated in those with cardiovascular disease.3 Note also that topical phenylephrine is commonly used with a topical antimuscarinic to enhance mydriasis.

Inotropes and Vasopressors + Calcium compounds

Calcium chloride infusions reduce the cardiotoxic effects of adrenaline (epinephrine) and dobutamine, but not those of amrinone.

Clinical evidence, mechanism, importance and management

In a double-blind, randomised, crossover study in 12 patients following coronary artery bypass grafting, calcium chloride (10 mg/kg bolus followed by 2 mg/kg per hour infusion) was found to attenuate the effects of adrenaline (epinephrine) 10 and 30 nanograms/kg per minute, given for 8 minutes each. Adrenaline alone produced a significant increase in the cardiac index, but following the calcium infusion adrenaline had no significant effect and the maximal adrenaline-induced increase in cardiac index was reduced by 70%. Adrenaline 30 nanograms/kg per minute alone increased mean arterial blood pressure from 87 to 95 mmHg; calcium chloride also raised blood pressure from 85 to 93 mmHg. After calcium was given, adrenaline had no further significant effect on blood pressure.1 Some of these workers also studied the mode of action of dobutamine in 22 patients recovering from coronary artery bypass surgery.2 It was found that an infusion of calcium chloride (1 mg/kg per minute initially, then 0.25 mg/kg per minute) reduced the increase in cardiac output produced by an infusion of dobutamine 2.5 to 5 micrograms/kg per minute by 30%. In a group of 24 similar patients the cardiotoxic actions of amrinone (a phosphodiesterase inhibitor) were unaffected by the calcium infusion.2

Just how the calcium alters the effects of adrenaline and dobutamine is not known, but since they are both beta-receptor agonists a reasonable suggestion is that calcium interferes with the signal transduction through the beta-adrenergic receptor complex. The clinical importance of these findings is uncertain.

Inotropes and Vasopressors + Cimetidine

An exaggerated hypertensive response to dobutamine occurred during anaesthetic induction in a patient taking cimetidine. Another case report describes supraventricular tachycardia, which occurred when a patient receiving dobutamine and dopamine was given cimetidine.

Clinical evidence, mechanism, importance and management

A patient about to undergo coronary artery bypass grafting was anaesthetised with midazolam, fentanyl, vecuronium and oxygen. When a 5 micrograms/kg per minute infusion of dobutamine was given the patient developed unexpectedly marked hypertension of 210/100 mmHg. The infusion was stopped and over the next 15 minutes the blood pressure fell to 90/50 mmHg. A new infusion had the same hypertensive effect, and the patient’s blood pressure was subsequently controlled at 120/80 mmHg with dobutamine 1 microgram/kg per minute.1 The authors of the report suggest that this exaggerated response to dobutamine may have been due to cimetidine 1 g daily, which the patient was also taking. They postulate that the cimetidine may possibly have inhibited the metabolism and clearance of the dobutamine by the liver, thereby increasing its effects.4

A post-operative patient receiving dopamine and dobutamine infusions developed a supraventricular tachycardia 30 seconds after an intravenous injection of cimetidine. Similar episodes of tachycardia occurred on re-challenge with both drugs, but not when each drug was given separately.2 These are isolated cases and the general importance is not known but it seems likely to be small.

**Inotropes and Vasopressors + Clonidine**

Experimental studies in patients show that pretreatment with clonidine decreases the blood pressure response to small doses of dopamine; does not affect the blood pressure response to noradrenaline (norepinephrine); and can increase the blood pressure responses to dobutamine, ephedrine, isoprenaline (isoproterenol) and phenylephrine.

**Clinical evidence**

In a study in 70 patients undergoing elective surgery, 35 patients were given clonidine 5 micrograms/kg 90 minutes before the induction of anaesthesia and 35 patients were used as a control group. While under anaesthesia, and when haemodynamically stable for at least 10 minutes, all patients were given a 10-minute infusion of dopamine 3 or 5 micrograms/kg per minute or dobutamine 0.5, 1, or 3 micrograms/kg per minute. Clonidine attenuated the response to the 5 micrograms/kg per minute dose of dopamine (blood pressure rise 19/10 mmHg in the control group but only 40/0 mmHg in the clonidine group). However, dopamine 3 micrograms/kg per minute did not significantly affect blood pressure in either the control group or the clonidine group. Conversely, clonidine enhanced the response to dobutamine at all 3 doses. The study had to be stopped after 2 minutes in the clonidine group receiving the highest dose of dobutamine as the rise in blood pressure exceeded the study limits (rise 45/24 mmHg compared with 16/7 mmHg in the control group). In a study of the same design, 20 clonidine-treated patients and 20 controls were given a bolus infusion of phenylephrine 3 micrograms/kg or isoprenaline (isoproterenol) 0.02 micrograms/kg. Those who received clonidine had a greater and more prolonged increase in arterial pressure and heart rate with phenylephrine (10 minutes compared with 2 to 3 minutes) and increase in heart rate (but not arterial pressure) with isoprenaline (isoproterenol).

In another similar study, 77 patients (38 premedicated with clonidine 5 micrograms/kg and famotidine 20 mg, 90 minutes before anaesthetic induction, and a control group of 39 given only famotidine) were given noradrenaline (norepinephrine) 0.5 micrograms/kg or phenylephrine 2 micrograms/kg. It was found that the overall response to noradrenaline (norepinephrine) was not significantly affected by clonidine, although 2 to 4 minutes after administration the mean arterial blood pressure was raised in the clonidine group. The blood pressure rise in response to phenylephrine was found to be augmented. There were no significant differences between the groups in terms of the incidence of hypertension, arrhythmias or bradycardia. Similar results have been reported with phenylephrine in other studies (see below). The same group of workers repeated this study using two doses of ephedrine 100 micrograms/kg as the vasopressor. Clonidine prolonged the response to ephedrine by 2 minutes and increased the rise in blood pressure (rise in mean blood pressure in response to ephedrine at 3 minutes of 12.7 mmHg with clonidine, compared with 6.6 mmHg without clonidine). The rise in blood pressure was greater in both groups after a second dose of ephedrine was given but the effect in the clonidine group was still greater (rise in mean blood pressure in response to ephedrine at 4 minutes of 15 mmHg with clonidine compared with 9.4 mmHg without clonidine).

Further study by these same workers, using enflurane and nitrous oxide/oxygen for anaesthesia, found that the mean maximum blood pressure increase in a group of patients premedicated with clonidine and given intravenous phenylephrine 2 micrograms/kg was 26% and 32%, for awake and anaesthetised subjects, respectively. This was greater than the blood pressure rises seen in a group not given clonidine, which were 13% and 18%, for awake and anaesthetised subjects, respectively.

Similar additional effects on blood pressure were found in patients given intravenous ephedrine 100 micrograms/kg after pretreatment with clonidine.

**Mechanism**

Not understood, although clonidine is an alpha, agonist, which blocks the release of noradrenaline (norepinephrine) from the nerve endings, and most suggested mechanisms consider noradrenaline release to be involved in some way.

**Importance and management**

An interaction is established, although the exact outcome of the concurrent use of clonidine and these sympathomimetic vasopressors is not clear. It has been suggested that the effects may be different at different doses of dopamine. The authors of the one report, studying phenylephrine and noradrenaline (norepinephrine) with clonidine, suggested that the increase in pressor response was unlikely to be clinically significant.

Be aware that dobutamine, ephedrine, and phenylephrine may have a greater than expected effect if clonidine has been taken. Some of these drugs may also be used as nasal decongestants (e.g. ephedrine, and phenylephrine). The outcome of the concurrent use of clonidine in these circumstances is unclear, but a rise in blood pressure seems possible. However, note that these products are usually cautioned in patients with hypertension.

**Inotropes and Vasopressors + Ergometrine (Ergonovine)**

An isolated report attributes the development of gangrene and subsequently fatal septicaemia to the use of dopamine following the use of ergometrine. A similar case has been reported with ergometrine and noradrenaline (norepinephrine).

**Clinical evidence, mechanism, importance and management**

One patient developed gangrene of the hands and feet after being given an infusion of dopamine (10 micrograms/kg per minute, later doubled) started approximately 2 hours after the use of ergometrine (two 400 microgram doses). This would seem to have resulted from the additive peripheral vasoconstrictor effects of both drugs, which reduced the circulation to such an extent that gangrene and then fatal septicaemia developed. Note that gangrene has been reported with the use of both drugs alone, and it is recommended that peripheral tissue perfusion should be monitored in elderly patients or patients with a history of peripheral vascular disease receiving dopamine. This would also seem to be a prudent precaution in those who have previously received ergometrine.

A similar case report describes a pregnant woman (24-week gestation) with severe burns who received ergometrine to treat post-partum bleeding after spontaneous abortion and noradrenaline (norepinephrine) to treat hypotensive septic shock. The combination of these two vasoconstrictors is thought to have contributed to ischaemia of the fingers, resulting in loss of some digits. In the rare circumstances when it may be necessary to use both of these drugs, close attention should be paid to peripheral tissue perfusion.

2. Dopamine Sterile Concentrate (Dopamine hydrochloride). Mayne Pharma plc. UK Summary of product characteristics, April 2003.

**Inotropes and Vasopressors + Guanethidine**

The pressor effects of noradrenaline (norepinephrine), phenylephrine, and metaraminol can be increased in the presence of guanethidine. These drugs can also be used as eye drops, and in this situation their mydriatic effects are similarly enhanced and prolonged by guanethidine.
Clinical evidence

(a) Blood pressure response

A study in 6 normotensive subjects given guanethidine 200 mg on the first day of the study and 100 mg daily for the next 2 days, found that their mean arterial blood pressure in response to a range of doses of noradrenaline (norepinephrine), was increased by 6 to 18% (a 6 to 20 mmHg increase). Moreover, cardiac arrhythmias appeared at lower doses of noradrenaline and with greater frequency than in the absence of guanethidine, and were more serious in nature.1

In another report, a patient taking guanethidine 20 mg daily was given intramuscular metaraminol 10 mg, which rapidly caused the blood pressure to rise to 220/130 mmHg accompanied by severe headache and extreme angina.2 An increase in blood pressure from 165/90 to 170/110 mmHg was also seen in a patient taking guanethidine who, prior to surgery, was given phenylephrine eye drops.3

(b) Mydriatic response

The mydriasis due to phenylephrine given as a 10% eye drop solution was prolonged for up to 10 hours in a patient taking guanethidine for hypertension.4 This enhanced mydriatic response has been described in another study using guanethidine eye drops with adrenaline (epinephrine), phenylephrine or methoxamine eye drops.5

Mechanism

By preventing the release of noradrenaline from adrenergic neurones, guanethidine and other adrenergic neurone blockers cause a temporary ‘drug-induced sympathectomy’, which is also accomplished by hypersensitivity of the receptors. This results in the increased response to the stimulation of the receptors by directly-acting sympathomimetics such as noradrenaline and phenylephrine.

Importance and management

An established, well-documented and potentially serious interaction. Since the pressor effects can be grossly exaggerated, dosages of directly-acting sympathomimetics should be reduced appropriately. In addition it should be remembered that the incidence and severity of the pressor effects can be greatly increased, dosages of directly-acting sympathomimetics such as epinephrine, metaraminol, and methoxamine. Dopamine also possess direct sympathomimetic activity and may be expected to interact similarly. If as a result of this interaction the blood pressure becomes grossly elevated, it can be controlled by giving an alpha-adrenergic blocker such as phentolamine. Phenylephrine is contained in a number of non-prescription cough and cold preparations, which may contain 12 mg in a dose. A single dose of this size is only likely to cause a moderate blood pressure rise. However, this requires confirmation, particularly since the non-prescription products may be taken up to 4 times daily for up to 7 days, and higher doses may be available in some countries.

An exaggerated pressor response is clearly more potentially serious than enhanced and prolonged mydriasis, but the latter is also possible and undesirable. The same precautions apply about using smaller amounts of the sympathomimetic drugs. Note that many indirectly-acting sympathomimetics (alpha-agonists) should be used with caution. Direct evidence seems to be limited to noradrenaline (norepinephrine), phenylephrine, metaraminol, and methoxamine. Dopamine and phenylephrine are decreased in the presence of lithium carbonate, which is caused by the stores of noradrenaline (norepinephrine) being replenished. The mydriatic effects of ephedrine have also been shown to be antagonised by pretreatment with reserpine. However, in contrast, one report claimed that ephedrine 25 mg given orally or intramuscularly, once or twice daily, proved to be an effective treatment for reserpine-induced hypotension and bradycardia in schizophrenic patients. Studies in dogs have demonstrated that adrenaline (epinephrine), noradrenaline (norepinephrine) and phenylephrine (all sympathomimetics with direct actions) remain effective vasopressors after treatment with reserpine, and their actions are enhanced to some extent. Metaraminol has also been successfully used to raise blood pressure in reserpine-treated patients.9

Clinical evidence, mechanism, importance and management

A study in 8 patients with ‘manic depression’ found that after taking lithium carbonate for 7 to 10 days (serum level range 0.72 to 1.62 mmol/L) the dosage of a norepinephrine (noradrenaline) infusion had to be increased by 1.8 micrograms in 7 patients to maintain a blood pressure increase of 25 mmHg. This equated to a 22% reduction in the pressor effect of norepinephrine (noradrenaline). A study in 17 depressed patients with serum lithium levels in the range 0.8 to 1.2 mmol/L found that 12% more norepinephrine (noradrenaline) and 31% more phenylephrine was needed to raise the blood pressure by 30 mmHg.2 The reasons for this interaction are not known.

These decreases in the pressor response to norepinephrine (noradrenaline) and to phenylephrine in the presence of lithium carbonate are both relatively small and it seems unlikely that they will present any problems in practice.

Inotropes and Vasopressors + Reserpine

The effects of adrenaline (epinephrine), noradrenaline (norepinephrine) and other directly-acting sympathomimetics are slightly increased in the presence of reserpine.

Clinical evidence

Pretreatment with phenylephrine 10% eye drops caused a blood pressure increase of 30/12 mmHg in 11 patients taking reserpine, whereas no significant increase in blood pressure occurred in 176 patients who were given phenylephrine eye drops and who were not taking reserpine. After 7 healthy subjects took reserpine 0.25 to 1 mg daily for 2 weeks the increase in the blood pressure response to noradrenaline (norepinephrine) was increased by 20 to 40%.2 A man taking reserpine who became hypotensive while undergoing surgery failed to respond to an intravenous injection of ephedrine, but did so after 30 minutes treatment with noradrenaline, presumably because the stores of noradrenaline at adrenergic neurones had become replenished.3 The mydriatic effects of ephedrine have also been shown to be antagonised by pretreatment with reserpine. However, in contrast, one report claimed that ephedrine 25 mg given orally or intramuscularly, once or twice daily, proved to be an effective treatment for reserpine-induced hypotension and bradycardia in schizophrenic patients.5

Studies in dogs have demonstrated that adrenaline (epinephrine), noradrenaline (norepinephrine) and phenylephrine (all sympathomimetics with direct actions) remain effective vasopressors after treatment with reserpine, and their actions are enhanced to some extent.6,8 Metaraminol has also been successfully used to raise blood pressure in reserpine-treated patients.9

Mechanism

The rauwolfia alkaloids (e.g. reserpine) cause adrenergic neurones to lose their stores of noradrenaline (norepinephrine), so that they can no longer stimulate adrenergic receptors and transmission ceases. Indirectly-acting sympathomimetics, which work by stimulating the release of stored noradrenaline, may therefore be expected to become ineffective. In contrast, the effects of directly-acting sympathomimetics should remain unchanged. However, their effects may be enhanced (as described above) because when the receptors are deprived of stimulation by noradrenaline their effects may be increased. In the presence of lithium carbonate, which is caused by the stores of noradrenaline (norepinephrine) being replenished, the mydriatic effects of ephedrine have also been shown to be antagonised by pretreatment with reserpine. However, in contrast, one report claimed that ephedrine 25 mg given orally or intramuscularly, once or twice daily, proved to be an effective treatment for reserpine-induced hypotension and bradycardia in schizophrenic patients.5

Importance and management

These are established interactions, but the paucity of clinical information suggests that in practice they do not present many problems, perhaps because the effects of these vasopressors are so closely monitored, and titrated to effect. If a pressor drug is required, a directly-acting drug such as noradrenaline (norepinephrine) or phenylephrine may be expected to be effective. The receptors may show some supersensitivity so that a dosage

Inotropes and Vasopressors + Reserpine

The pressor effects of noradrenaline (norepinephrine) and phenylephrine are slightly reduced by lithium carbonate.
reduction may be required. ‘Table 24.1’, (p.879) gives a classification of the sympathomimetics.

### Inotropes and Vasopressors; Dobutamine + Dipyridamole

The addition of dipyridamole to dobutamine for echocardiography can cause potentially hazardous hypotension.

**Clinical evidence, mechanism, importance and management**

Ten patients with a low probability of coronary artery disease underwent dobutamine echocardiography. Five were given dobutamine alone, while the other 5 were given a low intravenous dose of dipyridamole with the maximal dose of dobutamine, to see whether the sensitivity of the test could be improved. Four of the patients given both drugs experienced severe hypotension while no hypotension was seen in the control group. The conclusion was reached that this combination of drugs can be hazardous and should not be used in patients suspected of coronary heart disease. Note that, although both of these drugs are commonly used in stress echocardiography, they are not given together.

### Inotropes and Vasopressors; Dopamine + Phenylephrine

Some limited evidence suggests that patients needing dopamine to support their blood pressure can become severely hypotensive if they are also given intravenous phenylephrine.

**Clinical evidence, mechanism, importance and management**

Five critically ill patients treated with a number of different drugs, were given dopamine to maintain an adequate blood pressure. When seizures developed they were given intravenous phenylephrine at an infusion rate of 5 to 25 mg/minute. Their previously stable blood pressures then fell rapidly, one patient became bradycardic, and two patients died from cardiac arrest. A similar reaction was found in dogs made hypovolaemic and hypotensive by bleeding, and then given dopamine followed by a phenylephrine infusion. However, another study in dogs was unable to find evidence of the serious adverse interaction. Two of the patients given both drugs experienced severe hypotension while no hypotension was seen in the control group. The documentation of this adverse interaction therefore appears to be limited to this single report. However, intravenous phenylephrine is known to cause hypotension if it is given rapidly, particularly in gravely ill patients. Blood pressure is difficult being monitored in patients receiving dopamine, and should be monitored when phenylephrine is given intravenously.

### Inotropes and Vasopressors; Dopamine + Selegiline

A case report describes a hypertensive reaction attributed to the concurrent use of dopamine and selegiline.

**Clinical evidence, mechanism, importance and management**

A 75-year-old man, who was taking selegiline 5 mg twice daily for Parkinson’s disease, was given intravenous dopamine 1.5 micrograms/kg per minute because of a decline in blood pressure and urine output following a serious road traffic accident. Twenty minutes after the infusion was started his blood pressure had hardly changed, but 30 minutes later it had risen from 108/33 to 228/50 mmHg. The dopamine infusion was discontinued and the blood pressure decreased to 121/40 mmHg over the next 30 minutes. The dopamine infusion was reinitiated twice more at lower doses (1.03 and 0.9 micrograms/kg per minute), but each time similar reactions occurred. The exaggerated vasoconstrictor response was thought to be due to inhibition of dopamine metabolism by selegiline.

The authors of the report and the manufacturers of selegiline recommend that dopamine should be used cautiously, and only after careful risk-benefit assessment, in patients who are currently taking selegiline or who have taken selegiline in the 2 weeks prior to dopamine therapy. In addition, the manufacturers of dopamine warn that in patients who have received MAOIs within the previous 2 to 3 weeks, the initial dose of dopamine should be no greater than 10% of the usual dose.

2. Elderyl (Selegiline hydrochloride). Orion Pharma (UK) Ltd. UK Summary of product characteristics, July 2006.

### Inotropes and Vasopressors; Dopamine + Tolazoline

Acute and eventually fatal hypotension occurred in a patient given dopamine and tolazoline.

**Clinical evidence**

A patient receiving ventilatory support following surgery was given dopamine on the third postoperative day. Pulmonary arterial pressure had been steadily rising since the surgery, so on day 4 he was given a slow 2-mg/kg bolus injection of tolazoline. Systemic arterial pressure immediately fell to 50/30 mmHg so the dopamine infusion was increased but, contrary to the expected effect, the arterial pressure then fell even further to 38/15 mmHg. The dopamine was stopped and ephedrine, methoxamine and fresh frozen plasma were given. Two hours later his blood pressure was 70/40 mmHg. Two further attempts were made to give dopamine, but the arterial pressure fell to 40/15 mmHg on the first occasion, and to 38/20 mmHg on the second, which resulted in a fatal cardiac arrest.

**Mechanism**

Not fully understood. Dopamine has both alpha (vasoconstrictor) and beta (vasodilator) activity. With the alpha effects on the systemic circulation competitively blocked by the tolazoline, its vasodilatory actions would predominate, resulting in paradoxical hypotension.

**Importance and management**

Information is limited but this interaction would appear to be established. The authors of this report warn that an infusion of dopamine should not be considered for hypertension hours after even a small single dose of tolazoline has been given. They point out that impaired renal function often accompanies severe respiratory failure, which may significantly prolong the effects of tolazoline.

Ivabradine + CYP3A4 inducers

The metabolism of ivabradine may be increased by CYP3A4 inducers including barbiturates, phenytoin, rifampin, and St John’s wort.

Clinical evidence, mechanism, importance and management

St John’s wort (Hypericum perforatum) reduced the AUC of ivabradine 10 mg twice daily by half.1 St John’s wort is a known inducer of the cytochrome P450 isoenzyme CYP3A4, by which ivabradine is metabolised. Concurrent use therefore decreases ivabradine levels, and as a result probably reduces its effects (although this does not appear to have been studied) increase the metabolism of ivabradine, which results in a reduction in its plasma levels.1 The manufacturers suggest that the use of St John’s wort should be restricted in patients taking ivabradine. They also advise that patients taking other CYP3A4 inducers (they specifically name barbiturates, phenytoin, and rifampin) may need dosage increases of ivabradine.1 Monitor concurrent use for ivabradine efficacy and adjust the dose as necessary. Remember to re-adjust the dose of ivabradine if concurrent use of these drugs is stopped.

Ivabradine + CYP3A4 inhibitors

Ivabradine is metabolised by CYP3A4 and its levels may therefore be increased significantly in the presence of inhibitors of this isoenzyme, such as some azoles, diltiazem, some macrolides, nefazodone, protease inhibitors, or verapamil.

Clinical evidence

A study found that ketoconazole 200 mg daily or josamycin 1 g twice daily increased ivabradine plasma levels by seven to eightfold. Studies in healthy subjects given diltiazem or verapamil have resulted in an increase in the AUC of ivabradine of two to threefold, and an additional heart rate reduction of 5 bpm.1

Mechanism

Ivabradine is a substrate of the cytochrome P450 isoenzyme CYP3A4, and its metabolism is reduced by inhibitors of CYP3A4, resulting in increased plasma levels and increased therapeutic effects.1

Importance and management

The manufacturers contraindicate the use of potent inhibitors of CYP3A4 with ivabradine, (they specifically mention clarithromycin, oral erythromycin, itraconazole, josamycin, ketoconazole, nefazodone, neflinavir, ritonavir, and telithromycin). The manufacturers suggest that if moderate inhibitors of CYP3A4 are given (they name fluconazole) ivabradine may be used, but at a lower starting dose of 2.5 mg, with consideration of heart rate monitoring.1 Diltiazem and verapamil are also moderate inhibitors of CYP3A4, but their use is not recommended because of their effects on heart rate. Note that clinically relevant inhibitors of CYP3A4 are listed in ‘Table 1.4’, (p.6).

Ivabradine + Drugs that prolong the QT interval

The manufacturers advise that ivabradine should not be taken with drugs that prolong the QT interval. Bradycardia is a pharmacological effect of ivabradine, and QT prolongation may be exacerbated by heart rate reductions.1 For a list of drugs known to affect the QT interval see ‘Table 9.2’, (p.257).

Ivabradine + Grapefruit juice

Grapefruit juice inhibits the metabolism of ivabradine.

Clinical evidence, mechanism, importance and management

Grapefruit juice increases the exposure to ivabradine exposure twofold. This interaction probably occurs because grapefruit inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestine, by which ivabradine is metabolised. This leads to increased levels, which increases the risks of adverse effects such as profound bradycardia. The manufacturers recommend that the intake of grapefruit juice by patients also taking ivabradine is restricted.1 However, note that they contraindicate the use of other drugs that increase ivabradine levels by a similar amount, and so it would seem that concurrent use is best avoided.

Ivabradine + Miscellaneous

The manufacturers say that in specific drug-drug interaction studies, ivabradine was not found to interact with proton pump inhibitors (omeprazole, lansoprazole), sildenafil, statins (simvastatin), dihydroxyridine calcium-channel blockers (amlodipine, la-cidipine), digoxin and warfarin. During clinical studies, ivabradine was taken with ACE inhibitors, angiotensin II receptor antagonists, diuretics, short and long acting nitrates, statins, fibrates, proton pump inhibitors, oral antidiabetics, aspirin and other antplatelet drugs, and there was no evidence of safety concerns.1

Ketanserin + Beta blockers

There is no pharmacokinetic interaction between ketanserin and propranolol, but additive hypotensive effects may occur. Very marked acute hypotension has been seen in two patients taking atenolol when they were first given ketanserin.

Clinical evidence, mechanism, importance and management

A study in 6 patients and 2 healthy subjects given ketanserin 40 mg twice daily for 3 weeks found that propranolol 80 mg twice daily for 6 days did not significantly alter the steady-state plasma levels of ketanserin.2 Another study in healthy subjects, using single doses of both drugs, found that neither drug affected the pharmacokinetics of the other.2 In a third study, propranolol 80 mg twice daily had no effect on the pharmacokinetics of a single 10-mg intravenous dose of ketanserin. However, ketanserin 40 mg twice daily modestly decreased the clearance of a single 160-mg dose of propranolol by 29% and increased its maximum serum level by 38%, although neither of these changes were statistically significant.3 The hypotensive effects of ketanserin were slightly increased by propranolol in the first study,1 and additive hypotensive effects were seen in another study in patients with essential hypertension.4

Acute hypotension is reported to have occurred in two patients taking atenolol within an hour of taking a 40-mg oral dose of ketanserin. One of them briefly lost consciousness.5

The concurrent use of ketanserin and beta blockers can be valuable and uneventful, but a few patients may experience marked hypotensive effects when first given ketanserin. Patients should be warned.

Ketanserin + Diuretics

Sudden deaths, probably from cardiac arrhythmias, were markedly increased in patients taking potassium-depleting diuretics and high doses of ketanserin. No interaction occurred with low doses of ketanserin in those with normal potassium levels. Potassium-sparing diuretics do not interact in this way.

Clinical evidence

A large multi-national study in 3899 patients found that a harmful and potentially fatal interaction could occur in those given ketanserin 40 mg three times daily and potassium-depleting diuretics. Of 249 patients taking both drugs, 35 died (16 suddenly) compared with only 15 (5 suddenly) of 260 patients taking a placebo and potassium-depleting diuretics. No significant increase in the number of deaths occurred in those taking ketanserin and potassium-sparing diuretics.

It was found that the corrected QT interval was prolonged as follows: ketanserin alone 18 milliseconds, ketanserin with potassium-sparing diuretics 24 milliseconds, ketanserin with potassium-depleting diuretics 30 milliseconds. Preliminary results of a later study in 33 patients using a smaller dose of ketanserin (20 mg twice daily) with potassium-depleting diuretics (furosemide, thiazides) found no evidence of a prolonged QTc interval in patients with normal potassium levels. The pharmacokinetics of a single 20-mg dose of ketanserin were not altered by single 25-mg doses of hydrochlorothiazide.

Mechanism

Potassium-depleting diuretics may cause hypokalaemia, which increases the risk of QT-prolongation and torsade de pointes arrhythmia, which can result in sudden death. Ketanserin also prolongs the QT interval in a dose-related way, and its effects would be expected to be additive with that of diuretic-induced hypokalaemia. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Importance and management

The use of potassium-depleting diuretics (see ‘Table 26.1’, (p.944)) with ketanserin 40 mg three times daily should be avoided. Lower doses of ketanserin (20 mg twice daily) have less effect on the QT interval, and can probably be used cautiously with potassium-depleting diuretics, as long as serum potassium levels are maintained. Potassium-sparing diuretics do not interact.

Ketanserin + Miscellaneous

Ketanserin should not be given with certain antiarrhythmics, nifedipfuryl, or tricyclic antidepressants because of the risk of potentially fatal cardiac arrhythmias. Drowsiness and dizziness are common adverse effects, which may possibly be additive with the effects of other CNS depressants.

Clinical evidence, mechanism, importance and management

Ketanserin has weak class III antiarrhythmic activity and can prolong the QTc interval. For safety reasons it has therefore been advised that it should be avoided in patients with existing QTc prolongation, ativoventricular or sinoauricular block of higher degree, or severe bradycardia of less than 50 bpm. For the same reason the concurrent use of drugs that affect repolarisation (class IA, IC and III antiarrhythmics) or those that cause conduction disturbances (nifedipfuryl, tricyclic antidepressants) should be avoided. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257, and ‘Ketanserin + Diuretics’, above.

Dizziness and dizziness are common adverse effects of ketanserin and therefore it seems likely that these will be additive with other CNS depressants and alcohol, which may possibly make driving more hazardous, but this needs confirmation.

Ketanserin + Nifedipine

Two patients experienced an increase in cardiac arrhythmias when they were given ketanserin with nifedipine.

Clinical evidence, mechanism, importance and management

A study in 20 subjects aged 60 years or more, with normal or slightly raised blood pressures, found that the concurrent use of ketanserin and nifedipine for a week did not, on average, affect their blood pressures, heart rates, or QT intervals, but two of the subjects monitored over 24 hours showed a marked increase in the frequency of ectopic beats, couplets and ventricular tachycardia. The reasons are not understood. The authors of this study say that their findings do not exclude the possibility that the concurrent use of these two drugs might therefore increase arrhythmia in some elderly patients. Concurrent use should be monitored.

Levosimendan + Miscellaneous

Orthostatic hypotension occurred when levosimendan was given with isosorbide mononitrate. The haemodynamic effects of levosimendan were not significantly altered by captopril, carvedilol or other unnamed beta blockers, or felodipine. Levosimendan does not alter the effects of warfarin. Itraconazole does not alter the pharmacokinetics of levosimendan. Levosimendan appears not to interact adversely with alcohol.

Clinical evidence, mechanism, importance and management

(a) Alcohol

A double-blind, randomised, crossover study in 12 healthy subjects given oral alcohol 0.8 g/kg with intravenous levosimendan 1 mg found no clinically significant pharmacokinetic or pharmacodynamic interactions.

(b) Beta blockers

In 12 healthy subjects carvedilol 25 mg twice daily for 7 to 9 days did not alter the effects of a single 2-mg intravenous dose of levosimendan on cardiac contractility. In addition, the heart rate and diastolic blood pressure responses were not altered, but the systolic blood pressure response was blunted. In a study to compare levosimendan with dobutamine in patients with severe, low-output heart failure, 33 of the 102 patients receiving levosimendan were also given unnamed beta blockers. The use of a beta blocker was shown not to reduce the haemodynamic effects of levosimendan. The authors say this suggests that there may be a place for levosimendan in the management of exacerbations of heart failure not controlled by beta blockers.

(c) Captopril

Captopril, in doses of up to 50 mg twice daily, did not change the haemodynamic effects of a single 1- or 2-mg intravenous dose of levosimendan in 24 patients with heart failure. No additional decrease in blood pressure was observed. No special precautions appear to be required if levosimendan is given to patients taking captopril.

(d) Felodipine

A study of the use of oral levosimendan 500 micrograms four times daily and felodipine 5 mg once daily in 24 men with coronary heart disease found that concurrent use was well tolerated. The felodipine did not antagonise the positive inotropic effects of the levosimendan and had no effect on exercise capacity. Both drugs increased the heart rate during exercise, and there was a slight additional effect with the combination (5 to 8 bpm
for levosimendan alone versus 6 to 10 bpm for the combination). There would appear to be no reason for avoiding concurrent use.

(e) *Isorosibe mononiträren*

In 12 healthy subjects at rest giving an infusion of levosimendan (12 micromg/kg over 10 minutes, then 0.2 micromg/kg/minute for 110 minutes) with a single 2-mg oral dose of isorosibe mononiträren had no additional effects on haemodynamic parameters (heart rate, blood pressure, leg blood flow, cardiac output). However, during an orthostatic test, the circulatory response of the combination was significantly potentiated, and three subjects were unable to remain standing for the stipulated time. Care is therefore required when levsimendan and isosorbide mononiträren, or similar drugs, are used concurrently.

(f) *Itraconazole*

A study in 12 healthy subjects found that the pharmacokinetics of a single 2-mg oral dose of levsimendan were unchanged by itraconazole 200 mg daily for 5 days, and there was no change in heart rates or ECGs (including the QTc interval). It was concluded that because itraconazole, a potent inhibitor of the cytochrome P450 isozyme CYP3A4, does not interact significantly with levsimendan, interactions with other CYP3A4 inhibitors are unlikely.7

(g) *Warfarin*

In an open, randomised, crossover study, 10 healthy subjects were given a single 25-mg oral dose of warfarin both before and on day 4 of a 9-day course of oral levsimendan 500 micrograms four times daily. No clinically relevant changes in the anticoagulant effects of the warfarin were seen, and levsimendan alone had no effect on blood coagulation. In addition, there was no important pharmacokinetic interaction between warfarin and levsimendan. No interactions would therefore be expected if both drugs are used concurrently.8

Methyldopa + Barbiturates

Methyldopa plasma levels are not altered by the use of phenobarbital.

Clinical evidence, mechanism, importance and management

Indirect evidence from one study in hypertensive subjects suggested that phenobarbital could reduce methyldopa levels,1 but later work, which directly measured the plasma levels of methyldopa, did not find any evidence of a pharmacokinetic interaction.2,3

Methyldopa + Bile-acid binding resins

Colestyramine and colestipol are reported to have no important effect on the absorption of methyldopa.1

Methyldopa + Cephalosporins

Pustular eruptions developed in two women taking methyldopa and cefadroxil or cefazolin. The use of methyldopa may have been coincidental.

Clinical evidence, mechanism, importance and management

A 74-year-old black woman taking methyldopa and insulin developed pruritus on her arms and legs within 2 hours of starting to take cefadroxil 250 mg every 6 hours. *Cefadroxil* was stopped after 7 doses. Over the next 2 days, fever and a widespread pustular eruption developed.1 Another 65-year-old black woman taking methyldopa and furosemide experienced severe pruritus within 8 hours of starting to receive intravenous cefazolin sodium 1 g every 12 hours. Over the next 2 days superficial and coalescing pustules appeared on her trunk, arms and legs.2 The authors of the first report attributed the reaction to *cefadroxil*,1 The authors of the second report note that the concurrent use of methyldopa may or may not have been a contributing factor in both reports.2 There seem to be no other reports of this reaction.

Methyldopa + Disulfiram

An isolated report describes a patient with hypertension, which was unresponsive to methyldopa in the presence of disulfiram.

Clinical evidence, mechanism, importance and management

An alcoholic patient taking disulfiram did not respond to moderate to high doses of intravenous methyldopa, given to control his hypertension, but responded to oral low-dose chloramide. The suggested reason for this lack of response to methyldopa is that disulfiram blocks the activity of dopamine beta-hydroxylase, the enzyme responsible for the conversion of the methyldopa to its active form.1 The general importance of this apparent interaction is uncertain.

Methyldopa + Haloperidol

Two cases of marked CNS adverse effects have been attributed to the use of methyldopa and haloperidol. Another patient became irritable and aggressive. In a small pilot study, the combination of methyldopa and haloperidol lowered blood pressure, and symptomatic hypotension occurred in one patient. The combination also caused marked sedation.

Clinical evidence

Two patients who had been taking methyldopa 1 to 1.5 g daily for hypertension, without problems, developed a dementia syndrome (cognitive disabilities, loss of memory, disorientation, etc.) within 3 days of starting to take haloperidol 6 to 8 mg daily for anxiety. The symptoms totally cleared within 72 hours of stopping the haloperidol.1 Another patient treated with haloperidol for schizophrenia, and methyldopa for hypertension, became very irritable and aggressive. When the methyldopa was replaced with hydrochlorothiazide, the patient’s behaviour improved dramatically.2

Methyldopa + Haloperidol

Two cases of marked CNS adverse effects have been attributed to the use of methyldopa and haloperidol. Another patient became irritable and aggressive. In a small pilot study, the combination of methyldopa and haloperidol lowered blood pressure, and symptomatic hypotension occurred in one patient. The combination also caused marked sedation.

Clinical evidence

Two patients who had been taking methyldopa 1 to 1.5 g daily for hypertension, without problems, developed a dementia syndrome (cognitive disabilities, loss of memory, disorientation, etc.) within 3 days of starting to take haloperidol 6 to 8 mg daily for anxiety. The symptoms totally cleared within 72 hours of stopping the haloperidol.1 Another patient treated with haloperidol for schizophrenia, and methyldopa for hypertension, became very irritable and aggressive. When the methyldopa was replaced with hydrochlorothiazide, the patient’s behaviour improved dramatically.2

In a pilot study of the therapeutic potential of using haloperidol 10 mg daily with methyldopa 500 mg daily for 4 weeks, in the treatment of schizophrenia, the supine diastolic blood pressure decreased significantly from 65 to 59.5 mmHg. Six of the 10 patients complained of dizziness, and one patient needed a reduction in the drug doses because of transient hypotension. Somnolence occurred in 8 of the 10 patients.3

**Mechanism**

The hypotensive effects of methyldopa and haloperidol might be expected to be additive. The CNS effects are not understood, although methyldopa can cause sedation, depression and dementia, and haloperidol can cause drowsiness, dizziness and depression.

**Importance and management**

Concurrent use need not be avoided, but it would be prudent to be on the alert for excessive sedation, excessive reductions in blood pressure or the development of other unexpected CNS adverse effects, particularly in the initial stages of concurrent use.

---

### Methyldopa + Iron compounds

The antihypertensive effects of methyldopa can be reduced by ferrous sulfate. Ferrous gluconate appears to interact similarly.

**Clinical evidence**

Ferrous sulfate 325 mg three times daily was given to 5 hypertensive patients who had been taking methyldopa 250 mg to 1.5 g daily for more than a year. After 2 weeks the blood pressures of all of them had risen, and the systolic pressures of 3 of them had risen by more than 15 mmHg.1 The renal excretion of unmetabolised methyldopa was reduced by 88% and 79% when methyldopa was given with ferrous sulfate and ferrous gluconate, respectively.2 A further study found that if the ferrous sulfate was given 2 hours before, 1 hour before or with the methyldopa, its bioavailability was reduced by 42%, 55%, and 83%, respectively.2

**Mechanism**

It appears that methyldopa chelates or complexes with the iron in the gut, reducing its absorption by about 50%.1,3,4 The increase in the metabolic formation is a likely mechanism. Methyldopa appears to interact like ferrous sulfate, and all iron compounds seem to be additive. The CNS effects are not understood, although methyldopa can cause sedation, depression and dementia, and haloperidol can cause drowsiness, dizziness and depression.

**Importance and management**

Information is limited, but this interaction appears to be established and clinically important. Monitor the effects of concurrent use and increase the methyldopa dosage as necessary. Separating the dosages by up to 2 hours apparently only partially reduces the effect of this interaction. Ferrous gluconate appears to interact like ferrous sulfate, and all iron compounds would be expected to interact similarly.

---

### Methyldopa + Oxazepam

A single, unsubstantiated case report suggests that blood pressure control with methyldopa may possibly be made more difficult in the presence of oxazepam.

**Clinical evidence, mechanism, importance and management**

A 54-year-old woman with insomnia and essential hypertension had unexplained variability in blood pressure while taking methyldopa 750 mg three times daily and a thiazide diuretic. Within a week of stopping oxazepam 60 mg at night, she developed grand mal convulsions and hypertension (190/90 mmHg standing, 240/140 mmHg lying). Her hypertension was then successfully controlled by switching to atenolol and prazosin. The authors of this report suggest that short-acting benzodiazepines such as oxazepam can cause transient hypertension after a dose, but that hypertension may occur on withdrawal. These effects may complicate the management of hypertension.1 The general importance of this possible interaction is not established, but it seems likely to be limited.

---

### Methyldopa + Phenothiazines

The hypotensive adverse effects of chlorpromazine and other phenothiazines may be additive with the antihypertensive effects of methyldopa. Patients may feel faint and dizzy if they stand up quickly. An isolated report describes paradoxical hypertension in a patient given methyldopa and trifluoperazine.

**Clinical evidence**

In one study, 8 normotensive patients given methyldopa 500 mg to 1 g daily with chlorpromazine 200 to 400 mg daily for schizophrenia experienced orthostatic dizziness and had reductions in their standing systolic blood pressure. In contrast, an isolated report describes a paradoxical rise in blood pressure in a patient with systemic lupus erythematosus and renal failure when methyldopa and trifluoperazine were given. When the trifluoperazine was stopped, the blood pressure fell.2

**Mechanism**

Simple addition of the hypotensive effects of both drugs seems to be the explanation for the increased hypotension and orthostasis. The suggested explanation for the hypertensive interaction with methyldopa and trifluoperazine is that the phenothiazine blocked the reuptake of the ‘false transmitter’ (alpha-methyl noradrenaline) that is produced during when methyldopa is given.3

**Importance and management**

The increased hypotension and orthostasis that can occur if chlorpromazine or other phenothiazines are used with antihypertensive drugs such as methyldopa is established. Note that, of the phenothiazines, levomepromazine is particularly associated with postural hypotension. Warn patients that they may feel faint and dizzy particularly during the initial stages of concurrent use, and that if this occurs they should lie down, and that they should remain lying down until symptoms abate completely. Dosage adjustments may be necessary.

The manufacturers of methyldopa note that a reduced antihypertensive effect may occur with phenothiazines, as well as mentioning the risk of additive hypotensive effects.

---

### Methyldopa + Phenoxybenzamine

An isolated case report describes a patient who had undergone bilateral lumbar sympathectomy who developed total urinary incontinence when given methyldopa 500 mg to 1.5 g with phenoxybenzamine 12.5 mg daily, but not when she was taking either drug alone. This would seem to be the outcome.

**Clinical evidence, mechanism, importance and management**

A woman who had previously had bilateral lumbar sympathectomy for Raynaud’s disease developed total urinary incontinence when given methyldopa 500 mg to 1.5 g with phenoxybenzamine 12.5 mg daily, but not when she was taking either drug alone. This would seem to be the outcome.
of the additive effects of the sympathectomy and the two drugs on the sympathetic control of the bladder sphincters. Stress incontinence has previously been described with these drugs. The general importance of this interaction is probably small.

**Methyldopa + Sympathomimetics; Indirectly-acting**

Indirectly-acting sympathomimetics might be expected to cause a blood pressure rise in patients taking methyldopa, and an isolated case report describes such a reaction in a patient who took phenylpropanolamine, but in practice this interaction normally seems to be of little or no general practical importance. The mydriatic effects of ephedrine are reported to be reduced by methyldopa.

**Clinical evidence, mechanism, importance and management**

In a study in 5 hypertensive subjects taking methyldopa 2 to 3 g daily, the pressor (rise in blood pressure) effects of tyramine were doubled. In another study the pressor effect of tyramine was 50/16 mmHg, compared with 18/10 mmHg before methyldopa treatment.

A man with renal hypertension, whose blood pressure was well controlled with methyldopa 250 mg twice daily and oxprenolol 160 mg three times daily, had a rise in blood pressure from under 140/80 mmHg to 200/150 mmHg within 2 days of starting to take two tablets of Triogesic (phenylpropanolamine 12.5 mg and paracetamol 500 mg) three times daily. His blood pressure fell when the Triogesic was withdrawn.

The reason for this is uncertain. One suggestion is that the methyldopa causes the replacement of noradrenaline at adrenergic nerve endings by methylnoradrenaline, which has weaker pressor (alpha) activity but greater vasodilator (beta) activity. With the vasodilator activity blocked by the oxprenolol, the vasoconstrictor (pressor) activity of the phenylpropanolamine would be unopposed and exaggerated. Alternatively it could have been that he was unusually sensitive to the pressor effects of phenylpropanolamine.

Despite the information derived from the studies outlined above and the single report cited, there seems to be nothing else in the literature to suggest that indirectly-acting sympathomimetics normally cause an adverse reaction with methyldopa. One report briefly mentions that the antihypertensive effects of various drugs, including methyldopa, were not affected by diethylpropion.

In 9 patients with untreated hypertension, the normal mydriatic effects of ephedrine were reduced by 54% after they started treatment with methyldopa 500 mg to 1.5 g daily.

**Methyldopa + Tricyclic and related antidepressants**

The antihypertensive effects of methyldopa are not normally adversely affected by desipramine, but an isolated report describes hypertension, tachycardia, tremor and agitation in a man taking methyldopa and amitriptyline. The tetracyclic mianserin does not appear not to interact significantly.

There is some evidence that a 5-mg dose of glibenclamide, but not a 2.5-mg dose, may reduce the hypotensive effect of minoxidil.

**Clinical evidence**

A man with hypertension, taking methyldopa 250 mg three times daily and a thiazide diuretic, experienced tremor, agitation, tachycardia (148 bpm) and hypertension (a rise from under 150/90 mmHg to 170/110 mmHg) within 10 days of starting to take amitriptyline 25 mg three times daily. A week after stopping all treatment his pulse rate was 100 bpm and his blood pressure 160/90 mmHg. In contrast, a double-blind, crossover study in 5 subjects (one with mild hypertension) found that desipramine 25 mg three times daily for 3 days had no significant effect on the hypotensive effects of a single 750-mg dose of methyldopa.

Another study in 3 hypertensive patients taking methyldopa 2.5 to 3 g daily found that desipramine 75 mg daily for 5 to 6 days did not antagonise the hypotension of methyldopa. In fact, the blood pressure fell slightly. Mianserin 20 mg three times daily for 2 weeks had no effect on the control of blood pressure in 6 patients receiving methyldopa, although 2 patients developed symptomatic hypotension after the first dose of mianserin.

**Mechanism**

Not understood. Antagonism of the antihypertensive actions of methyldopa by tricyclic antidepressants is seen in animals and it seems to occur in the brain.

**Importance and management**

Normally no adverse interaction occurs, nevertheless it would seem prudent to monitor the effects of concurrent use if amitriptyline or any other tricyclic antidepressant is given to patients taking methyldopa. Note that methyldopa sometimes induces depression, and so it is generally considered contraindicated in depressed patients.

**Minoxidil + Glibenclamide (Glyburide)**

There is some evidence that a 5-mg dose of glibenclamide, but not a 2.5-mg dose, may reduce the hypotensive effect of minoxidil.

**Clinical evidence, mechanism, importance and management**

A single-dose study in 9 healthy subjects found that glibenclamide 2.5 mg did not alter the hypotensive effect of oral minoxidil 5 mg. However, in a further 4 subjects a 5-mg dose of glibenclamide appeared to cause some loss in the hypotensive effect of minoxidil, but this was not statistically significant. The authors therefore suggested that this interaction may be dose-related. The suggested reason for these effects is that these two drugs have opposing effects on the potassium channels of the smooth muscle of blood vessels. In this study, subjects were pre-treated with propranolol to prevent reflex tachycardia when given minoxidil, which is how minoxidil is used clinically. What is not yet clear is whether any interaction occurs between minoxidil and glibenclamide in a clinical setting.

**Minoxidil + Miscellaneous**

The manufacturer notes that excessive blood pressure reductions may occur if minoxidil is used in patients taking guanethidine, because of the adrenergic blocking effects of guanethidine. If ex-
cessive hypotension occurs with minoxidil, this should not be treated with adrenaline (epinephrine) or noradrenaline (norepinephrine), because this may result in excessive tachycardia.¹

Minoxidil; Topical + Miscellaneous

A study in 19 healthy subjects found that the absorption of topical minoxidil was increased by almost threefold by the use of topical tretinoin 0.05% applied 1 hour before the minoxidil.¹ The manufacturers note that topical drugs that alter the stratum corneum barrier, such as tretinoin or dithranol, could result in increased absorption of minoxidil if applied concurrently. They suggest that, theoretically, one possible effect of minoxidil absorption would be potentiation of orthostatic hypotension caused by vasodilator drugs.² The exact drugs are not stated but this caution would be expected to cover drugs such as the nitrates and hydralazine.

Moxonidine + Miscellaneous

On theoretical grounds the manufacturers of moxonidine advise withdrawing beta blockers before withdrawing moxonidine. They also advise avoiding alcohol and tricyclic antidepressants during the use of moxonidine. Moxonidine alone can cause sedation, and increases the sedative effects of lorazepam, therefore care is needed with other benzodiazepines, hypnotics and sedatives. No clinically significant pharmacokinetic interactions occur with moxonidine and digoxin, glibenclamide (glyburide), hydrochlorothiazide, moclobemide, or quinidine.

Clinical evidence, mechanism, importance and management

(a) Benzodiazepines and other sedatives and hypnotics

The cognitive function of 24 healthy subjects was not impaired by moxonidine 400 micrograms daily, but the presence of moxonidine was found to increase the cognitive impairment caused by lorazepam 1 mg daily.¹ For this reason the manufacturers warn that the sedative effects of the benzodiazepines may possibly be enhanced by moxonidine.² Sedation and dizziness may occur with moxonidine, which the manufacturers suggest may be additive with the effects of sedatives and hypnotics.² They also advise the avoidance of alcohol.²

(b) Beta blockers

The presence of a beta blocker can exacerbate the rebound hypertension that follows the withdrawal of clonidine (see ‘Clonidine + Beta blockers’, p.882). Moxonidine is reported to have less affinity for central alpha-receptors than clonidine, and no such rebound hypertension has actually been seen when moxonidine is withdrawn. However, to be on the safe side the manufacturers advise that any beta blocker should be stopped first, followed by the moxonidine a few days later.²³

(c) Digoxin

No clinically relevant pharmacokinetic interaction was seen at steady state between moxonidine 200 micrograms twice daily and digoxin 200 micrograms daily in 15 healthy subjects.⁴

(d) Glibenclamide (Glyburide)

Glibenclamide 2.5 mg daily had no effect on the steady-state pharmacokinetics of moxonidine 200 micrograms twice daily in 18 healthy subjects. There was a minor 12% decrease in the AUC of glibenclamide, and a 14% increase in clearance, but these changes are unlikely to be of any clinical relevance.⁵

Niconein + Miscellaneous

Neither cimetidine nor rifampicin had any clinically relevant effect on the pharmacokinetics of nicorandil. Nicorandil did not alter the anticoagulant effects of acenocoumarol. Although animal studies suggest antagonism of effects, a study in patients found no pharmacodynamic interaction between nicorandil and glibenclamide. Nicorandil may potentiate the hypotensive effects of other vasodilators, tricyclic antidepressants and alcohol.

Clinical evidence, mechanism, importance and management

(a) Aacenocoumarol

Nicorandil 10 mg twice daily for 4 days then 20 mg twice daily for 7 days did not alter the INR in 11 patients stabilised on acenocoumarol.¹

(b) Carnetmide

Cimetidine 400 mg twice daily for 7 days had no effect on the pharmacokinetics of nicorandil 20 mg twice daily for 7 days, except that the nicorandil AUC showed a minor 10% increase, which is not clinically important.¹

(c) Gibenclamide

Studies in animals have indicated that there may be antagonism between nicorandil and glibenclamide. However, in a study, 8 patients with diabetes and angina (taking glibenclamide), and 11 similar patients not receiving glibenclamide, were given nicorandil 15 mg daily for more than 8 weeks. In contrast to the findings in the animal studies, glibenclamide
did not cause inhibition of the anti-anginal effects of nicorandil, nor was there any disturbance of diabetic control.2

(d) Miscellaneous drugs

Combined data from clinical studies in 1152 patients using nicorandil found no evidence of increased adverse effects or an increased number of withdrawals in patients taking unnamed beta blockers (210 patients), calcium-channel blockers (117), long-acting nitrates (130), bepridil (18), diltiazem (91), verapamil (9), amiodarone (23) or molsidomine (30). It has also been reported that unnamed antihypertensives, antidiabetic or lipid-regulating drugs do not appear to interact adversely with nicorandil.3 No adverse ECG effects have been seen (including QT or ST segment modifications) with nicorandil.3 However, the manufacturers suggest that nicorandil may possibly potentiate the blood pressure-lowering effects of other vasodilators, tricyclic antidepressants or alcohol.4 For mention that phosphodiesterase inhibitors (e.g. sildenafil, tadalafil, vardenafil) should not be used with nicorandil, see ‘Phosphodiesterase type-5 inhibitors + Nitrates’, p.1272.

(e) Rifampicin

Rifampicin 600 mg daily for 5 days had no effect on the pharmacokinetics of nicorandil 20 mg twice daily for 5 days, except that the elimination half-life showed a minor 17% decrease, which is not clinically important.1

Mechanism

The evidence suggests that ciprofloxacin inhibits the metabolism of the pentoxifylline (a xanthine derivative) by the liver. Compare ‘Theophylline + Quinolones’, p.1192.

Importance and management

Information on this interaction and its clinical relevance is limited. The author of the pharmacokinetic study suggests that, if the drugs need to be used together, the dosage of pentoxifylline should be halved.1 In the absence of other information, if a short-course of ciprofloxacin is required in a patient taking pentoxifylline, this may be a sensible precaution. Alternatively, because the increase in AUC was minor, it may be sufficient to recommend a reduction in pentoxifylline dose only in those who experience adverse effects (e.g. nausea, headache). Note that ciprofloxacin has been used to boost pentoxifylline levels in studies investigating the possible therapeutic value of pentoxifylline’s ability to inhibit various cytokines. For example, ciprofloxacin 500 mg twice daily was used with pentoxifylline 800 mg three times daily for up to one year in patients with myelodysplastic syndrome.2

Clinical evidence, mechanism, importance and management

An 86-year-old woman taking perhexiline was admitted to hospital because of ataxia, falls, lethargy, nausea, and an inability to cope at home. She had started to take paroxetine 20 mg daily 5 weeks earlier. Her serum perhexiline levels were 2.02 mg/L, compared with the normal range of 0.15 to 0.6 mg/L.1 Perhexiline toxicity was also seen in two other elderly women, following the use of paroxetine in one case, and fluoxetine in the other. The perhexiline serum levels fell when both drugs were stopped, but in one case the fall was very slow.2 Another case report describes toxicity and raised perhexiline levels in an elderly man shortly after he started taking citalopram.3 The reason for the rise in perhexiline levels is not known, but it seems likely that these SSRIs can inhibit its metabolism, probably via the cytochrome P450 isoenzyme CYP2D6. The general importance of these interactions is also not known, but it would now be prudent to monitor the outcome of concurrent use for perhexiline toxicity and consider monitoring perhexiline serum levels where possible. The perhexiline dosage may need to be reduced. More study is needed.

Pentoxifylline + Cimetidine

Cimetidine increases plasma pentoxifylline levels to a moderate extent, which may increase the incidence of adverse effects.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects found that the mean steady-state plasma levels of controlled-release pentoxifylline 400 mg every 8 hours were raised by about 27% when cimetidine 300 mg four times daily for 7 days was added.1 Adverse effects such as headache, nausea, and vomiting were said to be more common and bothersome while taking the cimetidine.1

The reason for this interaction is not known. However, cimetidine is known to inhibit the metabolism of ‘theophylline’, (p.1181), to which pentoxifylline is structurally related.

The findings of this study suggest that this interaction may be clinically relevant. If cimetidine is required in a patient taking pentoxifylline, monitor for adverse effects, and decrease the pentoxifylline dose if problems occur.

Pentoxifylline + Ciprofloxacin

Evidence from one study suggests that ciprofloxacin increases the serum levels of pentoxifylline, and may increase the incidence of adverse effects. In some clinical studies ciprofloxacin has been used to boost the levels of pentoxifylline.

Clinical evidence

Because patients taking pentoxifylline and ciprofloxacin often complained of headache, the possibility of a pharmacokinetic interaction was studied in 6 healthy subjects. The study showed that ciprofloxacin 500 mg daily for 3 days increased the peak serum levels of a single 400-mg dose of pentoxifylline by almost 60% (from 114.5 to 179.5 nanograms/mL), and increased the AUC by 15%. All 6 subjects complained of a frontal headache.1

Mechanism

The evidence suggests that ciprofloxacin inhibits the metabolism of the pentoxifylline (a xanthine derivative) by the liver. Compare ‘Theophylline + Quinolones’, p.1192.

Importance and management

Information on this interaction and its clinical relevance is limited. The author of the pharmacokinetic study suggests that, if the drugs need to be used together, the dosage of pentoxifylline should be halved.1 In the absence of other information, if a short-course of ciprofloxacin is required in a patient taking pentoxifylline, this may be a sensible precaution. Alternatively, because the increase in AUC was minor, it may be sufficient to recommend a reduction in pentoxifylline dose only in those who experience adverse effects (e.g. nausea, headache). Note that ciprofloxacin has been used to boost pentoxifylline levels in studies investigating the possible therapeutic value of pentoxifylline’s ability to inhibit various cytokines. For example, ciprofloxacin 500 mg twice daily was used with pentoxifylline 800 mg three times daily for up to one year in patients with myelodysplastic syndrome.2

Perhexiline + SSRIs

Case reports describe an increase in perhexiline serum levels resulting in toxicity when citalopram, fluoxetine or paroxetine were given.

Clinical evidence, mechanism, importance and management

An 86-year-old woman taking perhexiline was admitted to hospital because of ataxia, falls, lethargy, nausea, and an inability to cope at home. She had started to take paroxetine 20 mg daily 5 weeks earlier. Her serum perhexiline levels were 2.02 mg/L, compared with the normal range of 0.15 to 0.6 mg/L.1 Perhexiline toxicity was also seen in two other elderly women, following the use of paroxetine in one case, and fluoxetine in the other. The perhexiline serum levels fell when both drugs were stopped, but in one case the fall was very slow.2 Another case report describes toxicity and raised perhexiline levels in an elderly man shortly after he started taking citalopram.3 The reason for the rise in perhexiline levels is not known, but it seems likely that these SSRIs can inhibit its metabolism, probably via the cytochrome P450 isoenzyme CYP2D6. The general importance of these interactions is also not known, but it would now be prudent to monitor the outcome of concurrent use for perhexiline toxicity and consider monitoring perhexiline serum levels where possible. The perhexiline dosage may need to be reduced. More study is needed.

Ranolazine + Miscellaneous

The concurrent use of ranolazine and moderate or potent inhibitors of CYP3A4, such as some azoles, diltiazem, grapefruit juice, macrolide or protease inhibitors, or verapamil will result in increased levels of ranolazine, and can predispose the patient to adverse effects including QT interval prolongation. Cimetidine and paroxetine do not interact to a clinically significant extent. Ranolazine may increase levels of ciclosporin, digoxin or simvastatin.
Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

Moderate inhibitors of CYP3A4 (e.g. diltiazem and verapamil) cause a two- to threefold rise in ranolazine levels, and ketoconazole, a potent inhibitor of CYP3A4 causes an even greater rise (see below). Raised ranolazine levels can cause clinically significant QT prolongation. The manufacturer of ranolazine therefore contraindicates its use with these and other potent or moderately potent CYP3A4 inhibitors. They specifically name grapefruit juice and grapefruit-containing products, macrolides and protease inhibitors.1

A list of clinically relevant CYP3A4 inhibitors is given in ‘Table 1.4’.

1. Diltiazem. In a placebo-controlled study in 12 healthy subjects diltiazem 60 mg three times daily was given to 12 healthy subjects for 7 days, with ranolazine 240 mg three times daily on days 4 to 7. Ranolazine did not alter the pharmacokinetics of diltiazem, but diltiazem increased the AUC and maximum plasma level of ranolazine by 85% and twofold, respectively. A further study using modified-release diltiazem 180 mg, 240 mg, and 360 mg once daily, and a slow-release preparation of ranolazine 1g twice daily, resulted in increases in the AUC of ranolazine of 52%, 93%, and 139%, respectively.2

2. Ketoconazole. In a double-blind, randomised study, healthy subjects were given slow-release ranolazine 375 mg twice daily for 9 days, with ketoconazole 200 mg twice daily on days 3 to 9. The same study was repeated with ranolazine 1g twice daily. It was found that ketoconazole increased the AUC, levels (mean, peak and trough) and half-life of ranolazine by 2.5- to 4.5-fold. The most common adverse events were headaches, dizziness and nausea. In some patients the higher dose of ranolazine with ketoconazole resulted in intolerable adverse events.2

3. Verapamil. Plasma levels of ranolazine 750 mg twice daily are reported to be increased twofold by concurrent verapamil 120 mg three times daily.1

(b) Ciclosporin

Ranolazine inhibits P-glycoprotein. and has been shown to raise digoxin levels (see below), presumably by this mechanism. However, it is also a substrate of P-glycoprotein. The manufacturers of ranolazine therefore advise caution if it is given to patients taking ciclosporin, which is also a P-glycoprotein inhibitor [and substrate].1 Until more is known it would seem prudent to increase the frequency of ciclosporin and ranolazine monitoring if both drugs are given.

(c) CYP3A4 substrates

In an open-label study, simvastatin 80 mg daily was given with ranolazine 1g twice daily for 4 days. Simvastatin had no effect on the pharmacokinetics of ranolazine, but ranolazine increased the maximum plasma levels of simvastatin and its active metabolites by about twofold and increased its AUC by 40 to 60%.2

These changes may be clinically significant in some patients. If simvastatin is given to a patient taking ranolazine, it would seem prudent to start at the lowest dose and titrate cautiously. If ranolazine is given to patients already taking simvastatin consider reducing the dose of simvastatin (particularly with high simvastatin doses). All patients taking statins should be warned about the symptoms of myopathy and told to report muscle pain or weakness. It would be prudent to reinforce this advice if they are given ranolazine.

(d) Digoxin

A study in healthy subjects given ranolazine 1g twice daily and digoxin 125 micrograms found that ranolazine increased the plasma levels of digoxin by about 1.5-fold. Plasma levels of ranolazine were not significantly affected by concurrent digoxin.1 Ranolazine probably raises digoxin levels by inhibiting P-glycoprotein. It would seem prudent to monitor digoxin levels if ranolazine is started, anticipating the need to reduce the digoxin dose.

(e) Paroxetine

Paroxetine has been reported to increase the average steady state plasma concentrations of ranolazine 1.2-fold.1 Ranolazine is metabolised by the cytochrome P450 isoenzymes CYP2D6, which paroxetine inhibits. However, as CYP2D6 is not the main route of metabolism, only very modest effects are seen, and no dosage adjustment is necessary.1

(f) Ritonavir

Ranolazine and ritonavir are both substrates for and inhibitors of P-glycoprotein. The manufacturers of ranolazine advise caution if ranolazine is given to patients taking ritonavir.1

Sodium nitroprusside + Miscellaneous

Smaller doses of sodium nitroprusside might be required in patients receiving antihypertensive drugs. There is a risk of severe hypotension if phosphodiesterase inhibitors (e.g. sildenafil, tadalafil and vardenafil) are used with sodium nitroprusside.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

The manufacturer notes that smaller doses of sodium nitroprusside might be required in patients receiving antihypertensive drugs. In any event the required dose varies considerably between patients and so should be titrated to effect. When used for controlled hypotension during anaesthesia, the hypotensive effect of other drugs, particularly anaesthetics, should be remembered.1 They name halothane and enflurane.

(b) Phosphodiesterase inhibitors

The use of phosphodiesterase inhibitors (e.g. sildenafil, tadalafil and vardenafil) with sodium nitroprusside is contraindicated by the manufacturers, due to the risk of severe hypotension. See also ‘Phosphodiesterase type-5 inhibitors + Nitrates’, p.1272. A case report describes the therapeutic use of sildenafil to enhance the hypotensive effect of sodium nitroprusside and other antihypertensives in a patient with a hypertensive crisis.2

Tirilazad mesilate + Miscellaneous

Phenobarbital and phenytoin reduce the serum levels of tirilazad mesilate whereas ketoconazole increases them. Finasteride inhibits the metabolism of tirilazad to its active metabolite. No pharmacokinetic interaction appears to occur between cimetine or nifedipine and tirilazad.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

A study in 16 healthy men found that cimetine 300 mg every 6 hours for 4 days had no effect on the pharmacokinetics of a single 2mg/kg dose of tirilazad mesilate, given by infusion over 10 minutes on day 2, nor on U-89678, its active metabolite.1 No special precautions would seem necessary if cimetidine is given with tirilazad mesilate.

(b) Finasteride

In a study, 8 healthy men were given finasteride 5 mg daily for 10 days, with tirilazad mesilate 10 mg/kg orally or 2 mg/kg intravenously on day 7. Finasteride increased the AUCs of intravenous and oral tirilazad by 21% and 29%, respectively. Oral finasteride reduced the AUCs of the active metabolite (U-89678) by 92% when tirilazad was given intravenously and by 75% when tirilazad was given orally. Although the metabolism of tirilazad to U-89678 was inhibited there was only a moderate effect on the overall clearance of tirilazad and the interaction was considered unlikely to be of clinical significance.2

(c) Ketoconazole

Tirilazad mesilate, 10 mg/kg orally or 2 mg/kg intravenously, was given to 12 healthy men and women, either alone or on day 4 of a 7-day regimen of ketoconazole 200 mg daily. The ketoconazole more than doubled the absolute bioavailability of the oral tirilazad mesilate (from 8.7% to 20.9%), apparently because its metabolism by the cytochrome P450 iso-
zyme CYP3A in the gut wall and during the first pass through the liver was inhibited. The clinical importance of this interaction awaits assessment.

(d) Nimodipine

In a single-dose study in 12 healthy men, there was no pharmacokinetic or pharmacodynamic interaction between intravenous tirilazad mesilate 2 mg/kg and oral nimodipine 60 mg. No special precautions would seem necessary if nimodipine is given with tirilazad mesilate.

(e) Phenobarbital

The pharmacokinetics of tirilazad mesilate (1.5 mg/kg as 10 minute intravenous infusions every 6 hours for 29 doses) were studied in 15 healthy subjects before and after they took phenobarbital 100 mg daily for 8 days. The phenobarbital increased the clearance of the tirilazad by 25% in the male subjects and 29% in the female, and the AUC of the active metabolite of tirilazad (U-89678) was reduced by 51% in the males and 69% in the females. The reason is thought to be that the phenobarbital acts as an enzyme inducer, which increases the metabolism of the tirilazad. The clinical importance of these reductions awaits assessment, but be alert for evidence of reduced effects if both drugs are given. It is doubtful if the full enzyme-inducing effects of the phenobarbital would have been reached in this study after only one week, so anticipate a greater effect if it is given for a longer period.

(f) Phenytoin

After taking phenytoin 200 mg every 8 hours for 11 doses then 100 mg every 8 hours for 5 doses, the AUC0-6 of tirilazad mesilate was reduced by 35% in 12 healthy subjects. The AUC of the active metabolite, U-89678, was reduced by 87%. Another report by the same group of workers found that phenytoin every 8 hours for 7 days (9 doses of 200 mg followed by 13 doses of 100 mg) reduced the clearance of tirilazad by 92% and of U-89678 by 93%. In another report the authors noted that phenytoin increased the metabolism of tirilazad and its metabolite in men and women to similar extents. The clinical importance of these reductions is still to be assessed, but be alert for any evidence of reduced tirilazad effects if both drugs are given.

# Tolazoline + H2-receptor antagonists

Cimetidine and ranitidine can reduce or abolish the effects of tolazoline used as a pulmonary vasodilator in children.

## Clinical evidence

A newborn infant with persistent foetal circulation was given a continuous infusion of tolazoline to reduce pulmonary hypertension. The oxygenation improved but gastrointestinal bleeding occurred. When cimetidine was given, the condition of the child deteriorated with a decrease in oxygen saturation and arterial PO2 values. A second case report describes a similar outcome in a 2-day-old neonate, who had an initial improvement with tolazoline alone, but then developed worsening hypoxaemia when cimetidine was given.

These reports are similar to another, in which the tolazoline-induced reduction in pulmonary arterial pressure in a child was reversed when cimetidine was given.

Mechanism

Tolazoline dilates the pulmonary vascular system by stimulating both H1- and H2-receptors. Cimetidine and ranitidine block H2-receptors so that at least part of the effects of tolazoline are abolished. It has been suggested that this interaction is confined to children.

## Importance and management

An established interaction. Cimetidine and ranitidine are not suitable drugs for prophylaxis of the gastrointestinal adverse effects of tolazoline in children. Other H2-receptor antagonists would be expected to behave similarly.

Digitalis glycosides

Plant extracts containing cardiac glycosides have been in use for thousands of years. The ancient Egyptians were familiar with squill (a source of *proscillaridin*), as were the Romans who used it as a heart tonic and diuretic. The foxglove was mentioned in the writings of Welsh physicians in the thirteenth century and features in 'An Account of the Foxglove and some of its Medical Uses', published by William Withering in 1785, in which he described its application in the treatment of 'dropsy' or the oedema that results from heart failure.

The most commonly used cardiac glycosides are those obtained from the members of the foxglove family, *Digitalis purpurea* and *Digitalis lanata*. The leaves of *D. lanata* are the source of a number of purified glycosides including *digoxin*, *digitoxin*, *acetyldigoxin*, *acetyldigitoxin*, *lanatoside C*, *deslanoside*, of gitalin (an amorphous mixture largely composed of digitoxin and digoxin), and of powdered whole leaf *digitalis lanata leaf*. *D. purpurea* is the source of *digitoxin*, *digitalis leaf*, and the standardised preparation *digitalin*. *Metildigoxin* is a semi-synthetic digitalis glycoside. Occasionally ouabain or strophanthin-K (also of plant origin) are used for particular situations, while for a number of years the Russians have exploited cardiac glycosides from lily of the valley (*convallaria*). Bufalin is a related cardioactive compound obtained from toads, and is found in a number of Chinese medicines.

**Digitalisation**

The cardiac glycosides have two main actions and two main applications. They reduce conductivity within the atrioventricular (AV) node, hence are used for treating supraventricular tachycardias (especially atrial fibrillation), and they have a positive inotropic effect (i.e. increase the force of contraction), hence are used for congestive heart failure, although this use has declined.

Because the most commonly used glycosides are derived from digitalis, the achievement of the desired therapeutic serum concentration of any cardiac glycoside is usually referred to as digitalisation. Treatment may be started with a large loading dose so that the therapeutic concentrations are achieved reasonably quickly, but once these have been reached the amount is reduced to a maintenance dose. This has to be done carefully because there is a relatively narrow gap between therapeutic and toxic serum concentrations. Normal therapeutic levels are about one-third of those that are fatal, and serious toxic arrhythmias begin at about two-thirds of the fatal levels. The normal range for digoxin levels is 0.8 to 2 nanograms/mL (or 1.02 to 2.56 nanomol/L). To convert nanograms/mL to nanomol/L multiply by 1.28, or to convert nanomol/L to nanograms/mL multiply by 0.781. Note that micrograms/L is the same as nanograms/mL.

If a patient is over-digitalised, signs of toxicity will occur, which may include loss of appetite, nausea and vomiting, and bradycardia. These symptoms are often used as clinical indicators of toxicity, and a pulse rate of less than 60 bpm is usually considered to be an indication of over-treatment. Note that paroxysmal atrial tachycardia with AV block and junctional tachycardia can also occur as a result of digitalis toxicity. Other symptoms include visual disturbances, headache, drowsiness and occasionally diarrhoea. Death may result from cardiac arrhythmias. Patients treated for cardiac arrhythmias can therefore demonstrate arrhythmias when they are both under- as well as over-digitalised.

**Interactions of the cardiac glycosides**

The pharmacological actions of these glycosides are very similar, but their rates and degree of absorption, metabolism and clearance are different. For example, digoxin is mainly renally cleared whereas digitoxin undergoes a degree of metabolism by the liver. It is therefore most important not to extrapolate an interaction seen with one glycoside and apply it uncritically to any other. Because the therapeutic ratio of the cardiac glycosides is low, a quite small change in serum levels may lead to inadequate digitalisation or to toxicity. For this reason interactions that have a relatively modest effect on serum levels may sometimes have serious consequences.

Many interactions between digoxin and other drugs are mediated by P-glycoprotein. Drugs that inhibit the activity of P-glycoprotein in the renal tubules may reduce the elimination of digoxin in the urine and this may result in toxic serum levels. Further, the induction or inhibition of P-glycoprotein in the gut may affect the oral absorption of digoxin. See also 'Drug transporter proteins', (p.8).
Digitalis glycosides + ACE inhibitors

Most ACE inhibitors do not interact with digoxin to a clinically relevant extent. Some studies have found that serum digoxin levels rise by about 20% or more if captopril is used, but others have found no significant changes. It has been suggested that any interaction is likely to occur only in those patients who have pre-existing renal impairment. Digitoxin and captopril appear not to interact.

Clinical evidence

(a) Digitoxin and Captopril

A study in 12 healthy subjects given digitoxin 70 micrograms daily for up to 58 days found no evidence that the addition of captopril 25 mg daily had a relevant effect on the pharmacokinetics of digitoxin, or its effects on the heart.1

(b) Digoxin and Captopril

The serum digoxin levels of 16 patients with severe chronic congestive heart failure rose by 21%, from 1.1 to 1.3 nanograms/mL, while taking captopril (average dose 93.7 mg daily). Serum digoxin levels were above the therapeutic range at 2 nanograms/mL on 3 out of 63 occasions, but no toxicity was seen. All patients had impaired renal function and were being treated with diuretics.2,3 Another study4 found an approximate 30% rise in serum digoxin levels in patients with congestive heart failure class II and a further study5 found an approximate 60% rise in peak serum digoxin levels in patients with congestive heart failure class IV. Conversely, another study in 31 patients with stable congestive heart failure, given captopril 25 mg three times daily, found no significant changes in serum digoxin levels over a 6-month period.6 Two other studies in healthy subjects7 and patients with congestive heart failure8 also found no evidence of an interaction.

(c) Digoxin and Other ACE inhibitors

In general no significant interactions have been seen between ACE inhibitors and digoxin.

• Cilazapril 5 mg for 14 days did not alter the trough plasma digoxin levels in healthy subjects.9

• Enalapril 20 mg daily for 30 days had no significant effect on the pharmacokinetics of digoxin 250 micrograms daily in 7 patients with congestive heart failure.10

• Imidapril 10 mg daily had no effect on the serum digoxin levels of 12 healthy subjects, but slight reductions in levels of the active form imidapril and in ACE inhibition of about 15% were seen, which were of uncertain clinical relevance.11

• Lisinopril 5 mg daily for 4 weeks had no significant effect on the serum digoxin levels of 9 patients.12 This confirms the findings of a single-dose study.13

• Moxipril has been reported, by the manufacturer, to have had no important pharmacokinetic interaction with digoxin in healthy subjects.14 They also have clinical studies that show no evidence of clinically important adverse interactions when moxipril was used with digoxin.15

• Perindopril 2 to 4 mg daily for a month had no effect on the steady-state serum digoxin levels of 10 patients with mild chronic heart failure.16

• Quinapril is also reported not to alter the steady-state levels of digoxin in healthy subjects,17 and patients with congestive heart failure.18

• Ramipril 5 mg daily for 14 days had no effect on the serum digoxin levels of 12 healthy subjects.19

• Spirapril 12 to 48 mg daily did not significantly affect the pharmacokinetics nor the steady-state serum levels of digoxin in 15 healthy subjects taking digoxin 250 micrograms twice daily.20

• Trandolapril has been shown to have no significant pharmacokinetic interaction with digoxin in healthy subjects.21 The manufacturers also note that, in patients with left ventricular dysfunction after myocardial infarction, no clinical interactions have been found between trandolapril and digoxin.22,23

Mechanism

Not fully understood. It has been suggested that an interaction is only likely to occur in those who have renal impairment because the glomerular filtration rate of these patients may be maintained by the vasconstrictor action of angiotensin II on the post-glomerular blood vessels, which would be impaired by ACE inhibition. As a result some of the loss of digoxin through the tubules is reduced.7

Importance and management

The overall picture is that no clinically important adverse interaction occurs between digoxin and ACE inhibitors in patients with normal renal function, and that serum digoxin monitoring is only needed in those who have a high risk of reversible ACE inhibitor induced renal failure (e.g. patients with congestive heart failure during diuretic treatment, with bilateral renal artery stenosis or unilateral renal artery stenosis in a solitary kidney);2 however, note these latter two conditions are contraindications to the use of ACE inhibitors. The critical factor does not seem to be the particular ACE inhibitor used but the existence of abnormal renal function or conditions that increase the risk of renal impairment. This needs confirmation.

No interaction apparently occurs between digitoxin and captopril in healthy subjects, but this needs confirmation in patients.

Digitalis glycosides + Acipimox

One study suggests that acipimox does not interact with digoxin.

Clinical evidence, mechanism, importance and management

In 6 elderly patients acipimox 250 mg three times daily for a week was found to have no significant effect on plasma digoxin levels, clinical con-
dution, ECGs, plasma urea or electrolyte levels.\(^1\) No special precautions during concurrent use would seem necessary.

**Digitalis glycosides + Allopurinol**

Allopurinol does not appear to affect serum digoxin levels.

**Clinical evidence, mechanism, importance and management**

No significant changes in the serum digoxin levels of 5 healthy subjects occurred over a 7-day period while they were taking allopurinol 300 mg daily.\(^1\) No additional precautions would appear to be necessary on concurrent use.

**Digitalis glycosides + Alpha blockers**

A rapid and marked rise in serum digoxin levels occurred in one study when prazosin was also given. Alfuzosin, doxazosin, tamsulosin and terazosin appear not to interact with digoxin.

**Clinical evidence, mechanism, importance and management**

(a) **Alfuzosin**

The manufacturers of alfuzosin report that no pharmacodynamic or pharmacokinetic interaction was observed in healthy subjects given alfuzosin 10 mg [daily] with digoxin 250 micrograms daily for 7 days.\(^1,2\)

(b) **Doxazosin**

Doxazosin is highly bound to plasma proteins (98%), but the manufacturer notes that in vitro data in human plasma indicated that doxazosin did not affect the protein binding of digoxin.\(^3,4\) Although there appears to be no clinical evidence of an interaction between digoxin and doxazosin, an in vitro study found that doxazosin inhibited the P-glycoprotein-mediated transcellular transport of digoxin, suggesting that an interaction is possible, as digoxin renal transport may be inhibited.\(^5\) More study is needed.

(c) **Prazosin**

In 20 patients prazosin 2.5 mg twice daily increased the mean steady-state plasma digoxin level by 43% from 0.94 to 1.34 nanograms/mL after one day, and by 60% from 0.94 to 1.51 nanograms/mL after 3 days, although the individual response varied from an increase to a decrease, or no effect. Three days after the prazosin was stopped, by which time it would be totally cleared from the body, the serum digoxin concentrations had fallen to their previous levels.\(^6\) The reason for this response is not understood. There do not appear to be any other reports in the literature, and the manufacturer notes that, in clinical experience, prazosin has been given with digoxin (and ‘digitalis’) without any adverse drug interaction.\(^7\) However, bear this interaction in mind in case of an unexpected response to treatment.

(d) **Tamsulosin**

A placebo-controlled study in 10 healthy subjects found that tamsulosin 800 micrograms daily had no effect on the pharmacokinetics of a single 500-microgram intravenous dose of digoxin. The most frequently reported adverse effect was dizziness and the safety profile was considered acceptable.\(^8\) The manufacturers note that dosage adjustments are not necessary when tamsulosin is given with digoxin.\(^9\)

(e) **Terazosin**

The manufacturer of terazosin states that terazosin has been given with cardiac glycosides without evidence of an interaction.\(^10\)

Digitalis glycosides + Aminoglutethimide

The clearance of digoxin is markedly increased by aminoglutethimide and a reduction in its effects would be expected.

Clinical evidence, mechanism, importance and management

The clearance of digoxin was increased by a mean of 109% in 5 patients who took aminoglutethimide (250 mg four times a day in four, and 125 mg twice daily in one).1,2 The likely reason is that aminoglutethimide increases the metabolism of the digoxin by the liver.

This increase in clearance would be expected to be clinically important, but this does not appear to have been assessed. Check that patients do not become under-digalised during concurrent treatment. No interaction would be expected with digoxin because it is largely excreted unchanged in the urine and therefore metabolism by the liver has little part to play in its clearance.

Digitalis glycosides + Aminoglycosides

Serum levels of digoxin can be reduced by the concurrent use of oral neomycin and increased by intramuscular gentamicin.

Clinical evidence

(a) Gentamicin

In a study in 12 patients with congestive heart failure taking digoxin 250 micrograms daily, the addition of gentamicin 80 mg intramuscularly twice daily for 7 days was found to increase serum digoxin levels by 129%. In a further 12 patients with congestive heart failure and diabetes, the same dosage of gentamicin increased digoxin levels more than two-fold to 2 nanograms/mL. However, no symptoms of digoxin toxicity were seen. It should be noted that serum creatinine levels were higher in both groups than those in healthy controls even before receiving gentamicin, and were further increased after gentamicin.

An earlier study similarly found that gentamicin prolonged the half-life of digoxin and increased serum levels from 1.9 to 2.8 nanograms/mL.

(b) Neomycin

Neomycin 1 to 3 g orally was found to reduce and delay the absorption of a single 500-microgram dose of digoxin in healthy subjects.3 The AUC was reduced by 41 to 51%. Absorption was affected even when the neomycin was given 3 to 6 hours before the digoxin. In a steady-state study, neomycin 2 g given with digoxin 250 to 500 micrograms daily reduced the serum level of digoxin by 8 to 49% (mean 28.2%).3

Mechanism

Gentamicin impairs renal function, so decreasing digoxin clearance.2 Higher digoxin levels and serum creatinine levels in diabetic compared with non-diabetic patients may be due to differences in renal function,1 with concurrent gentamicin causing further renal function impairment and even higher digoxin levels. The reduction in digoxin toxicity is not fully understood but changes in ionic transport may be involved. The inhibition by gentamicin of Na+/K+ ATPase, which acts as a specific receptor for digoxin, may also be a factor.1

Neomycin can cause a general but reversible malabsorption syndrome, which affects the absorption of several drugs. The extent of this is probably offset in some patients, because the neomycin also reduces the breakdown of digoxin by the bacteria in the gut.4

Importance and management

Information is limited, but patients should be monitored for increased digoxin effects if gentamicin is given, especially those with diabetes or any other patient with impaired renal function. Initially, checking pulse rate is probably adequate. There seems to be no information about other parenteral aminoglycosides.

Patients should be monitored for reduced digoxin effects if neomycin is given and suitable dosage adjustments made if necessary. Separating the dosages of the two drugs does not prevent this interaction. Other aminoglycosides that can be given orally such as kanamycin and paromomycin might possibly interact similarly to neomycin, but this requires confirmation.

Digitalis glycosides + 5-Aminosalicylates

Serum digoxin levels can be reduced by sulfasalazine. The manufacturers of balsalazide suggest that it may interact similarly.

Clinical evidence, mechanism, importance and management

The observation that a patient taking sulfasalazine 8 g daily had low serum digoxin levels, prompted a crossover study in 10 healthy subjects. In this study a single 500-microgram dose of digoxin syrup was given alone, and after 6 days of treatment with sulfasalazine to 6 g daily. Digoxin absorption was reduced, ranging from 0 to 50% depending on the dosage of sulfasalazine used.1 Serum digoxin levels were reduced accordingly.1 The reasons for this effect are not understood. This seems to be the only report of this interaction. Concurrent use need not be avoided, but it would be prudent to check for under-digitalisation, initially by checking symptoms and pulse rate, and then taking digoxin levels if an interaction is suspected. In the one patient examined, separating the dosages appeared not to prevent this interaction.1

Although no interaction involving digoxin and balsalazide has been reported, based on the information with sulfasalazine, the manufacturers of balsalazide recommend that plasma levels of digoxin should be monitored in digitalised patients starting balsalazide.2

Digitalis glycosides + Aminosalicylic acid

Aminosalicylic acid causes a small reduction in digoxin levels in healthy subjects but the importance of this in patients is uncertain.

Clinical evidence, mechanism, importance and management

In one study in 10 healthy subjects, the bioavailability of a single 750-microgram dose of digoxin, using urinary excretion as a measure, was reduced by 20% by aminosalicylic acid 2 g four times daily for 2 weeks.1 This seems to be just another aspect of the general malabsorption caused by aminosalicylic acid. The importance of this interaction in patients is not known (it is probably small) but it would be prudent to monitor concurrent use.

It is thought that amiodarone can also inhibit the metabolism of digitoxin by the liver, which would explain why its serum levels are increased.24

Importance and management

The pharmacokinetic interaction between digoxin and amiodarone is well documented, well established and of considerable clinical importance. It occurs in most patients. It is clearly evident after a few days and develops over the course of 1 to 4 weeks.6 If no account is taken of this interaction the patient may develop digitalis toxicity. Reduce the digoxin dosage by between one-third to one-half when amiodarone is added,13,15,21 with further adjustment of the dosage after a week or two, and possibly a month or more,13 depending on digoxin levels. Particular care is needed in children, who may show much larger rises in digoxin levels than adults. Amiodarone has a long half-life so that the effects of this interaction will persist for several weeks after its withdrawal.17 A synergistic effect on heart rate and atrioventricular conduction is also possible, which may result in the development of new arrhythmias. Also note that some authors suggest that concurrent use may possibly worsen the prognosis in some patients.23,22

Far less is known about the interaction between digitoxin and amiodarone but the limited evidence available suggests that all of the precautions appropriate for digoxin should be used for digitoxin as well. Note that the interaction may possibly take months to develop.

Digitalis glycosides + Angiotensin II receptor antagonists

Candesartan, eprosartan, irbesartan, losartan, and valsartan do not appear to affect the pharmacokinetics of digoxin, but telmisartan may cause a rise in serum digoxin levels.

Clinical evidence

(a) Candesartan
There was no pharmacokinetic interaction between candesartan 16 mg daily and digoxin given as a loading dose of 750 micrograms then 250 micrograms daily in 12 healthy subjects.\(^5\)

(b) Eprosartan
A study in 12 healthy men given a single 600-microgram dose of digoxin found that eprosartan 200 mg every 12 hours for 4 days had no significant effect on the pharmacokinetics of digoxin.\(^2\)

(c) Irbesartan
A study in 10 healthy subjects taking digoxin for 2 weeks found no changes in the AUC or maximum serum levels of digoxin, when, during the second week, they also took irbesartan 150 mg daily.\(^2\)

(d) Losartan
In 13 healthy subjects the pharmacokinetics of a single 500-microgram oral or intravenous dose of digoxin were not affected by losartan 50 mg daily for a week.\(^4\)

(e) Telmisartan
A study in 12 healthy subjects given a 500-microgram loading dose of digoxin followed by 250 micrograms daily found that the maximum serum concentration, the trough serum concentration and the AUC were increased by 50%, 13%, and 22%, respectively, when telmisartan 120 mg daily was given for 7 days.\(^5\) No clinically relevant changes in vital signs or ECGs were noted.

(f) Valsartan
There was no adverse interaction between a single 160-mg dose of valsartan and digoxin 250 micrograms in a study in 12 healthy subjects.\(^6\)

Mechanism

It has been suggested that telmisartan may have caused digoxin to be more rapidly absorbed.\(^3\) An in vitro study found that candesartan and losartan do not appear to inhibit P-glycoprotein-mediated transcellular transport. Therefore interactions resulting in reduced digoxin renal excretion are unlikely.\(^3\)

Importance and management

No special precautions seem to be necessary when digoxin is used with candesartan, eprosartan, irbesartan, losartan, or valsartan. However, note that information for eprosartan, losartan, and valsartan is from single-dose studies, although the authors of the eprosartan study consider that a clinical relevance interaction with multiple doses of digoxin is unlikely.\(^2\) The small increase in trough serum digoxin level with telmisartan suggests that the dose of digoxin need not automatically be reduced when telmisartan is started, but consideration should be given to monitoring digoxin effects (e.g. monitor for bradycardia) and take digoxin levels if necessary.\(^5\)

2. Martin DE, Tompson D, Boike SC, Tenero D, Ilson B, Citerone D, Jorkasky DK. Lack of effect in 13 healthy subjects the pharmacokinetics of a single 500-microgram oral or intravenous dose of digoxin were not affected by losartan 50 mg daily for a week.\(^4\)

Digitalis glycosides + Antacids

Although some studies suggest that antacids can reduce the bioavailability of digoxin and digitoxin, there is other evidence suggesting that no clinically relevant interactions occur.

Clinical evidence

(a) Digoxin

\(\text{I. Evidence of an interaction. A study in 10 healthy subjects given digoxin 750 micrograms with 60 mL of either 4% aluminium hydroxide gel, 8% magnesium hydroxide gel or magnesium trisilicate found that the cumulative 6-day urinary excretion, expressed as a percentage of the original dose, was 40% for control; 31% for aluminium hydroxide; 27% for magnesium hydroxide; and 29% for magnesium trisilicate.}^{1}\)

Other studies describe reductions in digoxin absorption of 11% with aluminium hydroxide, 15% with bismuth carbonate and light magnesium carbonate, and 99.5% with magnesium trisilicate.\(^2\)

When digoxin was given with 30 mL of an aluminium/magnesium hydroxide antacid and mexiletine, the digoxin AUC was approximately halved. As ‘mexiletine’, (p.931) does not appear to interact with digoxin the interaction was attributed to the antacid.\(^3\)

\(\text{2. Evidence of no interaction. A study in 4 patients chronically treated with digoxin 250 to 500 micrograms daily, found that the concurrent use of either 10 mL of aluminium hydroxide mixture BP or magnesium trisilicate mixture BP, three times daily, did not reduce the bioavailability of the digoxin and none of the patients showed any reduction in the control of their symptoms.}^{4}\)

Other bioavailability studies have not found a significant interaction between digoxin capsules and aluminium/magnesium hydroxide.\(^5\)

(b) Other cardiac glycosides

\(\text{In vitro studies with digitoxin suggest that it might possibly interact like digoxin, and be absorbed by various antacids,}^{6}\) but lanatoside C probably does not interact.\(^7\)

Bioavailability studies have not found a significant interaction between beta-acetyldigoxin and aluminium/magnesium hydroxide.\(^8\)

A study in 10 patients with heart failure showed that their steady-state serum digitoxin levels were slightly, but not significantly raised (from 13.6 to 15.1 nanograms/mL) while taking 20 mL of aluminium/magnesium hydroxide gel three or four times daily, separated from the digitoxin dosage by at least 1 to 2 hours.\(^9\)

Mechanism

Not established. One suggestion is that the digoxin can become adsorbed onto the antacids and therefore unavailable for absorption.\(^1\) This is probably also true for digitoxin. However, some results are not consistent with this idea.

Importance and management

The interactions between digoxin or digitoxin and antacids are only moderately well documented, and the evidence is inconsistent. No clearly clinically relevant interactions have been reported. Separating the dosages by 1 to 2 hours to minimise admixture is effective with many other drugs that interact in the gut, and seems to work with digitoxin. However, unless further information becomes available it seems unlikely that separating administration is necessary, although it may be worth bearing in mind if, on rare occasions, a patient experiences an interaction.

Digitalis glycosides + Anticholinesterases; Centrally acting

There is no pharmacokinetic interaction between digoxin and ta-
crine or donepezil. The bradycardic effects of anticholinesterases
digoxin may possibly be additive.

Clinical evidence, mechanism, importance and management

A single-dose study in 12 healthy subjects found that the pharmacokinetics
of donepezil 5 mg and digoxin 250 micrograms were not affected by concurrent use and no clinically relevant changes in cardiac conduction parameters occurred.1

In one study in healthy subjects given a single 500-microgram dose of
digoxin, the pharmacokinetics of the digoxin were unchanged by tacrine
20 mg every 6 hours.2 Although no special precautions would seem necess-
ary on a pharmacokinetic basis, check to see that the combined bradyc-
ardic effects of digoxin and tacrine do not become excessive.

Similarly, the manufacturers of galantamine3 say that no pharmacoki-
netic interactions have been seen with digoxin, but caution about the pos-
sibility of a pharmacodynamic interaction that may result in bradycardia.

The manufacturers of rivastigmine4 say that the combination has no phar-
cmacokinetic interaction, nor does it interfere with cardiac conduction. It
would however seem prudent to monitor heart rate if any of these combi-
nations are used.

Digitalis glycosides + Antiepileptics; Miscellaneous

There is little evidence to suggest that carbamazepine interacts
digoxin, and topiramate causes only a small reduction in digo-
serum levels. Levetiracetam and tiagabine do not appear to interact with digoxin.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

In an early clinical study, bradycardia seen in 3 patients taking digal-
and carbamazepine was tentatively attributed to their concurrent
use.1 There appear to be no other reports to confirm or refute this.

(b) Levetiracetam

In a placebo-controlled study, 11 healthy subjects were given an initial
loading dose of digoxin 500 micrograms followed by 250 micrograms
daily with levetiracetam 1 g twice daily for one week. Levetiracetam did
not significantly affect the pharmacokinetics or pharmacodynamics of
digoxin, and the pharmacokinetics of levetiracetam were not significantly
altered by digoxin.2 No additional precautions seem necessary on concur-
rent use.

(c) Tiagabine

In a crossover study, 13 healthy subjects were given a loading dose of
digoxin 500 micrograms twice daily for one day then 250 micrograms
daily for 8 days, either alone or with tiagabine 4 mg three times daily for 9 days. It was found that the pharmacokinetics of digoxin were not significantly
altered by tiagabine.3

(d) Topiramate

Topiramate 100 mg twice daily for 9 days caused a small reduction in the serum
digoxin levels of 12 healthy subjects. The maximum serum levels
and the AUC were reduced by 15.8% and 12%, respectively, and the oral
digoxin clearance was increased by 13%.4,5 The manufacturers suggest
that monitoring of digoxin if topiramate is added or withdrawn,6 but changes in the pharmacokinetics of digoxin of this magnitude seem unlikely to be clinically relevant in most patients.

Digitalis glycosides + Antiepileptics; Phenytoin

Phenytoin reduces the serum levels of digoxin and digitoxin. Cases
of bradycardia have been seen in digitalised patients given phenytoin.
Phenytoin was formerly used for the treatment of digitalis-induced
cardiac arrhythmias, but sudden cardiac arrest has
been reported.

Clinical evidence

(a) Bradycardia and cardiac arrest

A patient with suspected digitalis-induced cardiac arrhythmias developed
bradycardia, then became asystolic and died, following an intravenous in-
jection of phenytoin.1 The discussion of this case briefly mentions a fur-
ther 6 fatalities in patients similarly treated.2 A patient with Down’s
syndrome and mitral valve insufficiency taking digoxin 250 micrograms
daily developed bradycardia of 34 bpm and complete heart block when his
phenytoin dose was increased from 200 to 300 mg daily.2

(b) Reduced digoxin levels

A study in 6 healthy subjects given beta-acetyldigoxin 400 micrograms
daily found that the half-life of digoxin was reduced by 30% (from 33.9 to
23.7 hours) and the AUC was reduced by 23% after they took phenytoin
200 mg twice daily for a week. Total digoxin clearance increased by 27%
(from 258.6 to 328.3 mL/minute).3

(c) Reduced digitoxin levels

The plasma digitoxin levels of a man were reduced on three occasions
when he was given phenytoin. On the third occasion, while taking digitox-
in 200 micrograms daily, the addition of phenytoin 900 mg daily caused a
60% fall in digitoxin levels (from 25 to 10 nanograms/mL) over a 7 to
10 day period.4

Mechanism

Phenytoin has a stabilising effect on the myocardial cells so that the toxic
threshold of digoxin at which arrhythmias occur is raised. However, the
bradycardic effects of the digitalis glycoside are not opposed and the lethal
dose is unaltered, so that the cardiac arrest reported would appear to be the
result of excessive bradycardia. It seems possible that the fall in plasma
digoxin levels may be due to a phenytoin-induced increase in the metab-
olism of the digoxin by the liver.5

Importance and management

Phenytoin was formerly used for treating digitalis-induced arrhythmias,
but this use now appears to be obsolete. Intravenous phenytoin should not
be used in patients with a high degree of heart block or marked bradycar-
dia because of the risk that cardiac arrest may occur. Information about the
effects of phenytoin on digitalis glycoside levels seems to be confined to
these single reports, but it may be prudent to check that patients who are
taking digitoxin (and possibly digoxin), and are subsequently given
phenytoin, do not become under-digitalised.

29, 49–53.
Digitalis glycosides + Antineoplastics

Treatment with radiation and/or antineoplastic cytotoxics can damage the lining of the intestine so that digoxin (given as tablets) is much less readily absorbed. This appears to be resolved by giving the digoxin in liquid or liquid-in-capsule form, or by substituting digitoxin.

Clinical evidence

A study in 13 patients with various forms of neoplastic disease showed that radiation therapy and/or various high-dose cytotoxic regimens (including carmustine, cyclophosphamide, melphalan, cytarabine and methotrexate) reduced the absorption of digoxin (from tablets (Lanoxin)) by almost 46%, but the reduction was not significant (15%) when the digoxin was given as capsules (Lanoxicaps).1

Other studies confirm that a 50% reduction in serum digoxin levels (using beta-acetyldigoxin) occurred in patients given cyclophosphamide, vincristine, procarbazine and prednisone (COPP); cyclophosphamide, vincristine and prednisone (COP); cyclophosphamide, vincristine, cytarabine and prednisone (COAP); and doxorubicin, bleomycin and prednisone (ABP). These effects disappeared about a week after a cytotoxic therapy finished.2 Radiation has a smaller effect.3 Digitoxin absorption does not seem to be affected by antineoplastics.4

Mechanism

The reduced absorption is thought to result from damage to the intestinal epithelium caused by the antineoplastic cytotoxics.5

Importance and management

The interaction appears to be established. Patients taking digoxin and receiving treatment with antineoplastic cytotoxics should be monitored for signs of under-digitalisation. The problem can be overcome by replacing digoxin tablets with digoxin in liquid form or in solution inside a capsule. The effects of the interaction are short-lived so that a downward readjustment may be necessary about a week after treatment is withdrawn. An alternative is to use digitoxin, which does not appear to be affected.6

Digitalis glycosides + Aprepitant

Aprepitant does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A placebo-controlled, randomised, study in 11 healthy subjects found that the pharmacokinetics of digoxin 250 micrograms daily were not affected by aprepitant (125 mg given on day 7 and 80 mg given daily on days 8 to 11). In vitro evidence indicates that aprepatin is a substrate and weak inhibitor of P-glycoprotein. However, at the doses used for the prevention of chemotherapy-induced nausea and vomiting, it appears unlikely to interact with P-glycoprotein substrates such as digoxin.1

Digitalis glycosides + Argatroban

No significant pharmacokinetic interaction occurs between digoxin and argatroban.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 12 healthy subjects found that the pharmacokinetics of steady-state digoxin 375 micrograms daily were not affected by an infusion of argatroban 2 micrograms/kg per minute for 120 hours. Steady-state argatroban levels were obtained within 3 hours and maintained throughout the infusion. Dosage adjustments should not be necessary during concurrent use.1

Digitalis glycosides + Azoles; Itraconazole

Itraconazole causes a marked increase in serum digoxin levels. Toxicity may occur unless the digoxin dosage is suitably reduced. Theoretically, itraconazole might also oppose the positive inotropic effects of digoxin.

Clinical evidence

In a placebo-controlled, crossover study, 10 healthy subjects taking digoxin 250 micrograms daily were given itraconazole 200 mg daily for 10 days. The serum digoxin levels increased by about 80% (from 1 to 1.8 nanograms/mL). New steady-state levels were increased by about 80% (from 1 to 1.8 nanograms/mL). He was later satisfactorily restabilised on the digoxin dosage while taking the same dose of itraconazole pulse therapy.1 Two cases of toxicity occurred during concurrent use of digoxin and ibuprofen.2

have been reported when itraconazole was given to renal transplant patients, but other factors may have contributed to the high levels of digoxin in these 2 patients.\(^1\)

**Mechanism**

Itraconazole inhibits P-glycoprotein, which transports digoxin out of kidney tubule cells into the urine, and therefore digoxin urinary clearance is reduced and serum levels are increased.5,10

**Importance and management**

An established and clinically important pharmacokinetic interaction. Monitor the effects of digoxin (e.g. bradycardia, nausea, vomiting) if itraconazole is started, anticipating the need to reduce the digoxin dosage. Halving the dose was suggested in one study.2 Two of the patients cited above were restabilised with a quarter of the digoxin dosage13 and another with about one-third of the original digoxin dose\(^2\) while taking itraconazole. More recent findings suggest that itraconazole may possess significant negative inotropic properties, and the CSM in the UK suggest that it should be used with caution in patients at risk of heart failure. 13 This suggests that itraconazole might oppose the pharmacological effects of digoxin.

### Digitalis glycosides + Barbiturates

**Clinical evidence**

Phenobarbital 60 mg three times daily for 12 days, halved the steady-state plasma levels of digoxin 100 micrograms daily.1 In associated studies the half-life of digoxin decreased from 7.8 to 4.5 days during phenoobarbital treatment.1 In another study2 the rate of conversion of digoxin to digoxin increased from 4% to 27% in one patient who took phenobarbital 96 mg daily for 13 days.

In contrast, a study in groups of 10 healthy subjects given either digoxin 400 micrograms, digoxin 1 mg or acetyldigoxin 800 micrograms daily did not find any changes in the serum concentrations of any of these digitalis glycosides when phenobarbitol 100 mg was given for three times daily for 7 to 9 days.2

**Mechanism**

Phenobarbital and other barbiturates are well-known potent liver enzyme inducers which, it would seem, can increase the metabolism and conversion of digoxin to digoxin.1,3 The lack of interaction in one study may possibly have been because the barbiturate was taken for a relatively short time.2

### Digitalis glycosides + Benzodiazepines and related drugs

Digoxin toxicity occurred in two elderly patients and rises in serum digoxin levels have been seen in others when they were given alprazolam. A reduction in the urinary clearance of digoxin has been described during the use of diazepam. No pharmacokinetic interaction seems to occur with digoxin and eszopiclone, zaleplon, or zolpidem.

---

Clinical evidence

(a) Benzodiazepines

1. Alprazolam. An elderly woman taking digoxin, maprotiline, isosorbide dinitrate, furosemide and potassium chloride showed signs of digoxin toxicity during the second week of taking alprazolam 1 mg daily. Her serum digoxin levels were later found to have risen almost 300%, from 1.6 to 4.3 nanograms/mL, and her apparent digoxin clearance had fallen from 126.3 to 49.8 L/day.1 A later study in 12 patients confirmed that digoxin levels can be significantly raised by alprazolam, particularly in those over 65 years old. One elderly man developed clinical digoxin toxicity.2 In contrast, a study in 8 healthy subjects found no changes in the clearance of digoxin after they took alprazolam 1.5 mg daily.3

2. Diazepam. The observation that 3 patients developed raised digoxin levels while also taking diazepam prompted a further study in 7 healthy subjects.4 After taking diazepam 5 mg with a single 500-microgram dose of digoxin, and diazepam 5 mg every 12 hours thereafter, all of them had a substantial reduction in the urinary excretion of digoxin and 5 of them had a moderate increase in the digoxin half-life. No further details were given.4

3. Metaclazepam. No statistically significant interaction was seen in 9 patients taking beta-acetyldigoxin when they were given metaclazepam.5

(b) Non-benzodiazepine hypnotics

1. Eszopiclone. In a study in 12 healthy subjects, a 3-mg single dose of eszopiclone did not alter the pharmacokinetics of digoxin, given for 7 days.6

2. Zaleplon. Zaleplon 10 mg daily given to 20 healthy subjects for 5 days had no significant effects on the steady-state pharmacokinetics of digoxin 375 micrograms daily. There were no significant differences in QTc or PR intervals.7

3. Zolpidem. No significant pharmacokinetic interaction occurs between zolpidem and digoxin.8

Mechanism

Uncertain. The suggestion is that diazepam may possibly alter the extent of the protein binding of digoxin within the plasma, which may have some influence on the renal tubular excretion, but see comments on protein binding interactions in ‘Drug distribution interactions’, (p.3). The reason for the interaction between digoxin and alprazolam is not understood.

Importance and management

The interaction between digoxin and alprazolam is established and clinically important. Monitor the effects of digoxin (e.g. bradycardia) in any patient if alprazolam is added, and reduce the digoxin dosage as necessary. What is known suggests that toxicity is more likely in the elderly. Other benzodiazepine hypnotics, eszopiclone, zaleplon and zolpidem do not appear to affect the pharmacokinetics of digoxin.

Digitalis glycosides + Beta-agonist bronchodilators

Oral salbutamol (albuterol) causes a small reduction in serum digoxin levels. Beta agonists can cause hypokalaemia, which could lead to the development of digitalis toxicity.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects who had taken digoxin 500 micrograms daily for 10 days1 found that, 3 hours after taking oral salbutamol (albuterol) 3 to 4 mg, their serum digoxin levels had fallen by 0.23 nanograms/mL, and their serum potassium levels had fallen by 0.58 mmol/L. A follow-up study suggested that the digoxin distribution to skeletal muscle may have been increased.2

Note that all beta, agonists can cause a fall in serum potassium, which could possibly affect the response of patients to digoxin. The clinical importance of these changes is uncertain but concurrent use should be monitored. Consider monitoring potassium levels if the effects of digoxin seem excessive.

Digitalis glycosides + Beta blockers

In general there appears to be no pharmacokinetic interaction between digoxin and beta blockers, although talinolol and carvedilol appear to increase the bioavailability of digoxin. Pharmacodynamic interactions, resulting in additive bradycardia, are possible. A few cases of excessive bradycardia have been reported when propranolol was used to control digitalis-induced arrhythmias.

Clinical evidence

(a) Pharmacokinetic interactions

1. Carvedilol. A 12-year-old boy with dilated cardiomyopathy taking digoxin 250 micrograms in the morning and 125 micrograms in the evening was subsequently given carvedilol 70 micrograms/kg twice daily. Several days later he became anorexic and started vomiting and his digoxin serum level was found to have increased from 1.6 to 2.3 nanograms/mL up to 4.2 nanograms/mL. Digoxin was stopped and subsequently restarted at half the original dose.6 In one study, 8 children aged 2 weeks to 8 years were given digoxin for ventricular failure secondary to congenital heart disease. When they were also given carvedilol 0.06 to 1.06 mg/kg daily the clearance of digoxin was approximately halved and 2 children experienced digoxin toxicity.1 A single-dose study in healthy adults given carvedilol 25 mg found that maximum plasma levels of a 500-microgram dose of digoxin were increased by 0.97 nanograms/mL (60%) and the AUC was increased by about 20%, but the clinical effects of these changes were considered likely to be small.2 No significant pharmacokinetic interaction was found in other single-dose studies in adults given carvedilol and digitoxin,3 or carvedilol and intravenous digoxin.2

In a multiple-dose study in adult patients with hypertension, carvedilol raised the maximum serum levels and AUC of digoxin 250 micrograms daily by 32% and 45%, respectively, after 2 weeks of treatment. Again, these changes were considered unlikely to be clinically significant.4 In another study in 12 male and 12 female patients taking digoxin 62.5 to 250 micrograms daily for heart failure, the addition of carvedilol 6.25 mg twice daily for 7 days increased the maximum concentration and the AUC0-24 of digoxin by 37% and 56%, respectively, in the men, but no significant changes to the pharmacokinetics of digoxin were noted in the women.5

2. Talinolol. In healthy subjects talinolol 100 mg orally substantially increased the bioavailability of a single 500-microgram dose of digoxin. The AUC0-72 and the maximum serum levels of digoxin were increased by 23% and 45%, respectively.6 Conversely, intravenous talinolol 30 mg had no effect on digoxin pharmacokinetics.6

3. Miscellaneous. A single dose of intravenous esmolol did not affect the pharmacokinetics of multiple-dose digoxin, except that a small increase was seen in the AUC0-6 of digoxin.7 The pharmacokinetics of multiple-dose digoxin have been shown to be unaffected by acebutolol,8 bevantolol 200 mg daily,9 bisoprolol 10 mg daily,10 nebivolol 10 mg daily,11 or sotalol 80 to 320 mg daily.12
Increased bradycardia is expected to occur with combinations of digoxin and beta blockers, but reports of this becoming a problem seem rare. One report notes marked bradycardia of 35 to 50 bpm in a 91-year-old patient taking digoxin and using timolol. 13 Bradycardia persisted on withdrawal of digoxin, and improved only after discontinuation of the timolol as well. Two cases, where propranolol 10 mg orally was used to treat arrhythmias associated with digoxin toxicity, are reported. 14 The first patient (who had heart failure) became bradycardic, asystolic and then died, while the second patient became bradycardic (30 bpm) but recovered after being given atropine. A further fatality was reported when intravenous propranolol was used. 15 In a placebo-controlled study of the use of sotalol in digitalised patients with chronic atrial fibrillation, 2 of 24 sotalol recipients were withdrawn due to bradycardia compared with none of 10 given placebo. However, the combination was still considered valuable. 12 In a prospective analysis of adverse drug reactions leading to hospital admission over a 4-year period, 83 patients were identified who had been admitted with bradycardia. Of these, 62 were taking digitalis glycosides, and 14 were also taking a beta blocker. 16

In healthy subjects, the pharmacodynamics of digoxin were unaffected by bevantolol, 17 and esmolol, 18 with no significant changes in heart rate or blood pressure occurring.

Mechanism

In most cases where the situation has had an adverse outcome the interaction seems to be due to the additive effects on the slowing of the heart. It has been suggested that the pharmacokinetic interaction with talinolol is due to competition with digoxin for intestinal P-glycoprotein, although this needs confirmation. 1 It would seem possible that this mechanism also accounts for the interaction between digoxin and carvedilol, and an in vitro study found that carvedilol (but not atenolol or metoprolol) inhibits P-glycoprotein-mediated transcellular transport of digoxin, 19 which may mean renal tubular secretion of digoxin is inhibited. It is conceivable that P-glycoprotein inhibition by carvedilol enhances the intestinal absorption of digoxin and also decreases its renal excretion. This may explain why the interaction is possibly more significant in children, as they have a higher renal clearance rate of digoxin than adults. 1 Women have lower P-glycoprotein activity in the gut than men, which may account for the gender differences seen with the interaction of carvedilol and digoxin. 4

It has also been suggested that the interaction between digoxin and talinolol may be dosage form dependent. More study is needed.

Importance and management

Concurrent use appears, on the whole, beneficial, but reports of this becoming a problem seem rare. One study found that carvedilol (but not atenolol or metoprolol) inhibits P-glycoprotein, although this needs confirmation. 6 It would seem possible that this mechanism also accounts for the interaction between digoxin and carvedilol, and an in vitro study found that carvedilol (but not atenolol or metoprolol) inhibits P-glycoprotein-mediated transcellular transport of digoxin, 19 which may mean renal tubular secretion of digoxin is inhibited. It is conceivable that P-glycoprotein inhibition by carvedilol enhances the intestinal absorption of digoxin and also decreases its renal excretion. This may explain why the interaction is possibly more significant in children, as they have a higher renal clearance rate of digoxin than adults. 1 Women have lower P-glycoprotein activity in the gut than men, which may account for the gender differences seen with the interaction of carvedilol and digoxin. 4

In healthy subjects, the pharmacodynamics of digoxin were unaffected by bevantolol, 17 and esmolol, 18 with no significant changes in heart rate or blood pressure occurring.

Mechanism

In most cases where the situation has had an adverse outcome the interaction seems to be due to the additive effects on the slowing of the heart. It has been suggested that the pharmacokinetic interaction with talinolol is due to competition with digoxin for intestinal P-glycoprotein, although this needs confirmation. 1 It would seem possible that this mechanism also accounts for the interaction between digoxin and carvedilol, and an in vitro study found that carvedilol (but not atenolol or metoprolol) inhibits P-glycoprotein-mediated transcellular transport of digoxin, 19 which may mean renal tubular secretion of digoxin is inhibited. It is conceivable that P-glycoprotein inhibition by carvedilol enhances the intestinal absorption of digoxin and also decreases its renal excretion. This may explain why the interaction is possibly more significant in children, as they have a higher renal clearance rate of digoxin than adults. 1 Women have lower P-glycoprotein activity in the gut than men, which may account for the gender differences seen with the interaction of carvedilol and digoxin. 4

It has also been suggested that the interaction between digoxin and talinolol may be dosage form dependent. More study is needed.

Importance and management

Concurrent use appears, on the whole, beneficial, but the potential for additive bradycardia should be born in mind. Use of beta blockers in cases of increased bradycardia should be borne in mind. Use of beta blockers in cases of increased bradycardia should be borne in mind. Use of beta blockers in cases of increased bradycardia should be borne in mind. Use of beta blockers in cases of increased bradycardia should be borne in mind. Use of beta blockers in cases of increased bradycardia should be borne in mind.

No interaction normally occurs between digoxin and amoxicillin, cefazolin, cefuroxime, flucloxacillin, phenoxymethylpenicillin or ticarcillin/clavulanic acid. No pharmacokinetic interaction occurs between ampicillin and digitoxin. In contrast, one early study found that cefadine increased serum levels of digoxin.

Clinical evidence

Ampicillin 500 mg four times daily for 5 days had no significant effect on the pharmacokinetics of a single 1-mg dose of digoxin in healthy subjects. 1 No significant changes in digoxin serum concentrations were found in 16 elderly patients given amoxicillin (2 patients also took erythromycin and one flucloxacillin), and 2 patients who took flucloxacillin and phenoxymethylpenicillin. However, a few patients complained of some ‘toxic’ symptoms (nausea, vomiting, anorexia, headache, fatigue, blurred vision, confusion), which the authors of the report attributed to the underlying illness or the antibacterials rather than to an interaction. 2 There was no significant change in digoxin pharmacokinetics in 15 patients given ticarcillin/clavulanic acid 1 g/200 mg intramuscularly every 12 hours for one week. 3 There was no reduction in the excretion of digoxin metabolites from the gut (see Mechanism) in 3 patients taking cefazolin, and a reduction occurred in only 1 of 10 patients taking penicillins (ampicillin 6, oxacillin 3, penicillin 1). 4

A case-control study using data from healthcare databases in Ontario from 1994 to 2000 identified 1051 patients who had been admitted to hospital with digoxin toxicity. Of these, 5 patients (0.5%) had been exposed to cefuroxime in the preceding 3 weeks when compared with 0.3% of controls, suggesting that digoxin toxicity was not significantly related to cefuroxime exposure. 5

In an early study, cefadine prolonged the half-life of digoxin and increased serum levels from 1.8 to 2.6 nanograms/mL. This effect was considered to occur as a result of reduced renal clearance. 6

Mechanism

Up to 10% of patients receiving oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be due to gut flora, 7 in particular Escherichia coli, which is anaerobic and Gram positive. It was suggested that inhibition of digoxin metabolism by gut flora was responsible for any interaction, but doubt has been thrown on this theory, see Mechanism in ‘Digitalis glycosides + Macrolides’, (p.929).
Digitalis glycosides + Bosentan

Bosentan does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In 18 healthy subjects bosentan 500 mg twice daily for a week did not significantly affect the steady-state peak or trough levels of digoxin 375 micrograms daily. There was a small reduction of about 12% in the AUC of digoxin, although this was not considered to be clinically relevant. There were no changes in ECG recordings and vital signs.\(^1\)

The results suggest that bosentan does not interact with digoxin, and that concurrent use need not be avoided. However, the authors note that further studies over the longer term, and in patients with renal impairment may be necessary to confirm this.

Digitalis glycosides + Calcium-channel blockers

Concurrent use can be valuable. Felodipine, gallopamil, lacidipine, nicardipine and nilsodipine cause small but normally clinically unimportant increases in digoxin levels, while amiodipine, isradipine and nimodipine appear not to interact. The situation with nitrendipine is uncertain but it possibly causes only a small rise in digoxin levels.

Clinical evidence

(a) Amlodipine

Amlodipine 5 mg daily had no significant effect on the serum levels or renal clearance of digoxin 375 micrograms daily given to 21 healthy subjects.\(^1\)

(b) Bepridil

In 12 healthy subjects bepridil 300 mg daily for a week raised the serum levels of digoxin 375 micrograms daily by 34% (from 0.93 to 1.25 nanograms/mL).\(^2\) Five of them had mild to moderate headache, nausea and dizziness for 1 to 3 days shortly after concurrent use was started. The bradycardic effects of the two drugs were found to be additive, while the negative inotropic effects of the bepridil and the positive inotropism of the increased serum digoxin levels were almost balanced.\(^2\)

In another study in 23 subjects given digoxin 250 micrograms and bepridil 300 mg daily for 14 days, peak plasma digoxin levels rose by 48% (from 1.49 to 2.2 nanograms/mL) and the AUC rose by 21%.\(^3\)

(c) Felodipine

Felodipine 10 mg twice daily for 8 weeks raised the serum digoxin levels in 11 patients by 15%, which was not clinically significant.\(^4\) In another study, 14 patients were given felodipine 10 mg daily for a week. Plain tablets raised the steady-state digoxin serum levels by 11%, but extended-release tablets had no significant effect.\(^5\) A third study found that, when taking felodipine, peak plasma digoxin levels were transiently raised by about 40% one hour after intake, but that digoxin AUCs were not significantly increased.\(^6\)

(d) Gallopamil

Gallopamil 50 mg three times daily for 2 weeks raised the serum levels of digoxin 375 micrograms daily by 16% (from 0.58 to 0.67 nanograms/mL) in 12 healthy subjects.\(^7\)

(e) Isradipine

Isradipine (given as 2.5 mg every 12 hours for 2 days, 5 mg every 12 hours for 2 days and then 5 mg three times daily for 10 days) did not interact significantly with a single 1-mg intravenous dose of digoxin given to 24 healthy subjects.\(^8\) A similar study by the same group found that the same dosage regimen of isradipine given with oral digoxin 250 micrograms twice daily caused a small increase in peak serum digoxin levels but no changes in its steady-state levels or AUC.\(^9\)

(f) Lacidipine

In 12 healthy subjects, a single 4-mg oral dose of lacidipine did not affect the AUC or minimum serum levels of digoxin 250 micrograms daily for 7 days, but the maximum serum levels of digoxin were increased by 34%. These changes were not considered to be clinically significant.\(^10\)

(g) Lercanidipine

The maximum serum levels of digoxin rose by 33% in healthy subjects also given lercanidipine. However, there was no evidence of a pharmacokinetic interaction in patients given metildigoxin with lercanidipine.\(^11\)

(h) Nicardipine

In 10 patients given nicardipine 20 mg three times daily for 14 days the plasma levels of digoxin 130 to 250 micrograms daily were increased by 15%, but this was not statistically significant.\(^12\) Another 20 patients with congestive heart failure also had no significant changes in steady-state serum digoxin levels while taking nicardipine 30 mg three times daily for 5 days.\(^13\) Yet another study in 9 patients confirmed the absence of an interaction.\(^14\)

(i) Nimodipine

Nimodipine 30 mg twice daily caused no change in the pharmacokinetics or haemodynamic effects of beta-acetyldigoxin in 12 healthy subjects.\(^15\)

(j) Nisoldipine

In 10 patients with heart failure nisoldipine 20 mg daily increased the plasma trough digoxin levels by about 15%.\(^16,17\) Nisoldipine 10 mg twice daily caused no changes in the pharmacokinetics or haemodynamic effects of digoxin in 8 healthy subjects.\(^15\)

(k) Nitrendipine

A study in 8 healthy subjects who had been taking digoxin 250 micrograms twice daily for 2 weeks, showed that nitrendipine 10 mg daily caused a slight but insignificant rise in plasma digoxin levels. Nitrendipine 20 mg daily increased the AUC of digoxin by 15%, its maximum plasma levels rose from 1.34 to 2.1 nanograms/mL, and its clearance fell by 13%. One subject dropped out of the study because of dizziness, nausea and vomiting, palpitations, insomnia and nervousness.\(^18,19\)

Another study found that plasma digoxin levels were approximately doubled when nitrendipine was given,\(^20\) but other studies in healthy subjects and patients found that nitrendipine 20 mg twice daily caused no changes in the pharmacokinetics or haemodynamic effects of digoxin.\(^13,21\) or beta-acetyldigoxin.\(^22\)

Mechanism

Where an interaction occurs it is probably due to changes in the renal excretion of the digoxin. An in vitro study found that several calcium-channel blockers including bepridil, nicardipine, and to a lesser extent nisoldipine (as well as barnidipine, benidipine, efonidipine, manidipine, nilvadipine, and verapamil) inhibited P-glycoprotein-mediated transcellular transport of digoxin. This suggests that any interaction may occur, at least in part, by affecting digoxin renal tubular excretion. Nitrendipine (and also diltiazem and nifedipine) only weakly inhibited the transcellular transport of digoxin.\(^23\)

Importance and management

The extent of the information varies from drug to drug, but the concurrent use of digoxin and calcium-channel blockers can be therapeutically valuable. Monitor the effects of digoxin (e.g. bradycardia) in patients given digoxin and bepridil or lercanidipine, and consider measuring levels if the effects of digoxin seem excessive. Reduce the digoxin dosage as necessary. The other calcium-channel blockers listed here either cause only minimal increases in digoxin levels, which are unlikely to be clinically important in most patients, or do not interact at all. The situation with nitrendipine needs clarification. For the interactions of digoxin with other calcium-channel blockers see ‘diltiazem’, (p.915), ‘nifedipine’, (p.915), and ‘verapamil’.\(^21,22\)

Serum digoxin levels are reported to be unchanged by diltiazem in a number of studies but others describe increases ranging from 20 to 85%. Serum digoxin levels have also been reported to rise in some patients, but only by about 20%. There is a risk of additive bradycardia when cardiac glycosides are given with diltiazem.

Clinical evidence

(a) Digoxin

Five out of 10 patients taking digoxin had a 6 to 31% (mean 21%) rise in plasma digoxin levels while taking diltiazem 180 mg daily for 4 to 6 weeks.1

(b) Diltiazem

1. Evidence of no interaction. Diltiazem 30 or 60 mg four times daily had no significant effect on the serum levels of digoxin 250 micrograms daily in 9 patients with cardiac diseases.2 Two similar studies on 12 patients3 and 8 healthy subjects,4 taking digoxin with diltiazem 120 to 360 mg daily confirmed the absence of an interaction. Two further studies in healthy subjects,5,6 found that diltiazem 120 mg daily did not affect the pharmacokinetics of a single 1-mg intravenous dose of digoxin.

2. Evidence of an interaction. A study in 17 Japanese patients (some with rheumatic valvular disease) taking either digoxin or metildigoxin found that diltiazem 60 mg three times daily for 2 weeks increased their serum digoxin levels measured at 24 hours by 36% and 51%, respectively.7 Another study in 8 patients with chronic heart failure secondary to ischaemic disease, taking digoxin 250 micrograms daily, found that diltiazem 60 mg three times daily increased the digoxin AUC and mean steady-state serum levels by about 50%, its peak serum level by 37% and elimination half-life by 29%. Diltiazem had no significant effects on haemodynamic parameters.8

Other studies in Western patients9,10 and healthy subjects11-14 have shown rises of 20 to 85% in plasma digoxin levels during diltiazem use. In one case report a 143% increase was seen.15 The authors of two of these studies noted that the effect was highly individual with some subjects showing no increase and some a large increase.10,12 There is also a case report of raised serum digoxin levels and toxicity in a man taking digoxin when given diltiazem with or without nifedipine.16

Mechanism

Not understood. In those individuals showing a pharmacokinetic interaction, falls in total digoxin clearance of about 25% have been described.9,10,11,17,18 Although several calcium-channel blockers may inhibit the P-glycoprotein-mediated renal clearance of digoxin, the results of an in vitro study19 suggest that this may not occur with diltiazem.

A synergistic effect on heart rate and atioventricular conduction is also possible.

Importance and management

A thoroughly investigated and well documented pharmacokinetic interaction but there is no clear explanation for the inconsistent results. All patients taking digoxin given diltiazem should be well monitored for signs of over-digitalisation (e.g. bradycardia) with digoxin levels measured as necessary. Dosage reductions may be necessary. Those most at risk are patients with digoxin levels near the top end of the range. Similar precautions would be necessary with digoxin, although the documentation of this interaction is very limited and the expected rise in levels only small. The potential for additive bradycardia and heart block should be borne in mind when using diltiazem with any digitalis glycoside.

Digitalis glycosides + Calcium-channel blockers; Nifedipine

Serum digoxin levels are normally unchanged or increased only to a small extent by nifedipine. However, one unexplained and conflicting study indicated that a 45% rise could occur. Digoxin appears not to interact.
Clinical evidence

(a) Digitoxin
A study in 18 subjects showed that nifedipine 40 to 60 mg daily had no significant effect on their steady-state plasma digitoxin levels over a 6-week period. This study has also been published elsewhere.2

(b) Digoxin
1. Serum digoxin levels unchanged. Studies in 25 patients3-5 and 28 healthy subjects6-8 showed that serum digoxin levels were not significantly reduced by nifedipine 30 to 60 mg daily. Similarly no significant changes in the pharmacokinetics of a single intravenous dose of digoxin were found in the 9 patients by 15% (from 0.87 to 1.04 nanograms/mL).16 A 61% increase in serum digoxin levels was found in a study involving nifedipine in daily doses of 30 mg.13

Mechanism
Not understood. Changes and lack of changes in both the renal and non-renal excretion of digoxin have been reported. A retrospective analysis of pharmacokinetic data suggests that clearance of digoxin may be reduced by 10% in patients also taking nifedipine. Although several calcium-channel blockers may inhibit the P-glycoprotein mediated renal clearance of digoxin, the results of an in vitro study suggest that this may not occur with nifedipine.

Importance and management
The pharmacokinetic interaction of digoxin and nifedipine is well documented but the findings are inconsistent. The weight of evidence appears to be that serum digoxin levels are normally unchanged or only modestly increased by nifedipine. Concurrent use appears normally to be safe and effective.20 One report suggests that nifedipine has some attenuating effect on the digoxin-induced inotropism.21 Another points out that under some circumstances (renal impairment or pre-existing digoxin overdosage) some risk of an undesirable interaction still exists.13 If undesirable bradycardia occurs in a patient taking digoxin and nifedipine consider measuring digoxin levels, and adjust the dose accordingly. Nifedipine appears not to interact with digitoxin to a clinically significantly extent.

Digitalis glycosides + Calcium-channel blockers; Verapamil

Serum digoxin levels are increased by about 40% by verapamil 160 mg daily, and by about 70% by verapamil 240 mg daily. Digoxin toxicity may develop if the dosage is not reduced. Deaths have occurred. Verapamil causes a rise of about 35% in digoxin levels. There is a risk of additive bradycardia and conduction disturbances when cardiac glycosides are given with verapamil.

Clinical evidence

(a) Digoxin
Eight out of 10 patients had a mean 35% rise (range 14 to 97%) in plasma digoxin levels over a 4 to 6 week period while taking verapamil 240 mg daily, in three divided doses. In 2 patients (and 3 other healthy subjects given a single dose of digitoxin) the pharmacokinetics of digoxin were not affected by verapamil.1,2

(b) Digoxin
After 2 weeks of treatment with verapamil 240 mg daily, in three divided doses, the mean serum digoxin levels of 49 patients with chronic atrial fibrillation had risen by 72%. The rise was seen in most patients, and it occurred largely within the first 7 days. A rise of about 40% has been seen with verapamil 160 mg daily.3,4 Reports in a total of 21 healthy subjects,5,6 and 54 patients7,8 describe rises in serum digoxin levels of 22 to 147% when verapamil 240 to 360 mg daily was added to digoxin. Similar rises are reported elsewhere.3,10,12 A rise in digoxin levels of about 50% was seen in chronic haemodialysis patients given verapamil 120 to 240 mg daily.3,9 Nine healthy subjects had a 53% rise in their digoxin levels while taking verapamil 240 mg three times daily for two weeks.5 Toxicity,14 and a fatalit,15 occurred in patients whose digoxin levels became markedly increased by verapamil. Both astystole and sinus arrest have been described.16,17 A single-dose study indicated that cirrhosis magnifies the extent of this interaction.18

Mechanism
The rise in serum digoxin levels is due to reductions in renal and especially extra-renal (biliary) clearance; a diminution in the volume of distribution also takes place.4,9,10,13 It has been suggested that P-glycoprotein may be involved.18 An in vitro study found that verapamil can inhibit the P-glycoprotein-mediated transcellular transport of digoxin,20 which suggests that any interaction may occur, at least in part, by inhibiting the renal tubular excretion of digoxin. Impaired extra-renal excretion is suggested as the reason for the rise in serum digoxin levels.1

The increased plasma levels of digoxin caused by verapamil are reported to increase both inotropism22 and toxic effects.23 Verapamil may enhance the digoxin-induced elevation of intracellular sodium, which may increase the risk of arrhythmias.23,24 A synergistic effect on heart rate and atrioventricular conduction is also possible.

Importance and management
The pharmacokinetic interaction between digoxin and verapamil is well documented, well established and it occurs in most patients.10,25 Serum digoxin levels should be well monitored and downward dosage adjustments made to avoid digoxin toxicity (deaths have occurred15). An initial 33 to 50% dosage reduction has been recommended.26,27 The interaction develops within 2 to 7 days, approaching or reaching a maximum within 14 days or so.2,5 The magnitude of the rise in serum digoxin is dose-dependent28 with a significant increase if the verapamil dosage is increased from 160 to 240 mg daily,2 but with no further significant increase if the dose is raised any higher.29 The further rise with verapamil 160 mg daily is about 40%, and with 240 mg or more is about 60 to 80%,
The levels of digitoxin were found to be increased by over 70% in two elderly patients when they were given hydroxychloroquine. A similar increase has been seen with chloroquine in dogs.

**Clinical evidence, mechanism, importance and management**

(a) Bufalin (Chan Su, Kyushin, and Lu-Shen-Wan)

Bufalin, a cardiotonic substance of amphibian origin and Chinese medicines such as Chan Su, Lu-Shen-Wan and Kyushin that contain bufalin can interfere with some immunoassay methods of digitoxin and digoxin, particularly the fluorescence polarization immunoassay. The digitoxin-like immunoreactivity of Kyushin was found to be equivalent to varying amounts of digoxin because of differences in the cross-reactivity of the antibody used in different immunoassays. A chemiluminescent assay for digitoxin did not cross-react with bufalin.

Bufalin and an extract of Chan Su displaced digoxin from protein-binding sites in vitro. Whether this would result in elevated free digoxin levels and toxicity in vivo is not known. However, this is probably unlikely since in vivo the free drug would be available for metabolism.

Another possibility, given the similarities between bufalin and cardionic glycosides, is that toxicity could result from additive cardiac effects. Cases of cardiotoxicity following the ingestion of bufalin (or toads) alone have been reported. In one case, the symptoms seen were very similar to those of digoxin toxicity, with nausea, vomiting, blurred vision, mental confusion, cardiopulmonary arrest and severe bradyarrhythmia. Assay for digoxin was positive (2.1 nanograms/mL) when measured by the fluorescence energy transfer immunoassay. The patient had ingested a bowel of toad soup (Bufo melanosticus Schneider) shortly before his symptoms developed.

(b) Danshen

Danshen appears not to have been reported to affect serum digoxin levels, but it can falsify laboratory measurements. A study found that a fluorescent polarization immunoassay method (Abbott Laboratories) for digoxin gave falsely high readings in the presence of danzhen, whereas a micro-particle enzyme immunoassay (Abbott Laboratories) gave falsely low readings. These false readings could be eliminated by monitoring the free drug (i.e. unbound) digoxin concentrations or by choosing assay systems that are unaffected by the presence of danzhen (said to be the Roche and Beckman systems or an enzyme linked chemiluminescent immunosorbent digoxin assay by Bayer HealthCare).

(c) Kanzo (Liquorice)

An 84-year-old man taking digoxin 125 micrograms daily and furosemide complained of loss of appetite, fatigue and oedema of the lower extremities 5 days after starting to take a Chinese herbal laxative containing liquorice (kanzo) 400 mg and rhubarb (dado) 1.6 g three times daily. It was suggested that heart failure occurred because of digoxin toxicity induced by liquorice-associated electrolyte imbalance, which may also have been exacerbated by the age of the patient, the diuretic and his existing cardiovascular disease.

Digitalis glycosides + Chinese herbal medicines

Bufalin can interfere with the assay of cardiac glycosides. Danshen appears not to interact with digoxin, but it can falsify the results of serum immunoassay methods. Digoxin toxicity in an elderly man was attributed to the use of a herbal laxative containing kanzo (liquorice).

Clinical evidence, mechanism, importance and management

(a) Bufalin (Chan Su, Kyushin, and Lu-Shen-Wan)

Bufalin, a cardiotonic substance of amphibian origin and Chinese medicines such as Chan Su, Lu-Shen-Wan and Kyushin that contain bufalin can interfere with some immunoassay methods of digitoxin and digoxin, particularly the fluorescence polarization immunoassay. The digitoxin-like immunoreactivity of Kyushin was found to be equivalent to varying amounts of digoxin because of differences in the cross-reactivity of the antibody used in different immunoassays. A chemiluminescent assay for digitoxin did not cross-react with bufalin.

Bufalin and an extract of Chan Su displaced digoxin from protein-binding sites in vitro. Whether this would result in elevated free digoxin levels and toxicity in vivo is not known. However, this is probably unlikely since in vivo the free drug would be available for metabolism.

Another possibility, given the similarities between bufalin and cardionic glycosides, is that toxicity could result from additive cardiac effects. It was suggested that heart failure occurred because of digoxin toxicity induced by liquorice-associated electrolyte imbalance, which may also have been exacerbated by the age of the patient, the diuretic and his existing cardiovascular disease.
ty during concurrent use, and one of them claimed that the regularity of her heart rhythm had been improved. The reason for this apparent interaction is not understood and its general significance is uncertain.

No interaction between digoxin and chloroquine has been described clinically, but increases in peak serum digoxin levels of about 77% have been seen in dogs.

Digitalis glycosides + Cibenzoline (Cifenline)

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects taking digoxin 250 to 375 micrograms daily showed that cibenzoline 160 mg twice daily for 7 days had no effect on the pharmacokinetics of digoxin. An in vitro study found that cibenzoline only slightly inhibited the P-glycoprotein-mediated transcellular transport of digoxin and therefore inhibition of the renal tubular secretion of digoxin is unlikely.

Digitalis glycosides + Ciclosporin

Ciclosporin causes a marked rise in serum digoxin levels in some patients.

Clinical evidence

Digoxin toxicity developed in 4 patients when they were given ciclosporin before cardiac transplantation. In the two cases described in detail, ciclosporin 10 mg/kg daily was added to digoxin 375 micrograms daily. Fourfold rises in digoxin levels, from 1.2 to 4.5 nanograms/mL and from 2 to 8.3 nanograms/mL, were seen within 2 to 3 days. This was accompanied by rises in serum creatinine levels from 110 to 120 micromol/L and from 84 to 181 micromol/L respectively, which were considered insufficient to explain the rise in digoxin levels. As a consequence of these findings, the same authors conducted a study in 4 patients given ciclosporin and digoxin. Two patients developed acute renal failure. In the other 2 patients, the volume of distribution of digoxin was decreased by 69% and 72%, while the clearance was reduced by 47% and 58%. In a further 7 patients, digoxin pharmacokinetics were assessed before cardiac transplantation, then after transplantation during maintenance ciclosporin therapy. The total body clearance of digoxin remained unchanged, which appeared to be at odds with the earlier results. It was suggested that haemodynamic improvements brought about by successful cardiac transplantation may have counterbalanced any inhibitory effect ciclosporin had on renal clearance.

Mechanism

Ciclosporin appears not to interfere with the absorption of either digoxin or digitoxin if it is given at least 1.5 hours after the digitoxin.

Clinical evidence, mechanism, importance and management

A single-dose study in which 26 healthy subjects were given digoxin 250 micrograms with or without colesvelam 4.5 g, followed by a standard meal, found that colesvelam did not significantly affect the absorption of digoxin. Because the bile-acid binding resins ‘colesteryamine’, (p.919) and ‘colestitol’, (below) may interact with digoxin it was suggested that colesvelam could also interact, although this appears not to be the case.

Digitalis glycosides + Colesevelam

The absorption of a single dose of digoxin is not affected by colesvelam.

Clinical evidence, mechanism, importance and management

Four patients with digitoxin toxicity were given colesvelam 10 g at once and 5 g every 6 to 8 hours thereafter to reduce their digitoxin serum levels. The average digitoxin half-life fell to 2.75 days compared with an untreated control patient in whom the digitoxin half-life was 9.3 days. In another patient with digitoxin toxicity who was similarly treated, the digitoxin half-life was 16 hours compared with 1.8 to 2 days in two other control patients.

Mechanism

Colesvelam is an ion-exchange resin, which can bind to digitalis glycosides. In cases of toxicity colesvelam may possibly reduce serum digitalis levels because under these circumstances the excretion of digitalis in the bile increases and more becomes available for binding in the gut.

Importance and management

This interaction is not well established. Giving either digoxin or digitoxin 1.5 hours before colesvelam appears to avoid any possible interaction in the gut. It is usually recommended that other drugs are given 1 hour before or 4 hours after colesvelam.

Digitalis glycosides + Colestyramine

The levels of both digoxin and digitoxin can be reduced by colestyramine, but the clinical importance of this is uncertain. Minimise the possible effects of this interaction by separating administration.

Clinical evidence

(a) Digitalis glycoside levels reduced

A study in 12 healthy subjects given digoxin 750 micrograms showed that the cumulative 6-day recovery of digoxin from the urine was reduced by almost 20% (from 40.5 to 33.1%) when colestyramine 4 g was given.1 Two patients with congestive heart failure and toxic serum levels of digoxin of 3 and 4 nanograms/mL were given colestyramine 4 g every 4 hours for 4 doses. The levels of digoxin fell to therapeutic levels within 13 to 24 hours.2 Other reports describe a fall in serum digoxin levels during the concurrent use of colestyramine3-5 and an increase in the loss of digoxin and its metabolites in the faeces during long-term use.6 Another study showed that giving digoxin as a solution in a capsule reduced the effects of this interaction.5 Other studies have found that colestyramine reduces the half-life of digitoxin by 35 to 40%.7,8

(b) Digitalis glycoside levels unaffected

Ten patients receiving long-term treatment with either digoxin 125 to 250 micrograms daily or digitoxin 100 to 200 micrograms daily were given colestyramine 12 g daily or a placebo taken 1.5 hour after the digitalis. Their plasma digitalis levels were not significantly altered by the colestyramine over a 1-year period.9 The half-life of digitoxin is reported to have remained unchanged when colestyramine was given.10 One study suggested that metildigoxin may be minimally affected by colestyramine.11

Mechanism

Not totally understood. Colestyramine appears to bind with digitoxin in the gut, thereby reducing its bioavailability and interfering with enterohepatic recirculation so that its half-life is shortened. Digoxin may interact similarly.2

Importance and management

The overall picture is far from clear. Some interaction seems possible but the extent to which it impairs the treatment of patients receiving these glycosides is uncertain. Be alert for any evidence of under-digitalisation if digoxin or, more particularly, digitoxin is given with colestyramine. The studies suggest that colestyramine should not be given less than 1.5 to 2 hours after the digitalis to minimise the possibility of an interaction.9 Note that the standard recommendation is to give other drugs 1 hour before or 4 to 6 hours after colestyramine.

Digitalis glycosides + Darifenacin or Solifenacin

Darifenacin increased digoxin exposure by a modest 16%, which would usually not be clinically significant. Solifenacin did not alter the pharmacokinetics of digoxin.

Digitalis glycosides + Co-trimoxazole or Trimethoprim

Serum digoxin levels can be modestly increased by about 22% by trimethoprim, although some individuals may show a much greater rise.

Clinical evidence

(a) Elderly patients

After taking trimethoprim 200 mg twice daily for 14 days the mean serum digoxin levels in 9 elderly patients (aged 62 to 92) had risen by an average of 22%, from 0.9 to 1.2 nanograms/mL. One patient had a 75% rise. A 34% increase in mean serum creatinine was also seen. When the trimethoprim was withdrawn, the serum digoxin levels returned to their previous value.1,2

(b) Young healthy adult subjects

Trimethoprim 200 mg twice daily for 10 days did not affect the total body clearance of a single 1-mg intravenous dose of digoxin in 6 young healthy subjects (aged 24 to 31). Renal clearance was reduced, but this was compensated for by an increase in extra-renal clearance.2

Mechanism

It is suggested that trimethoprim reduces the renal excretion of digoxin.1,2 The paradoxical finding between the elderly patients and the young healthy subjects may be the age difference, probably as the elderly patients may not be able to accommodate an increase in extra-renal digoxin clearance.

Importance and management

Information seems to be limited to the information cited. Although the serum digoxin rise in the elderly was modest, it would seem prudent to monitor the effects because some individuals can apparently experience a marked rise. Reduce the digoxin dosage if necessary. Trimethoprim is contained in co-trimoxazole but it is not known whether prophylactic doses of co-trimoxazole (160 mg trimethoprim a day, from 960 mg co-trimoxazole) will interact to a clinically significant degree. An interaction would seem likely with high-dose co-trimoxazole regimens and care with any co-trimoxazole regimen is needed in the elderly.

Digitalis glycosides + Danaparoid

No clinically significant interaction appears to occur between digoxin and danaparoid.

Clinical evidence, mechanism, importance and management

In a study, 6 healthy subjects were given digoxin 250 micrograms daily for 8 days, with a single 3250 anti-Xa-unit-bolus dose of danaparoid during day 7. The AUC of digoxin was slightly decreased, although this did not appear to be clinically significant. Digoxin did not alter the effects of danaparoid on clotting tests (including aPTT).1

Digitalis glycosides + Darifenacin or Solifenacin
Clinical evidence, mechanism, importance and management

(a) Darifenacin

The manufacturer notes that the concurrent use of digoxin 250 micrograms and darifenacin 30 mg daily increased digoxin exposure at steady state by a modest 16%. This small increase would generally not be clinically relevant.1

(b) Solifenacin

In a crossover study in 24 healthy subjects, solifenacin 10 mg daily for 10 days had no effect on the pharmacokinetics of digoxin 125 micrograms daily.2 This study suggests that no pharmacokinetic interaction occurs, and that no digoxin dose adjustment would be expected to be needed on concurrent use.

Digitalis glycosides + Dexmedetomidine

An isolated report describes bradycardia when an infant receiving digoxin was given dexmedetomidine.

Clinical evidence, mechanism, importance and management

A 5-week-old infant with an atioventricular septal defect, taking digoxin 10 micrograms twice daily and furosemide for mild congestive heart failure, developed respiratory failure requiring intubation and mechanical ventilation. She was given dexmedetomidine for sedation and received a loading dose of 0.5 micrograms/kg over 15 minutes, followed by an infusion of 0.44 micrograms/kg per hour. During the loading dose period her heart rate decreased from 133 to 116 bpm. Throughout the next 13 hours the rate continued to decrease to about 90 bpm, with episodes of sinus bradycardia (heart rate around 50 bpm). Within 1 hour of discontinuing dexmedetomidine, the heart rate increased to its baseline value and no further episodes of bradycardia were observed. The reasons for the interaction are not known, but caution is advised if dexmedetomidine is used for sedation in patients receiving digoxin.1

Digitalis glycosides + Dietary fibre and Laxatives

Bisacodyl reduces serum digoxin levels to a small extent. Large amounts of dietary fibre, guar gum and bulk-forming laxatives containing ispaghula or psyllium appear to have no significant effect on the absorption of digoxin. Single-dose studies show that macrogol 4000, a laxative polymer, reduces the serum levels of digoxin.

Clinical evidence

(a) Bisacodyl

Bisacodyl reduced the mean serum digoxin levels of 11 healthy subjects by about 12%. When the bisacodyl was taken 2 hours before the digoxin, serum digoxin levels were slightly raised, but not to a statistically significant extent.1

(b) Fibre

The serum digoxin levels of 12 patients taking digoxin 125 to 250 micrograms daily 15 to 30 minutes before breakfast were unchanged over a 10-day period when they were given a diet supplemented each day with 22 g of dietary fibre. The fibre was given in this way to simulate the conditions that might be encountered clinically (for example to reduce the symptoms of diverticular disease).2

Weart grain 7.5 g twice daily caused a small 10% reduction in the plasma digoxin levels of 14 geriatric patients after 2 weeks, but there was no significant change after 4 weeks.3 Bran fibre 11 g caused a 6 to 7% reduction in the absorption and the steady-state serum levels of digoxin in 16 healthy subjects.4 The cumulative urinary recovery of a single oral dose of digoxin in healthy subjects was reduced almost 20% by 5 g of fibre, whereas 0.75 g of fibre had no effect.5

(c) Guar gum

In 10 healthy subjects Guareum (95% guar gum) 5 g reduced the peak serum levels of a single 500-microgram oral dose of digoxin by 21% and the AUC0-6 was reduced by 16%, but the amount excreted in the urine over 24 hours was only minimally reduced.6 Guar gum 18 g in a test meal did not affect steady-state plasma digoxin levels in 11 healthy subjects given digoxin 1 mg on day 1, then 750 micrograms on day 2, then 500 micrograms daily for 3 days.7

(d) Ispaghula or psyllium

An ispaghula preparation (Vi-Siblin S) was found to have no significant effect on serum digoxin levels of 16 geriatric patients.8 The same lack of effect was seen in another study in 15 patients given 3.6 g of a psyllium preparation (Metamucil) three times a day.9

(e) Macrogol 4000

A randomised, crossover study in 18 healthy subjects found that 20 g of macrogol 4000 daily over an 8-day period reduced the maximum serum levels of a single 500-microgram dose of digoxin by 40%, and reduced the AUC by 30%. Heart rate and the PR interval were unchanged.9 More study is needed to assess the effects of this interaction on steady-state digoxin levels.

Mechanism

Not established. Digoxin can bind to some extent to fibre within the gut.10 However, in vitro studies (with bran, carrageenan, pectin, sodium pectinate, xylan and carboxymethylcellulose) have shown that most of the binding is reversible.11

Importance and management

Information seems to be limited to these reports. The reduction in serum digoxin levels caused by bisacodyl is small, and not expected to be of clinical importance, and apparently preventable by giving the bisacodyl 2 hours before the digoxin. Neither dietary fibre (bran), guar gum nor the two bulk-forming laxatives (Vi-Siblin and Metamucil) have a clinically important effect on serum digoxin levels. No special precautions would appear to be necessary. The importance of the interaction between digoxin and macrogol 4000 awaits further assessment, but on the available evidence it would be prudent to be alert for the need to increase the digoxin dosage.

Digitalis glycosides + Dihydropyroergocryptine

Dihydropyroergocryptine appears not to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study in 12 healthy subjects dihydropyroergocryptine 20 mg did not affect the pharmacokinetics of a single 500-microgram dose of digoxin. No clinically significant changes were seen in the ability of the heart to initiate and conduct impulses, or repolarise. The slight drop in blood pressure during the first 2 to 4 hours after digoxin was more pro-
nounced in the presence of dihydrolergocryptine, but there was no evidence of impaired orthostatic blood pressure control. 1 No special precautions would seem necessary during concurrent use.

Digitalis glycosides + Dipyridamole

Dipyridamole may cause a minor increase in the absorption of digoxin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that dipyridamole 150 mg twice daily for 5 doses increased the AUC₀₋₄ and the AUC₀₋₂₄ of a single 500-microgram oral dose of digoxin by 20% and 13%, respectively. This was attributed to an increase in digoxin absorption possibly mediated by intestinal P-glycoprotein inhibition. 2 In vitro studies 3–5 found that dipyridamole inhibits P-glycoprotein-mediated transport of digoxin, but in one study this was only at higher levels than those achieved clinically. 2 Therefore these minor changes are not fully explained. The changes in digoxin pharmacokinetics in the presence of dipyridamole are probably not clinically significant.

Digitalis glycosides + Disopyramide or Procainamide

Neither disopyramide nor procainamide normally cause a significant change in serum digoxin levels. A single report describes toxicity in a patient taking digoxin and disopyramide.

Clinical evidence, mechanism, importance and management

(a) Disopyramide

A number of studies have clearly shown that disopyramide causes only a very small increase or no increase at all in the serum levels of digoxin. 1–6 A small but insignificant reduction in heart rate has been seen 7 but the weight of evidence suggests that no adverse interaction occurs if digoxin and disopyramide are used together. However, a very brief report describes toxicity and serious arrhythmia in one patient given digoxin and disopyramide. 8

(b) Procainamide

A study in patients who had been taking digoxin for at least 7 days showed that procainamide did not affect their serum digoxin levels. 1 However, it should be noted that the manufacturers of procainamide say that, in digitalis toxicity, procainamide may further depress conduction, which may result in ventricular asystole or fibrillation. 9

Digitalis glycosides + Diuretics; Potassium-depleting

The potassium loss caused by potassium-depleting diuretics increases the toxicity of the digitalis glycosides.

Clinical evidence

(a) Evidence suggesting an interaction

A comparative study 1 of the medical records of 418 patients taking digitalis over the period 1950 to 1952, and of 679 patients over the period 1964 to 1966, showed that the incidence of digitalis toxicity had more than doubled. Of the earlier group 8.6% developed toxicity (58% taking diuretics, mainly the organomercurial type) compared with 17.2% of the latter group (81% taking diuretics, mainly chlorothiazides, furosemide, etacrynic acid, chloraltidone). It was concluded that the increased toxicity was related to the increased usage of potassium-depleting diuretics.

A retrospective study of over 400 patients taking digoxin showed that almost one in five had some toxic reactions attributable to the use of the glycoside. Of these, 16% had demonstrable hypokalaemia (defined as serum potassium loss below 3.5 mmol/L). Almost half of the patients who showed toxicity were taking potassium-depleting diuretics, notably hydrochlorothiazide or furosemide. 2 Similar results were found in other studies 3–5 in a considerable number of patients. There are other reports not listed here.

In addition there is also some evidence that furosemide may raise serum digoxin levels, 6 although two other studies found no evidence that furosemide affects the urinary excretion of digoxin. 7,8

(b) Evidence suggesting no interaction

A retrospective study of patients who developed digitalis toxicity showed that the likelihood of its development in those with potassium levels below 3.5 mmol/L was no greater than those with normal potassium levels. 9

Two other studies in a total of almost 200 patients failed to detect any association between the development of digitalis toxicity and the use of diuretics or changes in potassium levels. 10,11

A pharmacokinetic study in 6 patients that found that single 50-mg and 100-mg doses of cicletanine had no effect on the plasma levels of digoxin 125 to 250 micrograms daily. 12

Mechanism

Not fully understood. The cardiac glycosides inhibit sodium-potassium ATPase, which is concerned with the transport of sodium and potassium ions across the membranes of the myocardial cells. This is associated with an increase in the availability of calcium ions concerned with the contraction of the cells. Potassium loss caused by these diuretics exacerbates the potassium loss from the myocardial cells, thereby increasing the activity and the toxicity of the digitalis. Some loss of magnesium may also have a part to play. The mechanism of this interaction is still being debated.

Importance and management

A direct link between the use of these potassium-depleting diuretics and the development of digitalis toxicity is not established beyond doubt, but concurrent use can result in digitalis toxicity. It is therefore important that potassium levels remain within the accepted normal range during digitalis treatment. Potassium levels should be routinely monitored when diuretics are given and it may be prudent to recheck levels if patients develop symptoms of digitalis toxicity. See “Table 26.1,” (p. 944) for a list of potassium-depleting diuretics.

Serum digoxin levels may be increased by 25% by spironolactone, but because spironolactone or its metabolite, canrenone, can interfere with some digoxin assay methods, the evaluation of this interaction is difficult. Eplerenone may also cause a minor increase in digoxin levels. Amiloride has little effect on digoxin levels in healthy subjects, but it may reduce its inotropic effects. In patients with renal impairment it possibly raises plasma digoxin levels. The effects of digitoxin are reported to be both increased and decreased by spironolactone.

**Clinical evidence**

(a) Digitalin

A study in 6 healthy subjects who had been taking digitoxin 100 or 150 micrograms daily for 30 days showed that spironolactone 300 mg daily increased the digitoxin half-life by one-third (from 142 to 205 hours). In contrast, other studies have found that the digitoxin half-life was reduced (from 256 to 205 hours) by spironolactone.3

(b) Digoxin

1. Amiloride. In 6 healthy subjects amiloride 5 mg twice daily for 8 days almost doubled the renal clearance of digoxin from 1.3 to 2.4 mL/kg per minute, but reduced the extra-renal clearance from 2.1 to 0.1 mL/kg per minute. The balance of the two effects was to cause a small fall in total clearance and a small rise in plasma digoxin levels.5 The positive inotropic effects of digoxin were reduced, but whether this is clinically important is uncertain. In contrast, a later study in 8 healthy subjects found that a single 75-mg [sic] oral dose of amiloride given 3 hours before an infusion of digoxin did not reduce the inotropic effects of digoxin.6

2. Eplerenone. The UK manufacturer of eplerenone states that the AUC of spironolactone increased by 16% (90% confidence interval: 4% to 30%) when it was given with eplerenone.5 The clearance of a single 750-microgram intravenous dose of digoxin was reduced by about 25% in 4 patients and 4 healthy subjects following 5 days of treatment with spironolactone 100 mg twice daily. A marked fall in serum digoxin levels occurred in an elderly patient when spironolactone was withdrawn, but the accuracy of the assay method used is uncertain (see Importance and management below). One study found that no clinically important reduction in digoxin clearance occurred when Aldactazide (spironolactone-hydrochlorothiazide) was also given.5

**Mechanism**

Not fully understood. Spironolactone inhibits the excretion of digoxin by the kidney (by 13%) but does not affect its biliary clearance.10 Animal studies have suggested that spironolactone may induce P-glycoprotein expression, resulting in reduced intestinal absorption of substrates such as digoxin.11 Spironolactone probably also causes a reduction in the volume of distribution of digoxin. It has been suggested that amiloride may have increased the production of aldosterone, which suppressed the positive inotropic effects of digoxin.7 Studies in patients with congestive heart failure are needed.

**Importance and management**

The pharmacokinetic interaction between digoxin and spironolactone appears to be established. What is known suggests that a rise in digoxin levels of up to 25% is likely to occur, although much greater increases can apparently occur in some patients.6 Monitor concurrent use carefully for signs of over-digitalisation. Note that spironolactone or its metabolite, canrenone, can interfere with some digoxin assay methods.12 In one report, radioimmunoassay (RIA) and affinity-column-mediated immunoassay (ACMIA) were particularly affected by spironolactone and its metabolites.13 Conversely, falsely low digoxin readings with the Axsym MEIA assay method led to digoxin overdose and toxicity in one patient.14 This means that monitoring is difficult unless the digoxin assay method is known to be reliable. Measurement of free digoxin levels or use of a chemiluminescent assay (CLIA) or turbidometric immunoassay for digoxin has been reported to mostly eliminate interference from spironolactone, potassium canrenoate and canrenone.15,16 Eplerenone also appears to cause a small increase in digoxin levels. The UK manufacturers recommend that caution is warranted when digoxin is dosed near the upper limit of therapeutic range.7 However, the US manufacturer states that the pharmacokinetic interaction is not clinically significant.17 The situation with digitoxin and spironolactone is confusing because the reports are contradictory and the outcome uncertain. Concurrent use should be well monitored.

Patients with poor renal function would be expected to have a rise in digoxin levels when given amiloride (due to the increased reliance on renal clearance) but the clinical importance of this awaits confirmation.

**Digitalis glycosides + Dofetilide**

Dofetilide does not affect the pharmacokinetics of digoxin.

**Clinical evidence, mechanism, importance and management**

In a placebo-controlled study in 13 subjects, dofetilide 250 micrograms twice daily for 5 days had no effect on the steady-state pharmacokinetics of digoxin, given at a dose of 250 micrograms daily after a loading dose.1
The effects of digitalis glycosides might be increased by rises in blood calcium levels, and the use of intravenous calcium may result in the development of potentially life-threatening digitalis-induced cardiac arrhythmias. Teriparatide appears not to affect the calcium-mediated pharmacodynamics of digoxin.

Clinical evidence

(a) Calcium

Two patients developed cardiac arrhythmias and died after being given digitalis intramuscularly and either calcium chloride or calcium gluconate intravenously. No absolutely certain causative relationship was established.1

There is some evidence that increases or decreases in blood calcium levels can increase or decrease, respectively, the effects of digitalis. A patient with congestive heart failure and atrial fibrillation was resistant to the actions of digoxin serum levels of 1.5 to 3 nanograms/mL until his serum calcium levels were raised from 1.68 to about 2.13 mmol/L by oral calcium and vitamin D.2

(b) Other drugs affecting calcium

1. Disodium edetate. Disodium edetate,3-5 which lowers blood calcium levels, has been used successfully in the treatment of digitalis toxicity, although less toxic drugs are generally preferred.

2. Teriparatide. A placebo-controlled study in 15 healthy subjects given digoxin 500 micrograms daily, adjusted to maintain steady-state serum levels in the range 1 to 2 nanograms/mL, found that a single 20-microgram subcutaneous dose of teriparatide on day 15 or 16 did not alter the calcium-mediated effects of digoxin (systolic time interval), or heart rate. Serum calcium increased slightly, with a maximum increase of 0.05 mmol/L.6

Mechanism

The actions of the cardiac glycosides (even now not fully understood) are closely tied up with movement of calcium ions into heart muscle cells. Increased concentrations of calcium outside these cells increase the inflow of calcium and this enhances the activity of the glycosides. This can lead to effective over-digitalisation and even potentially life-threatening arrhythmias. Conversely, a drop in calcium levels can attenuate the activity of the glycosides. However, the clinical relevance of these changes in calcium is not fully established.

Importance and management

The report of deaths associated with digitalis and calcium compounds (published in 1936) seems to be the only direct clinical evidence of a serious adverse interaction, although there is plenty of less direct evidence that an interaction is possible. Intravenous calcium should be avoided in patients receiving cardiac glycosides. If that is not possible, it has been suggested7 that it should be given slowly or only in small amounts in order to avoid transient serum calcium levels higher than 7.5 mmol/L, but it seems likely that very large doses of calcium would be required to reach this level, even transiently.

The very slight increases in calcium observed with teriparatide were considered insufficient to increase cardiac sensitivity to digoxin at therapeutic dosage.8 Nevertheless, the manufacturer of teriparatide still advises caution in patients taking digitalis, because of the possibility for transiently raised calcium levels.9,10

Digitalis glycosides + Enoximone

Studies in patients receiving long-term treatment with digitalis glycosides (digoxin or digitoxin) showed that oral enoximone 100 mg three times daily for a week had no significant effect on the plasma levels of either of these digitalis glycosides. Cardiac function was improved.

Digitalis glycosides + + Etanercept

No clinically significant interaction appears to occur between digoxin and etanercept.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given an oral loading dose of digoxin 500 micrograms twice daily on day one followed by 250 micrograms daily found that concomitant use of etanercept 25 mg twice weekly did not significantly affect the pharmacokinetics of digoxin. The maximum serum levels and AUC of etanercept were 4.2% and 12.5% lower, respectively, during concurrent use but this was not considered to be clinically significant. The combination was well tolerated and there were no changes in ECG parameters. No special precautions therefore seem necessary if both drugs are given.

Digitalis glycosides + + Exenatide

Exenatide delayed the time to peak plasma digoxin levels, but this change is not expected to be clinically relevant.

Clinical evidence, mechanism, importance and management

To determine the effects of exenatide on the pharmacokinetics of digoxin, 21 healthy subjects were given a loading dose of digoxin 500 micrograms twice daily on day one, then 250 micrograms daily for 11 days, with subcutaneous exenatide 10 micrograms twice daily on days 8 to 12. The median time to maximum concentration of digoxin was increased from 1.5 hours to 4 hours, and there was a reduction of 17% in its maximum plasma level. There was no change in AUC and trough digoxin levels, and the renal clearance of digoxin was not altered. It is thought that the changes in digoxin pharmacokinetics occurred as a result of altered gastric emptying caused by exenatide. Nevertheless, the changes in digoxin pharmacokinetics are unlikely to be clinically relevant, and no digoxin dose adjustment is likely to be required on concurrent use.

Digitalis glycosides + + Flecainide

The plasma digoxin levels of 10 patients with congestive heart failure were unchanged when they took flecainide 100 to 200 mg twice daily for 7 days. A similar lack of interaction was also seen in 4 patients who took both drugs over a 4-week period.

In contrast, a study in 15 healthy subjects found that flecainide 200 mg twice daily increased the trough and peak plasma levels of digoxin 250 micrograms by 24% and 13%, respectively. The changes observed in vital signs were not clinically significant. Based on the results of a single-dose study the steady-state digoxin levels were predicted to rise by about 15% during the use of flecainide 200 mg twice daily.

Mechanism

Uncertain. It is suggested that any changes may be due to alterations in the volume of distribution.

Importance and management

Documentation is limited but what is known suggests that either no interaction occurs, or any changes are small and unlikely to be clinically relevant in most patients. However, the UK manufacturers of flecainide recommend that digoxin plasma levels should be measured not less than 6 hours after any digoxin dose, before or after the administration of flecainide. The US manufacturers do not advise any additional monitoring.

The authors of one of the reports suggest that patients with high drug
levels, atrioventricular nodal dysfunction, or both, should be monitored during concurrent treatment.

### Digitalis glycosides + Fondaparinux

No significant interaction appears to occur between digoxin and fondaparinux.

**Clinical evidence, mechanism, importance and management**

A phase I randomised study in 24 healthy subjects found that the pharmacokinetics of oral digoxin 250 micrograms twice daily for one day then 250 micrograms daily for 6 days was unaffected by subcutaneous fondaparinux 10 mg daily. The pharmacokinetics of fondaparinux were not affected by digoxin. The combination was well tolerated and no clinically significant changes in vital signs and ECGs were observed.1 No additional precautions therefore seem necessary on concurrent use.

### Digitalis glycosides + Grapefruit juice

Plasma digoxin levels are generally unaltered or only modestly increased by grapefruit juice, but in some individuals significant changes may occur.

**Clinical evidence**

A crossover study in 12 healthy subjects found that when they were given either grapefruit juice 220 mL or water, 30 minutes before and after 24-hour digoxin AUCs were increased by about 10%. The maximum plasma levels and renal clearance of digoxin were not significantly affected. However, in 2 subjects taking grapefruit juice, the ECGs taken 90 minutes after digoxin ingestion revealed an asymptomatic first-degree atrioventricular block. Plasma levels in these subjects had increased by 50% to 2.4 and 2.8 nanograms/mL, respectively.1 Another study found that grapefruit juice decreased the rate but not the extent of absorption of digoxin and had no effect on AUC or renal clearance, but there was significant inter-individual variability.2

**Mechanism**

The modest increases in digoxin levels may be due to increased intestinal absorption of digoxin, possibly due to inhibition of P-glycoprotein-mediated digoxin transport by grapefruit juice, although this mechanism has been questioned.1 In vitro, pomelo (Citrus grandis) and grapefruit juices inhibited P-glycoprotein transport of digoxin.3

**Importance and management**

Although grapefruit juice appears to have little effect on digoxin bioavailability, it is possible that in some individuals the interaction could be of clinical significance.2 Bear this interaction in mind in the case of an unexpected response to digoxin. More study is needed.

### Digitalis glycosides + Guanadrel

Guanadrel did not affect the pharmacokinetics of a single dose of digoxin.

**Clinical evidence, mechanism, importance and management**

In 13 healthy subjects guanadrel 10 mg orally every 12 hours for 8 days did not affect the pharmacokinetics of a single intravenous dose of digoxin given on day 5. One subject experienced a 10-minute episode of asymptomatic second-degree heart block (Wenckebach) 3 hours after the dose of digoxin, but the reason for this effect was not clear.1 There seem to be no reports of adverse interactions between the digitalis glycosides and any of the guanethidine-like antihypertensive drugs.

### Digitalis glycosides + H2-receptor antagonists

Small changes in serum digoxin levels, both rises and falls, have been seen in patients also given cimetidine, but these do not appear to be of clinical importance. Ranitidine does not appear to interact with metildigoxin.

**Clinical evidence, mechanism, importance and management**

While taking cimetidine 300 mg every 6 or 12 hours the steady-state serum digoxin levels of 11 patients with congestive heart failure fell, on average, by 25% (from 2 to 1.5 nanograms/mL), but none of them showed any ECG changes or signs that their condition had worsened.1 Four other patients with stable congestive heart failure had no significant changes in the pharmacokinetics of digoxin 125 to 250 micrograms daily when they were given cimetidine 300 mg every 6 hours.2 Three single-dose studies in a total of 19 healthy subjects, and 6 patients with duodenal ulcers3 found that cimetidine 600 mg to 1.2 g daily had no significant effect on the absorption4 or the pharmacokinetics5–6 of digoxin. Another study found a small increase in digoxin levels in healthy subjects, but only a small statistically insignificant rise in the steady-state levels of 11 patients given cimetidine 400 mg four times daily.6 Six patients with chronic congestive heart failure given metildigoxin had no changes in their serum digoxin levels when they were given ranitidine 150 mg twice daily for a week.7 No interaction of clinical importance with either of these H2-receptor antagonists has been established and no special precautions appear to be necessary.

### Digitalis glycosides + Herbal medicines; Cimicifuga

A standardised black cohosh extract (Cimicifuga) did not alter the pharmacokinetics of digoxin.

**Clinical evidence, mechanism, importance and management**

A study in 16 healthy subjects who were given a single 400-microgram dose of digoxin before and on the last day of a 14-day course of a standardised black cohosh (Cimicifuga racemosa) extract 20 mg twice daily, found no statistically significant changes in the pharmacokinetics of digoxin. The product used was standardised to 2.5% triterpene glycosides.1

Digoxin is a substrate of P-glycoprotein, and this study was conducted...
Many herbal remedies contain cardiac glycosides, which could in theory have additive effects with digoxin or digitoxin, or interfere with their assays. However, there appear to be few such interactions reported.

Clinical evidence, mechanism, importance and management

(a) Additive effects possible

A 26-year-old woman developed severe and unexplained chest pain, and was later noted to have a heart rate of 39 bpm and a blood pressure of 59/36 mmHg, but these rose to normal with conservative management. She was found to have a digoxin level of 0.9 nanograms/mL and was diagnosed as having digoxin toxicity, despite not taking any prescribed digoxin. The digoxin-like cardiac glycosides were thought to have come from an unnamed herbal remedy for stress, which contained black cohosh root (Cimicifuga racemosa), eayenne pepper fruit (Capsicum annuum), hops flowers (Humulus lupulus), skullcap herb (Scutellaria lateriflora), valerian root (Valeriana officinalis) and wood betony herb (Pedicularis canadensis). All of these had previously been shown to contain small amounts of digoxin-like compounds, which were only partially detected by digoxin antibody immunoassays. In this previous in vitro study, 46 commercially packaged herb teas and 78 teas prepared from herbs were assayed for digoxin-like factors by their cross-reactivity with digoxin antibody or inhibition of ouabain binding, and these values were used to give approximate equivalent daily doses of digoxin. Three packaged teas (Breathe Easy, black pepper, and jasmine) and 3 herbs (pleurisy root, chaparral, peppermint) were found to contain equivalent to more than 30 micrograms of digoxin equivalents per cup and were postulated to provide a therapeutic daily dose of digoxin if 5 cups a day were drunk. However, note that some common teas sampled in this study (e.g. English Breakfast, Earl Grey) contained over 20 micrograms of digoxin equivalents per cup, and tea drinking has not been associated with adverse cardiovascular risk. Therefore the interpretation of the findings of this study is unclear.

Theoretical interactions with herbal remedies are not always translated into practice, and there do not appear to be any cases of herbs interacting with digoxin because of their cardiac glycoside content. See also ‘Digitalis glycosides + Chinese herbal medicines’, p.917.

(b) Effects on digoxin assays

A 68-year-old woman who was given a loading dose of digitoxin 750 micrograms then 100 micrograms on the second day was found to have markedly elevated levels of digitoxin (greater than 100 nanograms/mL), but no clinical signs of toxicity. Two days before admission she had ingested 90 drops of Uzara, a preparation from Xysmaloium undulatum, which contains weak cardiac glycosides. Later investigations in 4 healthy subjects given 30 drops of Uzara confirmed that assays for digitoxin (CEDIA digitoxin test, Roche Diagnostics, Germany) and digoxin (Tina-quant digitoxin test, Roche Diagnostics, Germany) were markedly elevated by Uzara to levels well above usual therapeutic concentrations, but that there were no clinically relevant changes in heart rate and blood pressure.

In an in vitro study, plantain (Plantago major) extract from capsules, liquid extract, or dry leaf did not affect the results of digoxin assays when using fluorescence polarization immunoassay or microparticle enzyme immunoassay. Note that contamination of plantain with Digitalis lanata has been reported.

See also ‘Digitalis glycosides + Chinese herbal medicines’, p.917 and ‘Digitalis glycosides + Herbal medicines; Ginseng’, below for other herbs that can affect the results of digoxin assays.

Digitalis glycosides + Herbal medicines; Ginkgo biloba

A study in 8 healthy subjects found that ginkgo biloba leaf extract 80 mg three times daily had no significant effects on the pharmacokinetics of a single 500-microgram dose of digoxin.1

Digitalis glycosides + Herbal medicines; Ginseng

A man taking digoxin developed grossly elevated serum digoxin levels, without symptoms of toxicity, while taking Siberian ginseng. This was eventually attributed to an effect of ginseng on the digoxin assay. Both Chinese and Siberian ginseng may interfere with some digoxin assays.

Clinical evidence, mechanism, importance and management

A 74-year-old man who had been taking digoxin for many years (serum levels normally in the range 0.9 to 2.2 nanograms/mL) was found, during a routine check, to have digoxin levels of 5.2 nanograms/mL, but without evidence of toxicity or bradycardia or any other ECG changes. The levels remained high even when the digoxin was stopped. It turned out he had also been taking Siberian ginseng capsules. When the ginseng was stopped, the digoxin levels returned to the usual range, and digoxin was resumed. Later rechallenge with the ginseng caused a rise in his serum digoxin levels. No digoxin or digitoxin contamination was found in the capsules, and the authors of the report also rejected the idea that the eleutherosides (chemically related to cardiac glycosides) in ginseng might have been converted in vivo into digoxin, or that the renal elimination of digoxin might have been impaired, since the patient showed no signs of toxicity. One possible explanation is that the ginseng affected the accuracy of the digoxin assay so that it gave false results.1

Asian or Chinese ginseng (Panax ginseng) and Siberian ginseng (Eleutherococcus senticosus) have both been found to interfere with some digoxin assays including fluorescence polarization immunoassay (FPIA) and microparticle enzyme immunoassay (MEIA).2

Whether serum digoxin levels are actually affected is uncertain. Nevertheless it is may be sensible to ask about ginseng use when interpreting digoxin levels.

Digitalis glycosides + Herbal medicines; Goldenseal (Hydrastis)

A standardised goldenseal root extract did not alter the pharmacokinetics of digoxin.
Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given a single 500-microgram dose of digoxin before and on the last day of treatment with standardised goldenseal root extract (Hydrastis canadensis) 1070 mg three times daily for 14 days, found a 14% increase in the maximum digoxin plasma levels, but no other changes in the pharmacokinetics of digoxin. The product was standardised for isoquinoline alkaloid content.  

It was suggested that constituents of goldenseal may alter digoxin pharmacokinetics by affecting P-glycoprotein, since goldenseal alkaloids are modulators of P-glycoprotein in vitro. However, the clinical study showed that goldenseal does not cause clinically relevant changes in digoxin pharmacokinetics. Therefore no changes in digoxin levels would be anticipated on concurrent use, the caveat being that, as with all herbals, these results may not be applicable to all goldenseal products.

Digitalis glycosides + Herbal medicines; Hawthorn (Crataegus)

A standardised extract of hawthorn (Crataegus) did not have any clinically relevant effect on digoxin levels.

Clinical evidence, mechanism, importance and management

In a crossover study in 8 healthy subjects, a standardised extract of hawthorn leaves and flowers (Crataegus oxyacantha) 450 mg twice daily for 21 days had no effect on the steady-state pharmacokinetics of digoxin. The biggest difference was a non-significant 23% reduction in the trough level. There were no changes in ECG or blood pressure from baseline values for either digoxin alone or combined with hawthorn.

It was suggested that flavonol constituents of hawthorn might induce P-glycoprotein and therefore decrease digoxin levels, similar to ‘St John’s wort’, (below).

This study suggests that, at the most, hawthorn might cause a minor decrease in digoxin levels, and no adjustment of the digoxin dose is therefore likely to be needed on concurrent use. Although no pharmacodynamic effects were seen, the possibility that hawthorn’s cardioactive constituents might increase the effect of digoxin on cardiac contractility cannot be ruled out.

Digitalis glycosides + Herbal medicines; Kava

A standardised kava extract did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given a single 500-microgram dose of digoxin before and on the last day of treatment with a standardised kava rhizome (Piper methysticum) extract 1227 mg three times daily for 14 days, found no changes in the pharmacokinetics of digoxin. The product used was standardised for kavalactone content.

It was suggested that kava may alter digoxin pharmacokinetics by affecting P-glycoprotein, since kavalactones are modulators of P-glycoprotein in vitro. However, the clinical study showed that kava does not cause clinically relevant changes in digoxin pharmacokinetics. Therefore no changes in digoxin levels would be anticipated on concurrent use, the caveat being that, as with all herbals, these results may not be applicable to all kava products.

Digitalis glycosides + Herbal medicines; Milk thistle

A standardised milk thistle extract did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects who were given a single 400-microgram dose of digoxin before and on the last day of a 14-day course of a standardised milk thistle (Silybum marianum) extract 300 mg three times daily, found no statistically significant changes in the pharmacokinetics of digoxin. There was a trend towards a minor 10% reduction in the AUC of digoxin, but this did not reach statistical significance. The extract used was standardised to contain 80% silymarin.

It was suggested that milk thistle may alter digoxin pharmacokinetics by affecting P-glycoprotein, since silymarin is a modulator of P-glycoprotein in vitro. However, the clinical study showed that milk thistle does not cause clinically relevant changes in digoxin pharmacokinetics. Therefore no changes in digoxin levels would be anticipated on concurrent use, the caveat being that, as with all herbals, these results may not be applicable to all milk thistle products.

Digitalis glycosides + Herbal medicines; St John’s wort (Hypericum perforatum)

Digoxin toxicity occurred in a patient taking digoxin when he stopped taking St John’s wort. There is good evidence that some preparations of St John’s wort can reduce the levels of digoxin by about one-quarter to one-third.

Clinical evidence

An 80-year-old man taking long-term digoxin and St John’s wort herbal tea (2 litres daily) developed symptoms of digoxin toxicity (nodal bradycardia of 36 bpm and bigeminy) when he stopped taking the herbal tea.

In a study 13 healthy subjects were given digoxin for 5 days until steady-state had been achieved, and then St John’s wort extract (LI 160, Lichtwer Pharma) 300 mg three times daily for a further 10 days. The AUC and trough level of digoxin decreased by 28% and 37%, respectively. When compared with a parallel group of 12 subjects taking digoxin and placebo, the St John’s wort group had 26.3% lower maximum plasma digoxin levels, 33.3% lower trough digoxin levels and a 25% lower AUC.

In a further randomised placebo-controlled study, 93 healthy subjects were given digoxin alone for 7 days and then with one of ten St John’s wort preparations for 14 days. The extract used in the earlier study (LI 160, Jarsin 300, Lichtwer Pharma) 300 mg three time daily similarly reduced the digoxin AUC, peak and trough plasma levels by 25%, 37%, and 19%, respectively. Comparable results were found with hypericum powder containing similar amounts of hyperforin (about 21 mg daily), while hypericum powder with half the hyperforin content (about 10 mg daily) reduced the AUC, peak and trough plasma levels by about 18%, 21%, and 13%, respectively. Some St John’s wort products, including tea, juice, oil extract, and powder with low-dose hyperforin (all 5 mg daily or less), did not significantly affect the pharmacokinetics of digoxin. Similarly, a further study in 28 healthy subjects found no statistically significant change in digoxin pharmacokinetics when another low-hyperforin (about 3.5 mg daily) St John’s wort extract (Esbericum) 120 mg was given twice daily for 11 days to patients who had received a digoxin loading dose of 750 micrograms daily for 2 days before starting St John’s wort, and then received digoxin 250 micrograms daily each day during the study.

Mechanism

St John’s wort has been shown to increase the activity of the P-glycoprotein drug transporter protein in the intestines, which reduces the absorption of digoxin.
Importance and management

Information seems to be limited to these reports, but the interaction would appear to be established. The extent of the interaction may depend on the St John’s wort preparation involved and dose used and seems to be correlated with the dose of hyperforin. See also ‘Drug-herb interactions’, (p.10). Reductions in serum digoxin levels of the size seen with LI 160 could diminish the control of arrhythmias or heart failure. Digoxin serum levels should therefore be well monitored if St John’s work is either started or stopped and appropriate dosage adjustments made if necessary. The recommendation of the CSM in the UK is that St John’s work should not be used by patients taking digoxin.

Clinical evidence, mechanism, importance and management

Steady-state studies reflect the every-day situation much more closely than single-dose studies, and the one cited above indicates that the total reduction in digoxin absorption is small (15%). This is unlikely to be of clinical importance. However, if an interaction does occur the effects can seemingly be minimised by separating the dosages by 2 hours.

Clinical evidence, mechanism, importance and management

Ketanserin 40 mg twice daily did not cause any significant changes in the pharmacokinetics of single doses of either digoxin 1.25 mg or digitoxin 1 mg in healthy subjects, and it was concluded that ketanserin is unlikely to alter serum concentrations of either digitalis glycoside during clinical use.

No pharmacokinetic interaction occurs between digoxin and lithium but the addition of digoxin to lithium possibly has a detrimental short-term effect on the control of mania. An isolated report describes severe bradycardia in one patient given both drugs.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects taking lithium carbonate sufficient to achieve mean steady-state serum levels of 0.76 mmol/L (range 0.4 to 1 mmol/L) showed that the pharmacokinetics of a 750-microgram intravenous dose of digoxin were unchanged by lithium, and that there were no significant effects on sodium pump activity or electrolyte concentrations. However an experimental 7-day study in patients with manic-depressive psychoses found that there was a greater improvement in those given lithium with placebo than those given lithium with digoxin. This may be a reflection of changes in Na-K-ATPase. An isolated report describes tremor, confusion and severe nodal bradycardia in a patient given both drugs. The bradycardia worsened (30 bpm) even after both drugs were stopped. The clinical
significance of all of these findings is uncertain. Note that one UK manufacturer of digoxin lists lithium as a drug that may increase sensitivity to digoxin because it may cause hypokalaemia or intracellular potassium deficiency, consider also ‘drugs that lower potassium’. (p.923).

**Digitalis glycosides + Macrolides**

Clarithromycin markedly increases digoxin levels, and numerous cases of digoxin toxicity have been reported. Increases in serum digoxin levels also occur with telithromycin. Cases of rapid and marked two to fourfold increase in serum digoxin levels have also been reported for azithromycin, erythromycin, josamycin and roxithromycin. A similar case has been seen with digitoxin and azithromycin.

**Clinical evidence**

A. Digitoxin

A man with congestive heart failure taking digitoxin 70 micrograms daily for 5 days of each week, with enalapril and furosemide, was admitted to hospital with nausea and bradycardia of 26 bpm 4 days after starting a 3-day course of azithromycin (dosage not stated). His serum digitoxin levels were found to be raised from his usual baseline range of 9.9 to 19 nanograms/mL up to 34 nanograms/mL. His renal function was normal. Another patient treated with intravenous digitoxin 250 micrograms once daily had a marked rise from his steady-state digitoxin range of 11 to 15 nanograms/mL after being given azithromycin 500 mg daily for 3 days. The digitoxin was withdrawn one day later, but even so the levels climbed to a peak of 32 nanograms/mL after a further 3 days, and remained in the toxic range for yet another 3 days.1

B. Digoxin

(a) Azithromycin

A 31-month-old boy with Down’s syndrome and tetralogy of Fallot (a congenital heart defect resulting in reduced blood flow to the lungs) was discharged from hospital after repair of his heart defect. He was taking digoxin 60 micrograms twice daily, furosemide, and potassium chloride. Eight days later, when readmitted with symptoms of heart failure, intermittent fever and wheezing, he was given azithromycin (10 mg/kg on day 1, then 5 mg/kg daily for 4 days). Three days later his steady-state serum digoxin levels had risen from 1.79 to 2.37 nanograms/mL and he experienced anorexia, nausea, and second degree atrioventricular block. All the symptoms resolved when the digoxin was withdrawn. Digoxin was restarted at 50 micrograms twice daily after the azithromycin course was completed and steady-state digoxin levels of 1.42 nanograms/mL were noted.2

The manufacturers of azithromycin said that, as of October 2000, there were 230 cases of the concurrent use of azithromycin and digoxin on their database. Of these, 78 cases had adverse events indicating possible digoxin toxicity. However on review, 21 cases were clearly excluded. Of the remaining cases, only 13 provided digoxin levels, and of these, high serum digoxin concentrations were reported in 6, but generally insufficient data made interpretation difficult.3 The manufacturers concluded that the possibility that a patient may experience an increase in digoxin levels while taking azithromycin cannot be entirely excluded.3

(b) Clarithromycin

A woman receiving treatment with warfarin, heparin, carbamazepine and digoxin was admitted to hospital with syncope, vomiting and an irregular heart rhythm shortly after starting clarithromycin 1 g daily. Her serum digoxin levels were found to be raised. The clarithromycin was decreased, the carbamazepine and digoxin stopped, and she was treated with digoxin-specific antibody fragments (Digibind) and intravenous fluids. Her serum digoxin levels fell again and the digitalis toxicity disappeared.4

In 1995, the manufacturers of clarithromycin had a few other cases on their records of raised digoxin levels in patients following treatment with clarithromycin4 and there are many other case reports of this interaction in the literature,5-18 including a case series of 6 patients with end stage renal disease.20

A subsequent randomised, placebo-controlled study in 12 healthy subjects confirmed that clarithromycin 250 mg twice daily for 3 days increased the AUC of a single 750-microgram oral dose of digoxin by 70%. The non-glomerular renal clearance of digoxin was reduced by 40%.21 Intravenous digoxin was much less affected.21,22 In two further studies in which clarithromycin (500 mg twice daily for 7 days) was used as a positive control, a 57% and 35% increase in the AUC of digoxin was seen.23,24

Two studies that prospectively measured digoxin levels in patients before and during clarithromycin therapy found an important increase in all patients of 70%,25 and from a range of 1 to 1.6 nanograms/mL up to 2.3 to greater than 4 nanograms/mL.26 In one of these studies, there was a significant correlation between the dose of clarithromycin and the increase in digoxin serum levels.25

A case-control study using data from healthcare databases in Ontario from 1994 to 2000 identified 1051 patients who had been admitted to hospital with digoxin toxicity. Of these, 55 patients (5.2%) had been exposed to clarithromycin in the preceding 3 weeks, when compared with just 0.5% of controls, showing about a tenfold increase in risk.27

(c) Erythromycin

An elderly woman with a prosthetic heart valve being treated for left ventricular dysfunction with warfarin, furosemide, hydralazine, isosorbide dinitrate and digoxin, was given erythromycin. She took only four 250-mg doses. Four days later her serum digoxin levels were found to have risen to 2.6 nanograms/mL from a normal steady-state range of 1.4 to 1.7 nanograms/mL, and she showed evidence of digitalis toxicity.28 Another four similar cases have also been reported.29,30

A study in a man who was resistant to digoxin found that erythromycin 1 g daily increased the AUC of digoxin by 300%.31 A neonate given oral digoxin 5 micrograms/kg daily developed digoxin toxicity two days after erythromycin (10 mg three times daily, then 17 mg three times daily) was given. Digoxin levels rose from 1.8 to 16 nanograms/mL.32

(d) Josamycin

A case report describes a premature neonate receiving digoxin who had a 50% increase in digoxin levels from 2 to 2.95 nanograms/mL, resulting in bradycardia, and sinoatrial block after being given josamycin for 4 days. This was treated with antidigitalis Fab fragments.34

(e) Rokitamycin

Rokitamycin did not affect serum digoxin levels in a study in 10 subjects.35

(f) Roxithromycin

A 76-year-old woman taking digoxin and a number of other drugs (enalapril, isosorbide mononitrate, furosemide, diltiazem, glycerol trinitrate, slow-release potassium, prednisolone, omeprazole, calcitriol) developed signs of digoxin toxicity (nausea, vomiting, first degree heart block) within 4 days of starting to take roxithromycin 150 mg twice daily. Her serum digoxin levels were raised by about fourfold.36

(g) Telithromycin

A study in 26 healthy subjects given digoxin 500 micrograms twice daily on the first day followed by 250 micrograms twice daily found that telithromycin 800 mg daily increased the digoxin AUC by 37% and the maximum blood levels by 74%. Throughout plasma levels were increased by 21% and remained within the therapeutic range. No signs of digoxin toxicity were observed on ECGs.37

A 58-year-old woman taking digoxin 250 micrograms daily developed syncope and malaise after a 5-day course of telithromycin 800 mg daily. Her digoxin levels were 55% higher than her normal baseline level, and there were ECG changes.38

**Mechanism**

It was originally thought that this interaction was due to the effect of the antibiotics on gut flora. Up to 10% of patients receiving oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be the responsibility of the gut flora, 29 in particular Eubacterium lentum.
worth noting that most classes of antibacterials do not appear to interact with digoxin despite inhibiting \textit{E. lentum in vitro}.\footnote{See ‘Digitalis glycosides + Beta-lactam antibacterials’, p.913.} In addition, more recent data showing that digoxin levels are affected by clarithromycin in all, or the majority, of patients or subjects throw doubt on this theory.

A more plausible explanation for the interaction between digoxin and clarithromycin, and probably also erythromycin, is that the antibacterials inhibit the intestinal\footnote{22} or renal\footnote{25} \textit{P}-glycoprotein transport of digoxin, which would increase the oral bioavailability and reduce the nonglomerular renal clearance respectively. Both mechanisms may be important.\footnote{21}

Further, the increased gastric emptying due to erythromycin may also increase the bioavailability of digoxin\footnote{24} or digitoxin.\footnote{39}

\section*{Importance and management}

The pharmacokinetic interaction between oral digoxin and clarithromycin is established, and likely to occur in the majority of patients. Digoxin toxicity has been commonly reported. Monitor all patients well for signs of increased digoxin effects when clarithromycin is first given, reducing the digoxin dosage as necessary. Intravenous digoxin is unlikely to be affected increased digoxin effects when clarithromycin is first given, reducing the digoxin dosage as necessary. Telithromycin appears to interact similarly to a clinically relevant extent. Telithromycin appears to interact similarly to clarithromycin, and similar advice applies.

Information about azithromycin and erythromycin is limited to a relatively small number of patients, and there is only one report of an interaction between digoxin and josamycin or digoxin and roxithromycin. Until more is known, it would be prudent to monitor all patients well for signs of increased digoxin effects when any of these macrolide antibacterials is first given, reducing the digoxin dosage as necessary. In addition, remember that azithromycin has a long serum half-life (60 hours), which means that it can continue to interact for several days after it has been withdrawn. Rokitamycin appears not to interact.

\section*{Digitalis glycosides + Medroxyprogesterone acetate or Megestrol}

Doses of medroxyprogesterone acetate or megestrol used for malignant disease do not appear to interact with digoxin to a clinically relevant extent.

\section*{Clinical evidence, mechanism, importance and management}

Steady-state digoxin levels were monitored in 3 patients before and after 5 weeks of treatment with oral medroxyprogesterone acetate 500 mg twice daily or megestrol 160 mg daily. Only small and clinically irrelevant changes in digoxin levels and clearance were seen.\footnote{1} For the possible effect of HRT including medroxyprogesterone on digoxin, see ‘Digitalis glycosides + HRT’, p.928.

\section*{Digitalis glycosides + Methylprednisolone}

Methylprednisolone does not appear to affect serum digoxin levels, but marked bradycardia has been seen in two elderly women given both drugs.

\section*{Clinical evidence}

Methylpredisolone 250 mg daily had no effect on the steady-state serum levels of digoxin 250 micrograms daily in 8 healthy subjects.\footnote{1}

However, two elderly women with hypertension and left ventricular failure developed marked bradycardia when they were given digoxin with methylprednisolone 750 mg or 3.75 g daily but not when they were given digoxin alone. Average heart rates were 50 and 48 bpm while minimum heart rates were 32 and 38 bpm, respectively. They were subsequently discharged taking digoxin and hydralazine with heart rates within the normal range.\footnote{2}

\section*{Mechanism}

Uncertain. Both digoxin and methylprednisolone\footnote{3} can cause some bradycardia, but these effects seem to have been more than simply the sum of the individual drug effects on the autonomic nervous system.\footnote{2}
**Digitalis glycosides + Metoclopramide**

The serum levels of digoxin may be reduced by about one-third if metoclopramide is given with slowly dissolving forms of digoxin. No interaction is likely with digoxin in liquid form or in fast-dissolving preparations.

**Clinical evidence**

A study in 11 patients taking slowly dissolving digoxin tablets (Orion) found that metoclopramide 10 mg three times a day for 10 days reduced the serum digoxin levels by 36%, from 0.72 to 0.46 nanograms/mL. The digoxin concentrations rose to their former levels when the metoclopramide was withdrawn.

Another study in healthy subjects found metoclopramide 10 mg three times daily caused a 19% reduction in the AUC of digoxin and a 27% reduction in peak serum digoxin levels (digoxin formulation not stated). Yet another study in healthy subjects clearly showed that metoclopramide decreased the absorption of digoxin from tablets (Lanoxin) but not capsules (Lanoxicaps).

**Mechanism**

It would seem that the metoclopramide increases the motility of the gut to such an extent that full dissolution and absorption of some digoxin formulations does not occur.

**Importance and management**

Information is limited but the interaction seems to be established. It is not likely to occur with solid form, fast-dissolving digoxin preparations (e.g., liquid-filled capsules) or digoxin in liquid form, but with those preparations which are slowly dissolving (i.e., some tablet formulations). A reduction in digoxin levels of one-third could result in under-digitalisation effects having been seen.

Information is limited but the interaction seems to be established. It is not likely to occur with solid form, fast-dissolving digoxin preparations (e.g., liquid-filled capsules) or digoxin in liquid form, but with those preparations which are slowly dissolving (i.e., some tablet formulations). A reduction in digoxin levels of one-third could result in under-digitalisation effects having been seen.

**Digitalis glycosides + Moracizine**

**Clinical evidence, mechanism, importance and management**

Moracizine does not significantly increase serum digoxin levels in patients with normal renal function. However, some adverse conduction effects have been seen.

Thirteen patients taking digoxin 125 to 250 micrograms daily showed a non-significant rise in serum digoxin levels of 10 to 15% when they were given moracizine 10 mg/kg daily in three divided doses for 2 weeks. Nine patients taking digoxin and moracizine for 1 to 6 months had no significant changes in their serum digoxin levels.

No changes in the pharmacokinetics of digoxin were seen in a single-dose study of intravenous digoxin and moracizine in 9 healthy subjects or in a study in patients receiving maintenance treatment with digoxin over a 12.5-day period. However, cardiac arrhythmias (AV junctional rhythm and heart block) were seen, which resolved when the moracizine was stopped.
Digitalis glycosides + Nateglinide or Repaglinide

The pharmacokinetics of nateglinide and digoxin are not altered when they are given together. Repaglinide does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance, and management

(a) Nateglinide

A crossover study in 12 healthy subjects found that when a single 1-mg dose of digoxin was given with the first dose of nateglinide 120 mg three times daily for 2 days, there were no changes in the pharmacokinetics of digoxin, nor were the pharmacokinetics of nateglinide altered by the digoxin.

(b) Repaglinide

A crossover, multiple-dose study in 14 healthy subjects found that repaglinide 2 mg three times daily before meals had no effect on the pharmacokinetics of digoxin 250 micrograms daily. Concurrent use was well tolerated.

Digitalis glycosides + Nefazodone

Nefazodone causes a moderate increase in serum digoxin levels but this is of uncertain clinical importance. Digoxin does not appear to affect the pharmacokinetics of nefazodone.

Clinical evidence

Eighteen healthy subjects were given digoxin 200 micrograms daily for 8 days, then nefazodone 200 mg twice daily for 8 days, and then both drugs together for 8 days. Nefazodone increased the AUC of digoxin by 15%, and increased the peak and trough serum levels of digoxin by 29% and 27%, respectively. However, no clinically significant changes in ECG measurements occurred (PR, QRS and QT intervals), nor was the heart rate nor any other vital sign altered. The pharmacokinetics of the nefazodone were unchanged.

Mechanism

Not understood.

Importance and management

This interaction appears to be established, but its clinical importance is uncertain. The increase in the AUC of digoxin is modest, and would not generally be expected to be clinically significant, although some effect may be seen in patients with digoxin levels at the higher end of the therapeutic range. It may be prudent to monitor for symptoms of digoxin excess (e.g. bradycardia) and take digoxin levels if necessary.

Digitalis glycosides + Digitalis glycosides

Digitalis glycosides + Neuromuscular blockers

Serious cardiac arrhythmias can develop in patients receiving digitalis glycosides who are given suxamethonium (succinylcholine) or pancuronium.

Clinical evidence

Eight out of 17 digitalised patients (anaesthetised with thiopental and then maintained with nitrous oxide and oxygen) developed serious ventricular arrhythmias following the intravenous injection of suxamethonium (succinylcholine) 40 to 100 mg. Four out of the 8 patients reverted to their previous rhythm when they were given tubocurarine 15 to 30 mg, with one patient returning to a regular nodal rhythm from ventricular tachycardia.

Of the other 9 patients, 3 had immediate and definite ST-T wave changes, and the remaining 6 had no demonstrable changes. There are other reports of this interaction, including one that describes sinus tachycardia and atrial flutter in 6 out of 18 patients taking digoxin after they were given pancuronium.

Mechanism

Not understood. One possibility is that the suxamethonium may cause the rapid removal of potassium from the myocardial cells. Another idea is that it affects catecholamine-releasing cholinergic receptors.

Importance and management

Information is limited but the interaction appears to be established. Suxamethonium should be used with great caution in patients taking digitalis glycosides. Similarly, caution would seem appropriate with pancuronium.

Digitalis glycosides + NSAIDs

Diclofenac and indomethacin can cause potentially toxic rises in digitalis glycoside levels, while azapropazone, fenbufen and tiaprofenic acid raise levels to a lesser degree. Two studies found that ibuprofen raised serum digoxin levels, whereas another found no evidence of an interaction. Ioxiacid, ketoprofen, loroxin, meloxicam, nimexulide, piroxicam, and rofecoxib do not appear to interact significantly with digoxin. In contrast, phenylbutazone appears to lower plasma digitalis glycoside levels. NSAIDs can cause a deterioration in renal function, which could result in digoxin toxicity.

Clinical evidence

(a) Azapropazone

In 8 arthritic patients azapropazone 900 mg daily did not significantly alter the AUC of a single 500-microgram intravenous dose of digoxin, but its mean half-life was increased by about 10%. Two of the patients showed individual half-life increases of almost one-third.
A study in 7 healthy subjects found that diclofenac 100 mg daily for 10 days increased the serum levels of digoxin by 29%. Another study in 6 healthy subjects similarly found that diclofenac 50 mg three times daily raised the serum digoxin levels by about one-third. Digitoxin 100 micrograms had no effect on the plasma levels of diclofenac 50 mg twice daily in 8 subjects; digitoxin levels were not reported.

(c) Etoricoxib

A study in healthy subjects given digoxin found that the addition of etoricoxib 120 mg daily for 10 days did not alter the steady-state AUC of digoxin or its renal elimination, but the maximum serum digoxin levels were increased by about 33%. This change is unlikely to be clinically relevant in most patients but it might possibly affect a very small number whose digoxin levels are already high.

(d) Fenbufen

Fenbufen 900 mg daily was found to cause an insignificant rise in the serum levels of digoxin.

(e) Ibuprofen

The serum digoxin levels of 12 patients were reported to have risen by about 60% after they were given at least 1.6 g of ibuprofen daily for a week. However, after a month the digoxin levels had returned to their former amount. These findings may be unreliable because half of the patients were not satisfactorily compliant with treatment. Another study found that ibuprofen 1.2 g daily for 10 days raised the serum digoxin levels of 9 healthy subjects by 25%. Yet another study found that ibuprofen 600 mg three times daily for 10 days had no effect on steady-state serum digoxin levels of 8 patients.

(f) Indomethacin

1. Neonates. A study in 11 premature neonates (gestational age 25 to 33 weeks) given digoxin showed that when they were given indomethacin (mean total dose of 320 micrograms/kg over 12 to 24 hours) for patent ductus arteriosus, their mean serum digoxin levels rose on average by 40%. The digoxin was stopped in 5 of them because serum levels were potentially toxic. This confirms the observation of digitalis toxicity in 3 similarly treated premature neonates, and of toxic serum digoxin levels in another neonate. A further report describes very high digoxin levels (8.2 nanograms/mL) without symptoms of toxicity in a full-term neonate given indomethacin.

2. Adults. Indomethacin 50 mg three times daily for 10 days increased steady-state digoxin levels of 10 patients by about 40% (from 0.57 to 0.8 nanograms/mL), with a range of 0 to 100%. Indomethacin 150 mg daily for 10 days increased the serum digoxin levels of 9 healthy subjects by 25%. In yet another study, a 60% increase in digoxin levels was seen with indomethacin 150 mg daily. This contrasts with the results of single-dose studies in 2 groups of 6 healthy adult subjects, who were given a 4-hour infusion of digoxin. Both studies suggested that no interaction occurs with indomethacin.

(g) Isoxicam

Isoxicam 200 mg daily did not affect the steady-state plasma levels of 12 healthy subjects taking beta-acetyldigoxin. This confirms the findings of a previous study.

(h) Ketoprofen

Ketoprofen 50 mg four times daily for 4 days had no effect on the serum digoxin levels of 12 patients.

(i) Lornoxicam

In 12 healthy subjects the concurrent use of lornoxicam 4 mg twice daily for 14 days and digoxin 250 micrograms daily had only a small effect on the pharmacokinetics of each drug. The apparent clearance of the digoxin was decreased by 14% while the maximum serum level of the lornoxicam was decreased by 21% and its elimination half-life increased by 36%.

(j) Meloxicam

Meloxicam 15 mg daily for 8 days had no effect on the pharmacokinetics of digoxin (given as beta-acetyldigoxin) in 12 healthy subjects.

(k) Nimesulide

Nimesulide 100 mg twice daily for 7 days had little effect on the pharmacokinetics of digoxin 250 micrograms daily in 9 patients with mild heart failure. No major change in their clinical condition occurred.
proximate 30% reduction in dietary fat absorption induced by orlistat will be needed in patients who are given both drugs. Information seems to be limited to the reports cited. Patients taking digoxin should be checked for signs of under-digitalisation if penicillamine is administered. Evidence suggests that the influence of reduced dietary fat absorption induced by orlistat on the pharmacokinetics of digoxin in healthy volunteers. Dr. J Clin Pharm (1993) 40, 1516–21.

A study in healthy subjects found that rosiglitazone 8 mg once daily for 14 days had no effect on the steady-state pharmacokinetics of digoxin 250 micrograms daily. However, the US manufacturers advise caution with the use of pioglitazone or rosiglitazone in those with a history of heart failure because it may cause fluid retention which could lead to a deterioration in cardiac function. For the same reason the UK manufacturers contraindicate use in heart failure. If digitalis glycoside + pioglitazone or rosiglitazone is being used to treat cardiac failure, the use of pioglitazone or rosiglitazone would not therefore be recommended. This is not a drug-drug interaction but a drug-disease interaction.

### Digitalis glycosides + Pioglitazone or Rosiglitazone

**Clinical evidence**

A study in healthy subjects found that rosiglitazone 8 mg once daily for 14 days had no effect on the steady-state pharmacokinetics of digoxin 250 micrograms daily. However, the US manufacturers advise caution with the use of pioglitazone or rosiglitazone in those with a history of heart failure because it may cause fluid retention which could lead to a deterioration in cardiac function. For the same reason the UK manufacturers contraindicate use in heart failure. If digitalis glycoside + pioglitazone or rosiglitazone is being used to treat cardiac failure, the use of pioglitazone or rosiglitazone would not therefore be recommended. This is not a drug-drug interaction but a drug-disease interaction.

500 micrograms) twice daily for 3 days, their plasma digoxin levels were slightly but not significantly raised (from 0.67 to 0.7 nanograms/mL, and from 0.6 to 0.67 nanograms/mL, respectively). A study in 6 healthy subjects found that probenecid 2 g daily for 8 days had no significant effect on the pharmacokinetics of digoxin. No special precautions would seem necessary during concurrent use.

**Digitalis glycosides + Propafenone**

Propafenone can increase serum digoxin levels by 30 to 90% or even more in children.

**Clinical evidence**

Propafenone (increasing over 6 days to 300 mg every 8 hours) increased the mean steady-state serum levels of digoxin 125 to 250 micrograms daily by 83% in 5 patients. Three patients continued to take both drugs for 6 months, at which point the digoxin levels were 63% higher. No digitalis toxicity was seen. In another study, propafenone 600 mg daily in divided doses increased the steady-state serum digoxin levels of 10 patients by 90% (from 0.97 to 1.54 nanograms/mL), and two of them developed symptoms of toxicity (nausea, vomiting). An even greater increase was seen in 3 children who showed rises in serum digoxin levels of 112 to 254% over 3 to 24 days when given propafenone 250 to 500 mg/m² daily. The mean AUC of digoxin increased by 13.8% in 27 patients receiving propafenone 10 mg/kg daily in divided doses. However, there was great inter-individual variability, with 22 patients showing an increase in AUC, and 5 a decrease. One patient experienced digoxin toxicity resulting in fatal ventricular fibrillation.

Propafenone 450 mg daily increased the mean steady-state serum digoxin levels of 12 healthy subjects by about 35% (from 0.58 to 0.78 nanograms/mL), and the cardiac effects were increased accordingly. In a study in 6 subjects given a single 1-mg intravenous dose of digoxin, propafenone 150 or 300 mg every 8 hours increased the AUC of digoxin by 28% and decreased the total clearance of digoxin by 21.9%. A similar study with oral digoxin found a 25% increase in the AUC of digoxin when healthy subjects were given propafenone.

**Mechanism**

Not understood. One suggestion is that propafenone increases the bioavailability of the digoxin. Another is that the volume of distribution and non-renal clearance of digoxin are changed by the propafenone. Conversely, others reported that propafenone decreased the renal clearance of digoxin. There is certainly some in vitro evidence that propafenone and its metabolite inhibit the P-glycoprotein transporter, which is concerned with digoxin secretion by the renal tubular cells.

**Importance and management**

A very well established interaction of clinical importance. Monitor the effects of concurrent use and reduce the digoxin dosage appropriately in order to avoid toxicity. Most patients appear to be affected and dosage reductions in the range of 15 to 70% were found necessary in one of the studies cited. The data available suggest that the extent of the rise may possibly depend on the propafenone serum concentration rather than on its dose.

**Digitalis glycosides + Prostaglandins**

Iloprost does not significantly alter digoxin pharmacokinetics. Epoprostenol caused a small decrease in digoxin clearance in the short-term, which is of uncertain clinical importance.

**Clinical evidence, mechanism, importance and management**

A 6-hour intravenous infusion of iloprost 2 nanograms/kg per minute was given to 12 patients taking digoxin 250 micrograms daily over a period of 20 days. The mean time to maximum serum digoxin levels was delayed by an hour, but overall the pharmacokinetics of the digoxin were unchanged. No special precautions would seem to be necessary on concurrent use.

The digoxin clearance of 14 patients with congestive heart failure was reduced by an estimated 15% by epoprostenol given for 3 days, but this effect was no longer apparent by the end of 12 weeks concurrent use. However, the authors of the report suggest that the possible short-term changes in patients with high trough-serum digoxin levels and those...
prone to digoxin toxicity should be borne in mind when using the combination.  

### Digitalis glycosides + Proton pump inhibitors

A small rise in serum digoxin levels may occur with omeprazole, pantoprazole or rabeprazole, but this is not thought to be clinically significant. One case of digoxin toxicity has been reported with omeprazole.

#### Clinical evidence

(a) Lansoprazole

A study in 47 patients regularly taking digoxin and either lansoprazole or omeprazole found that changing the proton pump inhibitor to an equivalent dose of rabeprazole did not significantly change the mean serum digoxin level, although 12 of the patients had increases of more than 15%.

(b) Omeprazole

In a study in healthy subjects, omeprazole 20 mg daily for 11 days caused only minor changes in the disposition of a single 1 mg oral dose of digoxin. On average the AUC was increased by 10%. See also Lansoprazole, above. However, a 65-year-old woman showed signs of digoxin toxicity 3 months after starting to take omeprazole 20 mg daily. She was found to have a digoxin level of 3.9 nanograms/mL (previous level 0.9 nanograms/mL the addition of quinidine is unlikely to cause toxic digital. 

(c) Pantoprazole

Beta-acetyldigoxin 200 micrograms twice daily was given to 18 healthy subjects, with and without pantoprazole 40 mg daily, for 5 days. The pantoprazole caused a 10% rise in the digoxin AUC and a 9% rise in the maximum digoxin serum levels, but both were considered to be clinically irrelevant. No changes in the digoxin-induced height reduction in the T-wave occurred. 

(d) Rabeprazole

A preliminary report, giving few details, states that rabeprazole increased the minimum digoxin levels by about 20%, and increased the AUC and maximum levels. The US manufacturer states that rabeprazole increased the AUC and maximum level of digoxin by 19%, and 29%, respectively.

However, these changes are thought to be within the normal variations of digoxin levels and so are not considered clinically significant. 

See also Lansoprazole, above.

#### Mechanism

The increase in digoxin levels with omeprazole may be the result of higher gastric pH which results in less digoxin hydrolysis and an increase in digoxin absorption. Non-selective digoxin assay methods may fail to detect an interaction, whereas selective HPLC assay methods and ECG studies provide evidence that the bioavailability of digoxin may be increased by omeprazole.

An in vitro study found that omeprazole, pantoprazole and lansoprazole inhibit P-glycoprotein-mediated intestinal transport of digoxin.

#### Importance and management

Although some studies suggest small changes in digoxin pharmacokinetics may occur these changes are usually small and unlikely to be clinically significant. No special precautions would therefore seem to be necessary if proton pump inhibitors and digoxin are given concurrently.

### Digitalis glycosides + Quinidine

In most patients, on average, the serum levels of digoxin doubled within five days of starting quinidine. The digoxin dosage usually needs to be halved if toxicity is to be avoided. Digoxin levels are also increased but to a lesser extent and takes a longer period of time to develop.

#### Clinical evidence

(a) Digoxin

Quinidine 750 mg daily increased the steady-state serum digoxin levels of 8 healthy subjects by 45%, from 13.6 to 19.7 nanograms/mL, over 32 days. Another study found a 31% increase in serum digoxin levels over 10 days, whereas yet another found a 115% increase after 70 days of treatment with 360 mg quinidine three times daily. A study in 5 healthy subjects found that quinidine reduced the total body clearance of digoxin by 63%, resulting in raised serum digoxin levels.

(b) Digoxin

The observation that quinidine appeared to increase serum digoxin levels prompted a retrospective study of patient records, which revealed that 25 out of 27 patients taking digoxin had shown a significant rise in serum digoxin levels from 1.4 to 3.2 nanograms/mL when given quinidine. Of the patients who showed a rise, 16 showed typical signs of digoxin toxicity (nausea, vomiting, anorexia), which resolved in 10 of them when the digoxin dosage was reduced or withdrawn, and in 5 when the quinidine was withdrawn.

This is one of the first reports published in 1978 (two other groups independently reported it at a similar time) that clearly describes this interaction, although hints of its existence can be found in papers published over the previous 50 years. Since then large numbers of research reports, both retrospective and prospective, and case studies have confirmed and established the incidence and magnitude of this interaction. It occurs in over 90% of patients and, on average, there is a 100% increase in serum digoxin levels, although there are pronounced inter-individual differences, and the increase is somewhat dependent on the quinidine dose. There are numerous reports and reviews of this interaction, only a selection of which are listed here. Two reviews published in 1982 and 1983 contain valuable bibliographies.

#### Mechanism

Quinidine reduces the renal excretion of digoxin by 40 to 50%, and it also appears to have some effects on non-renal clearance, which includes a reduction in digoxin excretion in the bile. There is also evidence that the mechanism behind these effects on absorption and renal excretion is likely to be P-glycoprotein inhibition by quinidine. Digoxin also appears to cause a small reduction in the renal clearance of quinidine. Quinidine appears to increase digoxin serum levels by reducing its non-renal clearance.

#### Importance and management

The interaction between digoxin and quinidine is very well-documented, well-established and of definite clinical importance. Since serum digoxin levels are usually roughly doubled (up to fivefold increases have been seen) and over 90% of patients are affected, digitalis toxicity will develop unless the dosage of digoxin is reduced (approximately halved). A suggested rule of thumb is that if serum digoxin levels are no greater than 0.9 nanograms/mL the addition of quinidine is unlikely to cause toxic di-
digoxin levels (if serum potassium levels are normal) whereas with levels of 1 nanogram/mL or more, toxic concentrations may develop.18 Monitor the effects and adjust the dosage as necessary. Significant effects occur within a day of taking the quinidine and reach a maximum after about 3 to 6 days (quicker or slower in some patients), but digoxin levels will only stabilise when the quinidine has reached steady-state and that depends on whether a loading dose of quinidine is given. The effects are to some extent dose-related but the correlation is not good: less than 400 to 500 mg of quinidine daily has minimal effects, and increasing doses up to 1.2 g has greater effects.16,19 About 5 days are needed after withdrawing the quinidine before serum digoxin levels fall to their former levels. It has been recommended that patients with chronic renal failure should have their digoxin dosage reduced by as much as two-thirds.20-22 An appropriate upward readjustment will be necessary if the quinidine is subsequently withdrawn.

Far less is known about the interaction between digitoquinine and quinidine but similar precautions should be taken. It develops much more slowly.1

19. Fenster PE, Powell JR, Hager WD, Graves PE, Conrad KA, Goldman S. Effect of quinidine on intestinal microflora is unlikely.1

The digoxin levels of some but not all patients may rise by more than 60% if they are given quinidine.

Clinical evidence
After taking quinine 300 mg four times daily for a day the steady-state digoxin levels of 4 subjects taking digoxin 250 micrograms daily rose by 63%, from 0.49 to 0.8 nanograms/mL. After taking the quinine for a further 3 days the digoxin levels rose a further 11% (to 0.86 nanograms/mL). Digoxin renal clearance fell by 20%.1

Quinine sulfate 250 mg daily for 7 days increased the mean serum digoxin levels of 7 healthy subjects by 25%, from 0.64 to 0.8 nanograms/mL. When quinine sulfate 250 mg was given three times daily there was a further 8% rise. Considerable individual differences were seen; one subject had a 92% rise.2 In contrast, 17 patients given quinine 750 mg daily had only a small and statistically insignificant rise in mean serum digoxin levels, from 0.8 to 0.91 nanograms/mL. Serum levels were virtually unaffected in 11 patients, decreased in two and markedly increased (amount not stated) in four.3 Another study found that quinine reduced the total clearance of digoxin by 26%.4

Mechanism
Not fully understood. A reduction in non-renal clearance is apparently largely responsible for the rise in serum digoxin levels with quinine.5,3 This is possibly due to changes in digoxin metabolism or in its biliary excretion.5,4

Importance and management
An established interaction of clinical importance but only moderately documented. Monitor the effects of concurrent use (e.g. for bradycardia) and reduce the digoxin dosage where necessary. Some patients may have a substantial increase in serum digoxin levels whereas others will have only a small or moderate rise. There appear to be no case reports of digoxin toxicity arising from this interaction.

Digitalis glycosides + Quinolones
Levofloxacin, gemifloxacin, moxifloxacin and sparfloxacin do not affect the pharmacokinetics of digoxin. Similarly moxifloxacin does not interact with beta-acteyldigoxin. Gatifloxacin may cause small increases in digoxin levels, which are probably not clinically significant. The effects of garenoxacin are unclear.

Clinical evidence
(a) Garenoxacin
In a study designed to look at the effects of garenoxacin on gut flora, 16 healthy subjects were given digoxin 250 micrograms every 6 hours on day 1, then 250 micrograms daily to day 14, with garenoxacin 600 mg daily on days 8 to 14. Garenoxacin did not decrease (but may actually increase) the numbers of Escherichia coli in faeces (see ‘Digitalis glycosides + Macrolides’, p.929, for an explanation of the possible significance of these findings). Thus an interaction due to the effect of garenoxacin on intestinal microflora is unlikely.1

(b) Gatifloxacin
The vital signs of 12 healthy subjects given gatifloxacin 400 mg daily for 7 days while taking digoxin 250 micrograms daily were not altered. The AUC and steady-state levels of digoxin were increased by 19% and 12% respectively. Dosage adjustments were not considered necessary.2

(c) Gemifloxacin
No clinically relevant pharmacokinetic changes were seen in a study in 14 healthy elderly subjects given gemifloxacin 320 mg daily for 7 days while taking digoxin (Lanoxin) 250 micrograms daily. No clinically important changes in vital signs or ECGs were found.3

(d) Levofloxacin
The pharmacokinetics of a single 400-microgram dose of digoxin (Lanoxin) were unchanged when 12 healthy subjects were given levofloxacin 500 mg twice daily for 6 days.4

(e) Moxifloxacin
In 14 healthy subjects, moxifloxacin 400 mg daily for 14 days did not cause any clinically relevant changes in the steady-state pharmacokinetics of digoxin 250 micrograms daily.5 No pharmacokinetic changes were seen in another study in 12 healthy subjects given a single 600-microgram dose of beta-acteyldigoxin with moxifloxacin 400 mg daily for 2 days.6

(f) Sparfloxacin
Sparfloxacin, 400 mg as a loading dose, followed by 200 mg daily for 9 days did not affect the pharmacokinetics of digoxin (Lanoxin) 300 micrograms daily in 24 healthy subjects.7
Mechanism, importance and management

Information about other digitalis glycosides and quinolines seems to be lacking, but bearing in mind their extensive use, this silence in the literature would suggest that no problems normally arise. Despite in vitro susceptibility of E. lentum to a range of antibacterials including some quinolones there is currently no information to suggest such an interaction occurs between the quinolones and digoxin. 8 See ‘Digitalis glycosides + Macrolides’, p.929, for an explanation of the possible significance of E. lentum.

8. Ten Eick AP, Reed MD. Hiddent dangers of coadministration of antibiotics and digoxin. 98 See ‘Digitalis glycosides + Rifamycins’, p.929, for an explanation of the possible significance of rifampicin.

Clinical evidence

A comparative study in 21 patients with tuberculosis and 19 healthy subjects taking digoxin 100 micrograms daily found that the serum digoxin levels of the patients taking rifampicin (rifampin) were about half of the levels in healthy subjects not taking rifampicin (18.4 nanograms/mL compared with 39.1 nanograms/mL). 1 The half-life of digoxin was reduced from 8.2 to 4.5 days by the rifampicin. There are case reports confirming that rifampicin can markedly reduce serum digoxin levels.

Digitalis glycosides + Rifamycins

The serum levels of digoxin can be halved by rifampicin (rifampin). Digoxin serum levels are modestly reduced by rifampicin.

Clinical evidence

(a) Digoxin

A comparative study in 21 patients with tuberculosis and 19 healthy subjects taking digoxin 100 micrograms daily found that the serum digoxin levels of the patients taking rifampicin (rifampin) were about half of the levels in healthy subjects not taking rifampicin (18.4 nanograms/mL compared with 39.1 nanograms/mL). 1 The half-life of digoxin was reduced from 8.2 to 4.5 days by the rifampicin. There are case reports confirming that rifampicin can markedly reduce serum digoxin levels.

(b) Digoxin

A woman, hospitalised for endocarditis, taking digoxin 250 to 375 micrograms daily, furosemide, aspirin, isosorbide dinitrate and potassium chloride, had a marked fall of about 80% in her serum digoxin level when she was given rifampicin 600 mg daily. The serum digoxin returned to its former level over the 2 weeks following rifampicin withdrawal. 4 She had only moderate renal impairment (serum creatinine 221 micromol/L).

Another report describes 2 patients undergoing renal dialysis whose digoxin dosage needed to be doubled while they were taking rifampicin, and similarly reduced when the rifampicin was withdrawn. 5 This confirms an earlier report. 6

A study in 8 healthy subjects found that the AUC and maximum plasma levels of a single 1-mg oral dose of digoxin were reduced by 50% and 52%, respectively, by rifampicin 600 mg daily for 10 days. 7 In two further studies in which rifampicin 300 mg twice daily for 7 days was used as a positive control, the AUC of a single oral dose of digoxin was reduced by 16%, and the maximum levels were reduced by about 25%. 8,9

A 15% reduction in the AUC and maximum plasma levels of digoxin was seen when a single 1-mg intravenous dose of digoxin was given after pre-treatment with rifampicin 600 mg daily for 10 days. 10 Similarly, a study of 8 healthy subjects who were given a single 1-mg intravenous dose of digoxin after 14 days of treatment with rifampicin 600 mg daily found an increased excretion of digoxin into the bile, and a 27% reduction in the AUC of digoxin. 11

Mechanism

The interaction between digoxin and rifampicin is almost certainly due to the increase in digoxin metabolism caused by rifampicin, which is a potent enzyme inducer. 1 Digoxin is largely excreted unchanged in the urine and the interaction with rifampicin appears to be mainly due to induction of P-glycoprotein, resulting in reduced digoxin absorption from the intestine, 10 increased biliary excretion. 10

Importance and management

The interaction between digoxin and rifampicin is established and clinically important. Under-digitalisation may occur unless the digitoxin dosage is increased appropriately. Good monitoring is obviously advisable. The pharmacokinetic interaction with digoxin is also established, but rifampicin causes only a minor to modest reduction in digoxin levels, and the few case reports suggest these changes are generally not clinically relevant. However, it would be prudent to monitor the concurrent use of these drugs, being alert for the need to increase the digoxin dosage. It may
be that renal impairment increases the extent of this interaction, as several of the cases cited involved patients with some degree of renal impairment.

There does not seem to be any information regarding the other rafibutins, rifabutin (a weak enzyme inducer) and rifapentine (a moderate enzyme inducer). However, the UK manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including digitalis (but not digoxin).1,12

Digitalis glycosides + Rifampicin

A woman had elevated serum digoxin levels and signs of toxicity after she was given rifampicin. Pharmacokinetic studies have shown that rifampicin causes modest to marked increases in single-dose digoxin levels.

Clinical evidence

A 61-year-old HIV-positive woman taking lamivudine, indinavir, stavudine, pentamidine, warfarin with digoxin 250 micrograms daily for atrial fibrillation, presented with increasing nausea and vomiting 3 days after starting to take rifampir 200 mg twice daily. Digoxin levels after 5 and 27 hours after her last dose were 5.6 nanograms/mL and 2.1 nanograms/mL, respectively.1

A study in 12 healthy subjects found that rifampicin 300 mg twice daily for 11 days significantly increased the AUC and volume of distribution of a single 500-microgram intravenous dose of digoxin by 86% and 77%, respectively. Non-renal and renal digoxin clearance were decreased by 48% and 35%, respectively, and its half-life increased by 156%.2 Another study found that rifampicin 200 mg twice daily for 15 days increased the AUC of a single 400-microgram oral dose of digoxin by 22%, with 9 of 12 subjects having an increase. Non-renal but not renal clearance was reduced.3

Mechanism

Raised digoxin levels are possibly due to inhibition of the P-glycoprotein-mediated renal transport of digoxin by rifampicin.1,3

Importance and management

A pharmacokinetic interaction between rifampicin and digoxin would appear to be established, although its extent is uncertain. The study with intravenous digoxin showed a marked effect, whereas the study with oral digoxin showed a much smaller effect. Nevertheless, given the case report, it would seem prudent to closely monitor patients taking digoxin when rifampicin is started or stopped. There do not appear to be any reports or studies of the interaction of digoxin with other protease inhibitors.

Digitalis glycosides + Sevelamer

The pharmacokinetics of single doses of digoxin are not affected by sevelamer.

Clinical evidence, mechanism, importance and management

In a randomised study a single 1-mg oral dose of digoxin was given with or without sevelamer 2.4 g followed by a standard breakfast. Five further doses of sevelamer were given immediately before subsequent meals over the following 2 days. During this time, the pharmacokinetic profile of digoxin was not altered.1

Sevelamer is a non-absorbed phosphate-binding polymer with bile-acid binding properties. Because the bile-acid binding resins ’colestipol’, (p.919) and ‘colestipol’, (p.918) may interact with digoxin, it was suggested that sevelamer could also interact, although this does not appear to be the case. This finding requires confirmation in long-term studies.

Digitalis glycosides + SSRIs

Citalopram, fluvoxamine, paroxetine, and sertraline appear not to affect the pharmacokinetics of digoxin. However, one case-control study found a small increased risk of digoxin toxicity after starting sertraline, paroxetine, fluvoxamine or fluvoxamine, and two isolated reports describe increased serum digoxin levels attributed to the use of fluoxetine or paroxetine.

Clinical evidence

A study in 11 healthy subjects found that citalopram 40 mg once daily for 28 days did not have any significant effect on the pharmacokinetics of a single 1-mg dose of digoxin taken on day 21. No clinically significant ECG changes were observed.1

After taking fluvoxamine 100 mg daily for 15 days, the pharmacokinetics of a single 1.25-mg intravenous dose of digoxin were unchanged in 8 healthy subjects.2

A study in healthy subjects found that paroxetine 30 mg daily had no effect on the pharmacokinetics of digoxin 250 micrograms daily. The pharmacokinetics of paroxetine were unaffected by digoxin.3

A placebo-controlled study in 19 healthy subjects found that sertraline, in an initial dose of 50 mg daily titrated to 200 mg daily, had no effect on the steady-state pharmacokinetics of digoxin, except for a decrease in time to maximum plasma levels.4
However, in a case-control study in 3144 patients who had been admitted to hospital with digoxin toxicity, these patients were significantly more likely than controls to have received a new prescription for sertraline, fluoxetine, fluvastatin, or paroxetine in the 30 days prior to admission (adjusted odds ratios, 3.29, 3.2, 2.8, and 2.6, respectively). This was after adjusting for renal disease and other interacting drugs. Nevertheless, this increased risk was not statistically significantly different to that in patients taking tricyclics (1.5) or benzodiazepines (2.1), which the authors considered have no known basis for an interaction (see ‘Digitalis glycosides + Benzodiazepines and related drugs’, p.911). In addition, it was small compared with the 12-fold increased risk found by the same authors in a similar study5 of ‘clarithromycin’, (p.929).

An isolated report describes a 93-year-old woman with congestive heart failure who developed increased serum digoxin levels on two occasions when fluoxetine was added.6 Another case report describes digoxin toxicity in a 68-year-old woman with atrial fibrillation and depression, which was attributed to the addition of paroxetine 20 mg daily. Her digoxin levels reached 5.2 nanograms/mL.7

Mechanism

It has been suggested that paroxetine might inhibit P-glycoprotein leading to reduced renal excretion of digoxin.7 This suggestion has been criticised by other authors who propose that the increase in levels seen in the case with paroxetine may be due to hospital-induced compliance or renal impairment.8,9 Moreover, the case-control study found no evidence of a significantly different risk of digoxin toxicity between those SSRIs with greater P-glycoprotein inhibitory activity (sertraline and paroxetine) than those with less (fluoxetine, fluvoxamine).3

Importance and management

The pharmacokinetic studies show that it is unlikely that, in general, SSRIs will affect the steady-state serum levels of digoxin. The excess risk seen in the case-control study was considered to be small and related to detection bias or confounding by indication,2 although the findings do introduce a note of caution. Nevertheless, the fact that there are only isolated case reports of possible interactions with digoxin for such a widely used class of drugs suggests that problems are rarely encountered. No special precautions would seem to be necessary.

Digitalis glycosides + Statins

Atorvastatin, fluvastatin and simvastatin cause small but probably clinically unimportant increases in the serum levels of digoxin. Pravastatin and rosuvastatin appear to have no effect on digoxin pharmacokinetics.

Clinical evidence

(a) Atorvastatin

Digoxin 250 micrograms daily was given to 24 healthy subjects for 10 days, with atorvastatin 10 or 80 mg daily for a further 10 days. The mean steady-state digoxin levels were unaffected by atorvastatin 10 mg, but atorvastatin 80 mg caused a 20% rise in maximum digoxin levels and a 15% rise in its AUC.1

(b) Fluvastatin

In a crossover study in 18 patients, fluvastatin 40 mg caused no significant changes in the pharmacokinetics of digoxin 100 to 375 micrograms daily.2 Another similar study in patients found changes of up to 15% in maximum plasma digoxin levels and clearance, but these were not considered to be clinically relevant.3

(c) Pravastatin

Pravastatin 20 mg daily for 9 days had no significant effect on the steady-state levels of digoxin 200 micrograms daily in 18 healthy subjects.4

(d) Rosuvastatin

In a randomised study, 18 healthy subjects were given rosuvastatin 40 mg daily or placebo for 12 days, with a single 500-microgram dose of digoxin on day 8. The absorption, renal excretion, AUC and maximum serum levels of digoxin were unaffected by rosuvastatin.5

(e) Simvastatin

Plasma digoxin levels can be slightly raised, by about 0.3 nanograms/mL, by simvastatin but this appears to be of little or no clinical importance.6

Mechanism

The small changes seen in digoxin levels are probably due to the inhibitory effects of these statins on P-glycoprotein. Pravastatin does not appear to inhibit P-glycoprotein.7

Importance and management

The small changes seen in the digoxin levels with statins seem unlikely to be clinically relevant in most patients.

Digitalis glycosides + Sucralfate

Sucralfate caused only a small reduction in the absorption of digoxin in one study, but an isolated report describes a marked reduction in one patient.

Clinical evidence

Sucralfate 1 g four times daily given to 12 healthy subjects for 2 days had no effect on most of the pharmacokinetics of a single 750-microgram dose of digoxin; however, the AUC was reduced by 19% and the amount of digoxin eliminated in the urine was reduced by 12%. Digoxin was also absorbed faster.1 No interaction occurred when the digoxin was given 2 hours before the sucralfate.1 One elderly patient is reported to have had subtherapeutic serum digoxin levels while taking sucralfate, even though the dosages were separated by 2 hours.2

Mechanism

Uncertain. One possibility is that the digoxin and sucralfate bind together in the gut, which reduces the digoxin absorption.

Importance and management

Information appears to be limited to the reports cited. The reduction in digoxin levels reported in the study is small and therefore normally unlikely
to be clinically relevant, but the unexplained and isolated case suggests that clinicians should at least be aware of the possibility of an interaction.

## Digitalis glycosides + Surfactant excipients

Non-ionic surfactants used as pharmaceutical excipients such as polyoxyl castor oil (Cremophor) may slightly enhance the absorption of digoxin.

### Clinical evidence, mechanism, importance and management

A placebo-controlled study in 12 healthy subjects found that polyoxyl castor oil (Cremophor RH40) 600 mg three times daily increased the AUC0-5 and peak plasma levels of a single 500-microgram oral dose of digoxin by about 22%. The absorption of digoxin was delayed. The pharmacodynamic effects of digoxin were not affected by Cremophor. It was suggested that Cremophor increases digoxin plasma levels by inhibiting intestinal P-glycoprotein, or that the Cremophor prolongs the dissolution of digoxin tablets resulting in delayed absorption from the intestines.1

Other surfactants inhibit P-glycoprotein mediated intestinal transport and an *in vitro* study found that the order of effectiveness for enhanced intestinal uptake of digoxin (starting with the most effective) was Labrasol, Inwitor 742, Aczone E, Softigen 767, Cremophor EL, Miglyol, Soludol HS 15, Sucrose monolaurate, Polysorbate 20, TPGS, Polysorbate 80.2 See also ‘Digitalis glycosides + Vitamin E substances’, p.943.

## Digitalis glycosides + Tegaserod

Tegaserod slightly reduces the AUC of digoxin, but this is unlikely to be clinically relevant.

### Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given tegaserod 6 mg twice daily for 5 days found that the time to peak levels of a single 1-mg dose of digoxin on day 4 was reduced by 30 minutes, and the mean AUC and maximum plasma concentrations were slightly reduced by 11.9% and 15%, respectively.1 These small changes are unlikely to be clinically relevant. Note that the manufacturer has discontinued marketing of tegaserod in the US because of a finding of an excess of serious cardiovascular ischaemic events.2

## Digitalis glycosides + Tetracycline

Limited early evidence suggested that tetracycline may cause a rise in serum digoxin levels.

### Clinical evidence

A patient taking digoxin tablets 500 micrograms daily was given tetracycline 500 mg every 6 hours for 5 days. His urinary excretion of digoxin metabolites (see Mechanism, below) fell sharply within 2 days, and his steady-state serum digoxin levels rose by 43%.1 Another subject had a marked fall in the excretion of digoxin metabolites from the gut after taking tetracycline.2

In one study, tetracycline prolonged the half-life of digoxin and increased serum levels from 1.7 to 2.9 nanograms/mL.3

### Mechanism

Uncertain. Up to 10% of patients taking oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be performed by the gut flora,1 in particular *Eubacterium lentum*, which is anaerobic and Gram positive.2,4 In the presence of some antibacterials, such as tetracycline, which can inhibit this organism, more digoxin becomes available for absorption, which results in a rise in serum levels. At the same time the inactive metabolites derived from the gut disappear.2 However, this is not necessarily the full explanation, see also ‘Digitalis glycosides + Macrolides’, p.929.

### Importance and management

The interaction between digoxin and tetracycline is not well established, the evidence is very limited, and its general clinical importance is uncertain. Bear this interaction in mind in case of an unexpected response to digoxin.

## Digitalis glycosides + Thyroid hormones and Antithyroid drugs

**Thyrotoxic patients** are relatively resistant to the effects of digitalis glycosides and may need reduced doses as treatment with antithyroid drugs (carbimazole, thiamazole) progresses, whereas patients with hypothyroidism may need increased doses of digitalis glycosides as treatment with thyroid hormones progresses. Carbimazole has been shown to reduce serum digoxin in healthy subjects.

### Clinical evidence

**(a) Carbimazole**

The observation of relatively low plasma digoxin levels in a patient taking carbimazole prompted a further study in 10 healthy subjects. In 9 out of the 10, steady-state peak serum digoxin levels were reduced by 23% (from 1.72 to 1.33 nanograms/mL) by a single 60-mg dose of carbimazole, but in the other subject the serum digoxin levels were increased. Other pharmacokinetic parameters were unaffected.

Carbimazole abolished the systolic blood pressure decrease seen in the first 3 hours with digoxin, and also reduced the duration of the digoxin-induced diastolic blood pressure fall from 12 to 6 hours. The changes in heart rates, cardiac output and stroke volumes were not statistically significant, but inter-individual differences were large.1,3

**(b) Thiamazole**

A study in 12 patients with hyperthyroidism found that normalisation of serum T3 and T4 by thiamazole treatment did not produce significant changes in the pharmacokinetics of digoxin.4

### Mechanism

One explanation for the changed response to digitalis with carbimazole is that there is a direct and altered response of the heart due to the raised or lowered thyroid hormone levels. Another is that changes in glomerular filtration rate associated with hypo- or hyperthyroidism result in increased or decreased serum digoxin, respectively.4 Why carbimazole reduced serum digoxin in healthy subjects (normal thyroid status) is not known.

### Importance and management

As thyroid status is returned to normal by the use of drugs (antithyroid drugs or thyroid hormones), the dosage of the digitalis glycosides may need to be adjusted appropriately. Hyperthyroid patients may need to have their digitalis dosage gradually reduced as treatment proceeds (because initially they are relatively resistant to the effects of digitalis and start off needing higher doses). They are also relatively insensitive to the chrono-
tropic effects of digitalis. Hypothyroid patients on the other hand may need a gradually increasing dosage (because initially they are relatively sensitive to digitalis). In either of these situations it would be prudent to monitor serum digoxin levels and haemodynamic effects of digoxin in healthy subjects. Eur J Clin Pharmacol (1995) 49, A159.

Digitalis glycosides + Ticlopidine

In 15 subjects ticlopidine 250 mg twice daily for 10 days reduced the peak serum levels and AUC of digoxin by about 10%. This reduction is small and unlikely to be of clinical importance.

Digitalis glycosides + Tiludronate

Tiludronate does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that tiludronate, 600 mg daily for 2 days then 400 mg daily for the next 10 days, caused no significant changes in the pharmacokinetics of digoxin 250 micrograms daily. No special precautions appear to be needed.

Digitalis glycosides + Urapidil

Urapidil does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects urapidil 60 mg twice daily on days 5 to 8 had no significant effects on the serum levels of digoxin 250 micrograms twice daily on day one, then 250 micrograms daily on days 2 to 8. Blood pressures and pulse rates were not significantly changed. No special precautions seem necessary if both drugs are given.

Digitalis glycosides + Valaciclovir

Valaciclovir appears not to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study, 12 healthy subjects were given 1 g of oral valaciclovir alone, two 750-microgram doses of digoxin alone, valaciclovir 1 g after the second of two 750-microgram doses of digoxin given 12 hours apart, and finally valaciclovir 1 g three times daily for 8 days starting 12 hours before the first digoxin dose. It was found that no clinically significant changes occurred in the pharmacokinetics of either drug and no ECG changes were seen and it was
therefore concluded that no dosage adjustments of either drug are needed if they are given concurrently.\(^1\) Since valaciclovir is a prodrug of aciclovir, it also seems unlikely that an interaction will occur between aciclovir and digoxin. Information about aciclovir and other analogues of aciclovir seems to be lacking.

**Digitalis glycosides + Valspodar**

Valspodar increases the AUC of digoxin two to threefold.

**Clinical evidence, mechanism, importance and management**

Twelve healthy subjects were given digoxin 1 mg on day 1, followed by 125 micrograms daily for the next 10 days. Starting on day 7 they were also given a single 400-mg dose of valsopad, followed by valsopad 200 mg twice daily for the following 4 days. The steady-state digoxin AUC was increased by 76% after the first valsopad dose, and by the end of valsopad dosing it had increased by 211%. This was apparently due to a 73% reduction in digoxin renal clearance and a 58% reduction in nonrenal clearance, probably because of reduced tubular secretion, reduced biliary elimination, and increased intestinal absorption caused by P-glycoprotein inhibition. No symptoms of digitalis toxicity were seen and there were no changes in vital signs or ECG parameters.\(^1\)

Information seems to be limited to this study in healthy subjects but it suggests that the digoxin dosage should be reduced if valsopad is given. An initial 50% reduction has been suggested.

**Digitalis glycosides + Vancomycin**

In one early study, vancomycin prolonged the half-life of digoxin and increased its serum levels from 1.6 to 3 nanograms/mL. It was suggested that this effect might be as a result of reduced renal clearance.\(^1\) This appears to be the only evidence of a possible interaction.

**Digitalis glycosides + Vardenafil**

Vardenafil does not appear to interact with digoxin.

**Clinical evidence, mechanism, importance and management**

In a placebo-controlled study, 19 healthy subjects were given digoxin 375 micrograms daily for 28 days, with vardenafil 20 mg once daily on alternate days from day 16 to day 28. The pharmacokinetics of digoxin were not significantly changed by vardenafil, and there was no alteration in vital signs, ECG readings and laboratory parameters (not stated). The incidence of mild to moderate headache rose slightly from 7 out of 19 with placebo to 13 out of 19 with digoxin.\(^1\) There would appear to be no reason to monitor digoxin levels in patients given vardenafil.

**Digitalis glycosides + Vasodilators**

Sodium nitroprusside or hydralazine infusions can reduce serum digoxin levels, but the importance of this is uncertain. Isosorbide dinitrate did not alter digoxin pharmacokinetics in one study.

**Clinical evidence, mechanism, importance and management**

(a) Hydralazine or Sodium nitroprusside

An experimental study in 8 patients with congestive heart failure found that when they were given either sodium nitroprusside by infusion (7 to 425 micrograms/minute) or hydralazine by intravenous injection (5 mg every 10 to 20 minutes to a total dose of 10 to 60 mg) the total renal digoxin clearance was increased by about 50% by both drugs and the serum digoxin levels were decreased by 20% by the nitroprusside and 11% by the hydralazine.\(^1\)

It is not known whether these changes would be sustained during chronic concurrent use, or the extent to which the digoxin dosage might need to be increased. More study is needed to find out if this interaction is of practical importance.

(b) Isosorbide dinitrate

In a crossover study in 8 patients with chronic heart failure given digoxin 250 micrograms daily for 20 days with isosorbide dinitrate 10 mg three times daily for the last 10 days, there was no change in the mean steady-state concentration, AUC or half-life of digoxin.\(^2\)

**Alpha tocopheril acetate had no effect on digoxin pharmacokinetics, but vitamin E formulations with polyethylene glycol might.**

**Clinical evidence, mechanism, importance and management**

In a study in healthy subjects, alpha tocopheril acetate 400 units twice daily for 15 days did not affect the pharmacokinetics of a single 500-microgram dose of digoxin given on day 15. This was in contrast to a formulation of vitamin E containing polyethylene glycol (alpha tocopheril acid succinate), which altered digoxin pharmacokinetics (amount not stated) without altering its ECG effects.

It was suggested that the effect of polyethylene glycol on digoxin was via P-glycoprotein inhibition,\(^1\) see also ‘Digitalis glycosides + Surfactant excipients’, p.941.

**Zileuton appears not to interact with digoxin.**

**Clinical evidence, mechanism, importance and management**

In a placebo-controlled study, 12 healthy subjects were given zileuton 600 mg every 6 hours for 13 days, with digoxin 250 micrograms daily from days 1 to 11. The zileuton had no effect on the steady-state digoxin pharmacokinetics, although the time to reach maximum plasma levels was reduced from 1.43 to 0.95 hours. Concurrent use was well tolerated.\(^1\) This evidence suggests that no special precautions are needed if these two drugs are used together.

The majority of the interactions of the diuretics appear to be pharmacodynamic in nature, that is, they appear to be due to the combined effects of the diuretic and the other interacting drug. Obvious examples of this would be hypotension caused by the use of a loop diuretic and a beta blocker, or hyperkalaemia caused by an ACE inhibitor and a potassium-sparing diuretic. Some commonly accepted interactions appear to be sparsely documented, most probably because they are perceived to be a predictable effect of using two drugs with similar actions together. ‘Table 26.1’, (below) lists the major diuretic drug groups classified by their effect on potassium. Carbonic anhydrase inhibitors are included under potassium-depleting diuretics, but note that hypokalaemia caused by this type of drug is said to be transient and rarely clinically significant.

Eplerenone, a selective aldosterone antagonist similar to spironolactone, is metabolised by the cytochrome P450 isoenzyme CYP3A4 and is therefore affected by other drugs that are inhibitors or inducers of this enzyme.

The interactions covered in this section are mainly those in which the diuretic is affected. There are many other interactions throughout the publication where diuretics affect the actions of other drugs.

### Acetazolamide + NSAIDs

A case of acute renal failure has been reported in a woman who underwent retinal surgery, which occurred after the postoperative use of a total of 2 g of acetazolamide, 80 g of mannitol and 700 mg of ketoprofen. There appear to be no other similar case reports, but note that ‘loop diuretics’, (p.949) are known to increase the risk of NSAID-induced acute renal failure.

### Acetazolamide + Sodium bicarbonate

Acetazolamide is associated with development of renal calculi and it is claimed that sodium bicarbonate, even on alternate days, potentiates the risk of calculus formation.

### Acetazolamide + Timolol

The use of acetazolamide tablets with timolol eye drops resulted in severe mixed acidosis in a patient with chronic obstructive pulmonary disease.

Clinical evidence, mechanism, importance and management

An elderly man with severe chronic obstructive pulmonary disease was given oral acetazolamide 750 mg daily and timolol maleate 0.5% eye drops, one drop in each eye twice daily, as premedication to reduce ocular hypertension before surgery for glaucoma. Five days later he developed progressively worsening dyspnoea and he was found to have a severe, mixed acidosis. This seems to have been caused by the additive effects of acetazolamide, which blocked the excretion of hydrogen ions in the kidney, and the bronchoconstrictor effects of the timolol, which was absorbed in sufficient amounts to exacerbate the airway obstruction in this patient, and thereby reduced the respiration. This isolated case emphasises the potential risks of using beta blockers, even as non-systemic preparations such as eye drops, in patients with obstructive pulmonary disease. The manufacturers of acetazolamide note that it should be used with caution in those with pulmonary obstruction or emphysema because of the increased risk of acidosis. This is in part, a drug-disease interaction.

### Cyclothiazide/triamterene + Pravastatin

Reversible diabetes mellitus developed in a woman taking cyclothiazide/triamterene when she was also given pravastatin.

Clinical evidence, mechanism, importance and management

A 63-year-old woman who had been taking cyclothiazide/triamterene and acebutolol for 4 years, developed polyuria and polydipsia within 3 weeks of starting to take pravastatin 20 mg daily, which gradually worsened. After another 4 months she was hospitalised for hyperglycaemia, which was treated with insulin and later glibenclamide (glyburide). The cyclothiazide/triamterene and pravastatin were stopped and gradually the diabetic symptoms began to abate. Five weeks after admission she was discharged without the need for any antidiabetic treatment with the diabetes fully resolved. The detailed reasons for this reaction are not understood, but it would seem that the pravastatin increased the hyperglycaemic potential of the thiazide diuretic to the point where frank diabetes developed. This is an isolated case and there would seem to be little reason normally to avoid the concurrent use of these drugs.

### Eplerenone + CYP3A4 inducers

**St John’s wort slightly decreased the AUC of eplerenone. The manufacturer recommends the avoidance of St John’s wort and other stronger inducers of CYP3A4 such as rifampicin because of the possible risk of decreased eplerenone efficacy.**

Clinical evidence, mechanism, importance and management

**St John’s wort** (*Hypericum perforatum*) caused a slight 30% decrease in the AUC of a single 100-mg dose of eplerenone. Eplerenone is metabolised by the cytochrome P450 isoenzyme CYP3A4, and therefore inducers of this isoenzyme, such as *St John’s wort*, would be expected to decrease its levels. In the UK, the manufacturer predicts that a more pronounced decrease in the AUC of eplerenone might occur with stronger CYP3A4 inducers, such as rifampicin (rifampin). Because of the possibility of decreased efficacity, they do not recommend the concurrent use of potent CYP3A4 inducers with eplerenone, and they specifically name carbamazepine, phenytoin, phenobarbital, rifampicin, and *St John’s wort*. However, it is unlikely that the decrease seen with *St John’s wort* is clinically relevant. Further study is needed of the other potential interactions to demonstrate their clinical significance.

### Eplerenone + CYP3A4 inhibitors

**Ketoconazole markedly raises the AUC of eplerenone, and the manufacturer contraindicates concurrent use. Similarly, the concurrent use of other potent inhibitors of CYP3A4 should be avoided. Mild to moderate inhibitors of CYP3A4 (including diltiazem, fluconazole, saquinavir and verapamil) increase the AUC of eplerenone by up to almost threefold. Grapefruit juice had a small but unimportant effect.**

Clinical evidence

(a) Azoles

Ketoconazole 200 mg twice daily for 7 days increased the AUC of a single 100-mg dose of eplerenone 5.4-fold in 18 healthy subjects, and fluconazole 200 mg daily for 7 days increased the AUC of eplerenone 2.2-fold in 18 healthy subjects. The manufacturer predicts that itraconazole will have a similar effect to ketoconazole.

(b) Calcium-channel blockers

In 24 healthy subjects the steady-state AUC of eplerenone 100 mg daily was increased by about twofold by verapamil 240 mg daily for 7 days. Diltiazem has caused similar increases.

(c) Grapefruit juice

Grapefruit juice caused only a small 25% increase in the AUC of eplerenone 100 mg.

(d) Macrolides

In 24 healthy subjects erythromycin 500 mg twice daily increased the steady-state AUC of eplerenone 100 mg daily by 2.9-fold. The manufacturer predicts that clarithromycin, telithromycin, and troleandomycin will have a greater effect. Eplerenone reduced the AUC of erythromycin by 14%, which was not considered clinically relevant.

(e) Protease inhibitors

In 24 healthy subjects saquinavir 1.2 g three times daily increased the steady-state AUC of eplerenone 100 mg daily by 2.1-fold. The manufacturer predicts that ritonavir and nelfinavir will have a greater effect.
Eplerenone reduced the maximum level of saquinavir by 30%, and the AUC by 21%, but the clinical relevance of this has not been assessed.

**Mechanism**

Eplerenone is metabolised by the cytochrome P450 isoenzyme CYP3A4, and therefore inhibitors of this isoenzyme will raise its levels.

**Importance and management**

These pharmacokinetic interactions are established. Although the clinical relevance has not been assessed, it is known that the risk of hyperkalaemia with eplerenone is related to its dose. Because the increase in the AUC of eplerenone with ketocazole is so great, the manufacturers contraindicate this combination. They also contraindicate the concurrent use of other potent inhibitors of CYP3A4, and they list clarithromycin, itraconazole, nefazodone, nelfinavir, ritonavir, telithromycin and troleandomycin.

In the UK, the manufacturers recommend that the dose of eplerenone should not exceed 25 mg daily in patients taking mild to moderate CYP3A4 inhibitors such as amiodarone, diltiazem, erythromycin, fluconazole, saquinavir and verapamil. In the US, the manufacturer recommends that the starting dose for hypertension should be reduced to 25 mg daily for patients taking these drugs. This seems a sensible precaution. However, note that in many cases erythromycin appears to be a more potent inhibitor of CYP3A4 than clarithromycin (and certainly the other moderate CYP3A4 inhibitors listed above), and so extra caution is probably warranted with this combination.

### Eplerenone + Miscellaneous

Caution is recommended when eplerenone is used with alpha blockers, antipsychotics, amphotericin, baclofen, corticosteroids, tetracosactide and tricyclic antidepressants. Lithium, ciclosporin, and tacrolimus should generally not be used with eplerenone. Antacids, cisapride, midazolam and simvastatin had no effect on eplerenone pharmacokinetics. Eplerenone had no important effect on cisapride, midazolam, warfarin or contraceptive steroid pharmacokinetics, but caused a slight increase in digoxin levels.

**Clinical evidence, mechanism, importance and management**

(a) Antacids

The manufacturer notes that aluminium/magnesium-containing antacids had no effect on the pharmacokinetics of eplerenone.1

(b) Cisapride

No clinically significant pharmacokinetic interaction was noted when eplerenone was given with cisaprin.2 Nevertheless, in the UK, the manufacturers state that cisaprin and tacrolimus may impair renal function and increase the risk of hyperkalaemia. Therefore, they recommend that the concurrent use of either cisaprin or tacrolimus with eplerenone should be avoided, or renal function and serum potassium should be closely monitored.3 See also ‘Cisapride + Diuretics’, p.1032 and ‘Tacrolimus + Miscellaneous’, p.1080.

(c) Cisapride

A pharmacokinetic study found no interaction between cisapride (a cytochrome P450 isoenzyme CYP3A4 substrate) and eplerenone.1 3

(d) Combined hormonal contraceptives

Eplerenone 100 mg daily was given to 24 healthy subjects on days 1 to 11 of a 28-day cycle of a combined hormonal contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg). There was no change in the ethinylestradiol AUC, but there was a small 17% increase in the norethisterone AUC, which is unlikely to be clinically relevant.1 2

(e) Corticosteroids

The concurrent use of corticosteroids may reduce the antihypertensive effect of eplerenone as they may cause fluid and sodium retention.3

(f) Digoxin

The steady-state AUC of digoxin 200 micrograms daily increased by 16% when it was given to healthy subjects with eplerenone 100 mg daily.2 3 The UK manufacturers warn that caution may be warranted in patients with digoxin levels near the upper end of the therapeutic range.2 Note that changes of this size are within the usual expected variation in the AUC of digoxin.

(g) Drugs that may cause postural hypotension

The manufacturer suggests that there is a risk of increased hypotensive effects and/or postural hypotension if eplerenone is given with alpha blockers (e.g. prazosin), tricyclic antidepressants, antipsychotics, amphotericin and baclofen. They suggest increased monitoring.5

(h) Lithium

No interaction study has been done with lithium and eplerenone.1 3 Serum lithium should be monitored frequently if eplerenone is given with lithium,1 3 although, in the UK, the manufacturers advise avoidance of the combination.5 This is because lithium toxicity has occurred with lithium and ‘ACE inhibitors’, (p.1112) or ‘diuretics’, (p.1122).

(i) Midazolam

A pharmacokinetic study has shown no pharmacokinetic interaction between midazolam (a cytochrome P450 isoenzyme CYP3A4 substrate) and eplerenone.1 3

(j) Simvastatin

In 18 healthy subjects simvastatin 40 mg once daily had no effect on the pharmacokinetics of eplerenone 100 mg once daily. The maximum level of simvastatin was modestly decreased by 32%, and the AUC by 14%, but this was not considered to be clinically relevant.1 2

(k) Tetracosactide

Tetracosactide can cause fluid and sodium retention and this may reduce the antihypertensive effect of eplerenone.3

(l) Warfarin

Eplerenone did not alter the pharmacokinetics of warfarin to a clinically significant extent.1 3 However, in the UK the manufacturer still recommends caution when the warfarin dose is near the upper limit of the therapeutic range.3

### Furosemide + Bile-acid binding resins

Colestyramine and colestipol markedly reduce the absorption and diuretic effects of furosemide.

**Clinical evidence**

In 6 healthy subjects colestyramine 8 g reduced the absorption of a single 40-mg dose of furosemide by 95%. The 4-hour diuretic response was reduced by 77% (urinary output reduced from 1510 to 350 mL). Colestipol 10 g reduced the furosemide absorption by 80% and the 4-hour diuretic response by 58% (urinary output reduced from 1510 to 630 mL).1

**Mechanism**

Both colestyramine and colestipol are anionic exchange resins, which can bind with furosemide within the gut, thereby reducing its absorption and its effects.

**Importance and management**

An established interaction, although direct evidence seems to be limited to this study. The absorption of furosemide is relatively rapid so that giving it 2 to 3 hours before either the colestyramine or colestipol should be an effective way of overcoming this interaction. This needs confirmation. Note that it is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine and 1 hour before or 4 hours after colestipol.

Furosemide + Cloral hydrate

Intravenous injection of furosemide after treatment with cloral hydrate occasionally causes sweating, hot flushes, a variable blood pressure and tachycardia.

Clinical evidence

Six patients in a coronary care unit given an intravenous bolus of 40 to 120 mg of furosemide and who had received cloral hydrate during the previous 24 hours developed sweating, hot flushes, variable blood pressure, and tachycardia. The reaction was immediate and lasted for about 15 minutes. No special treatment was given. Furosemide had caused no problems when given before the cloral hydrate was started.1

A retrospective study of hospital records revealed that, out of 43 patients who had received both cloral hydrate and furosemide, one patient developed this reaction and 2 others may have done so.2 The interaction has also been described in an 8-year-old boy.3

Mechanism

Not understood. One suggestion is that furosemide displaces trichloroacetic acid (the metabolite of cloral hydrate) from its protein binding sites, which in turn displaces levothyr oxine or alters the serum pH so that the levels of free levothyroxine rise leading to a hypermetabolic state.1

Importance and management

An established interaction, but information is limited to three reports. The incidence is uncertain but probably low. Concurrent use need not be avoided, but it would be prudent to give intravenous furosemide cautiously if cloral hydrate has been given recently. It seems possible that derivatives of cloral hydrate that break down in the body to release cloral hydrate (e.g. dichloralphenazone, cloral betaine) might interact similarly. There is no evidence that furosemide given orally or cloral hydrate given to patients already taking furosemide causes this reaction.2

Furosemide + Epoprostenol

An epoprostenol infusion did not significantly alter the pharmacokinetics of furosemide in a study modelling data from 23 patients with heart failure.1 Note that the combination of loop diuretics with epoprostenol may lead to an enhanced hypotensive effect.

Furosemide + Germanium

An isolated case report describes a man who became resistant to furosemide after he took germanium.

Clinical evidence, mechanism, importance and management

A 63-year-old man was hospitalised for hypertension and oedema 10 days after adding ginseng containing germanium to his usual treatment with cyclophosphamide and furosemide. He gained almost 13 kg in weight. After treatment with intravenous furosemide he was discharged and again took ginseng with germanium. This time he gained 12 kg in weight over 14 days, despite an increase in the dose of furosemide from 80 to 240 mg twice daily. The weight gain and oedema again resolved when the ginseng and germanium was withdrawn and he was given intravenous furosemide. The authors suggest that germanium was responsible for this interaction.1

This is an isolated report, and its general significance is unclear. However, note that it has been said that the use of germanium should be discouraged due to its potential to cause renal toxicity.2

Furosemide + Paracetamol (Acetaminophen)

In 10 healthy women paracetamol 1 g four times daily for 2 days was found to have no effect on the diuresis or natriuresis in response to intravenous furosemide 20 mg.1

Furosemide + Phenytoin

The diuretic effects of furosemide can be reduced as much as 50% if phenytoin is also given.

Clinical evidence

The observation that dependent oedema in a group of epileptics was higher than expected, and that the response to diuretic treatment seemed to be reduced, prompted further study. In 30 patients taking phenytoin 200 to 400 mg daily with phenobarbital 60 to 180 mg daily the maximal diuresis in response to furosemide 20 or 40 mg occurred after 3 to 4 hours instead of the usual 2 hours, and the total diuresis was reduced by 32% for the 20-mg dose and 49% for the 40-mg dose. When intravenous furosemide 20 mg was given, the total diuresis was reduced by 50%. Some of the patients were also taking carbamazepine, pheneturide, ethosuximide, diazepam or chlor diazepoxide.1

Another study in 5 healthy subjects given phenytoin 100 mg three times daily for 10 days found that the maximum serum levels of furosemide 20 mg, given orally or intravenously, were reduced by 50%.2

Mechanism

Not fully understood. One suggestion is that the phenytoin causes changes in the jejunal sodium pump activity, which reduces the absorption of the furosemide,1 but this is not the whole story because an interaction also occurs when furosemide is given intravenously.1 Another suggestion, based on in vitro evidence, is that the phenytoin generates a ‘liquid membrane,’ which blocks the transport of the furosemide to its active site.3

Furosemide + Sevelamer

Sevelamer abolished the diuretic effect of furosemide in a haemodialysis patient.

Clinical evidence, mechanism, importance and management

A haemodialysis patient taking furosemide 250 mg twice daily found that her urine output reduced from 950 mL/day to zero when she started taking sevelamer 800 mg at breakfast and lunchtime. 1.6 g with dinner. Urine output returned to the previous level within 24 hours of stopping the sevelamer. This effect also occurred on rechallenge. The dose times were adjusted so that she took furosemide 500 mg in the morning and sevelamer 1.6 g at lunch and dinner, and her urine output was unaffected and remained stable.1

Loop diuretics + Aspirin

Aspirin may reduce the diuretic effect of bumetanide or furosemide, and the venodilatation produced by furosemide.

Clinical evidence

(a) Bumetanide

In 8 healthy subjects aspirin 640 mg four times daily reduced the 24-hour urinary output in response to bumetanide 1 mg by 18%.

(b) Furosemide

A study in 11 patients with chronic heart failure found that both aspirin 75 mg daily and aspirin 300 mg daily for 14 days reduced the venodilatory effects produced by a single 20-mg intravenous dose of furosemide (as measured by the forearm venous capacitance). Six patients with cirrhosis and ascites had a reduced diuretic response to intravenous furosemide 40 mg when a single 450-mg dose of *lysine aspirin* was given before the injection.

Mechanism

See ‘Loop diuretics + NSAIDs’, p.81.

Importance and management

The clinical significance of these interactions is unclear. Note that the European Society of Cardiology (ESC) and American College of Cardiology/American Heart Association (ACC/AHA) heart failure guidelines say that the prophylactic use of aspirin in patients with heart failure has not been proven unless the patient has underlying ischaemic heart disease and should be avoided in patients with recurrent hospital admissions for worsening heart failure.

Clinical evidence

(a) Solutions or standard tablets

Ten healthy subjects were given furosemide 40 mg with and without a standard breakfast. The food reduced the peak plasma levels of furosemide by 55% and the bioavailability by about 30%. The results were almost identical when 5 of the subjects were given a heavy meal. The diuresis over 10 hours was reduced by 21% (from 2072 to 1640 mL) and over 24 hours by 15% (from 2668 to 2270 mL) by *furosemide* taken with breakfast. A comparative study in healthy subjects found that the absorption of both bumetanide 2 mg (9 subjects) and furosemide 40 mg (8 subjects), given as solutions, was delayed, and peak plasma levels were reduced, by a standard breakfast. However, although food reduced the oral bioavailability of furosemide by about one-third, from 76% to 43%, the bioavailability of bumetanide was not significantly reduced (75% with food and 84% fasting). Food delayed the absorption but did not significantly alter the bioavailability of furosemide as tablets or solutions in two other studies. In one of these studies, there was no difference in diuresis between fed and fasting subjects.

(b) Sustained-release tablets

In a single-dose, crossover study in 28 subjects given two different controlled-release formulations of furosemide 60 mg, the absorption of one preparation (*Furix Retard*) was reduced by about 32% when it was given with breakfast, but the extent of absorption of the other formulation (*Lasix Retard*) was increased by about 18%. In the fasting phase of the study, the first formulation had a higher extent and rate of absorption than the second formulation. However, the differences in diuresis and total natriuresis between the formulations, and between the fed and fasted state, were minor.

Mechanism

Not understood.

Importance and management

Information about the effect of food on furosemide absorption is somewhat contradictory. Of the four studies using solutions or standard tablets, just two found that the bioavailability of furosemide was modestly reduced by food (by about 30%) and the others found no effect. Moreover, the modest reduction in the AUC of furosemide did not result in a clinically relevant decrease in diuresis in the one study that assessed this. It would also seem that the absorption of controlled-release formulations of furosemide may be modestly affected by food, but this may lead to increased absorption depending on the preparation. The authors of this study noted that the amount of furosemide absorbed did not correlate with the extent of diuresis, and concluded that the urinary excretion profile of furosemide may be more important for producing diuresis than the amount of furosemide absorbed. It would seem that furosemide and bumetanide can be given to most patients without regard to meal times. Food does not affect the bioavailability of bumetanide given as solution.

Loop diuretics + H2-receptor antagonists

Ranitidine and cimetidine may cause a moderate increase in the bioavailability of furosemide, but with no associated increase in diuretic effect. Cimetidine appears not to interact with torsemide.

Clinical evidence, mechanism, importance and management

(a) Furosemide

In a study in 6 healthy subjects, a single 400-mg dose of cimetidine increased the mean AUC of furosemide by one-third, although there was wide inter-patient variation. However, there were no changes in the diu-
Loop diuretics + NSAIDs

The antihypertensive and diuretic effects of the loop diuretics appear to be reduced by NSAIDs, including coxibs, although the extent of this interaction largely depends on individual NSAIDs. Diuretics increase the risk of NSAID-induced acute renal failure. The concurrent use of NSAIDs with loop diuretics may exacerbate congestive heart failure and increase the risk of hospitalisation.

Clinical evidence

A. Bumetanide

(a) Celecoxib and other Coxibs

A patient taking celecoxib with bumetanide developed a moderately raised serum creatinine. Another patient taking an ACE inhibitor, spironolactone and bumetanide developed severely raised serum creatinine, hyperkalaemia, and worsening of congestive heart failure shortly after starting celecoxib. A similar case occurred in another patient taking bumetanide about 8 days after starting rofecoxib.

(b) Indomethacin

In two studies, a single 100-mg dose of indomethacin was found to reduce the bumetanide-induced output of urine, sodium and chloride (but not potassium) by about 25%. Diuresis was reduced by 42% and weight gain was noted. There are other reports confirming this interaction between bumetanide and indomethacin, including a clinical study, and a report of a patient who developed heart failure as a result of this interaction.

(c) Sulindac

A study in 8 healthy subjects found that a single 300-mg dose of sulindac did not significantly reduce the diuretic response (measured by urinary volume, sodium, potassium and chloride) to a single 1-mg dose of bumetanide. However, another study in 9 healthy subjects found that pre-treatment with sulindac 200 mg twice daily for 5 days reduced the diuretic effect of a single 1-mg dose of bumetanide (mean urine flow rate after 2 hours reduced by 21% and cumulative sodium excretion at 3 hours reduced by 22%).

(d) Tolfenamic acid

A study in 8 healthy subjects found that tolfenamic acid 300 mg reduced the diuretic response to a single 1-mg dose of bumetanide by 34% at 2 hours (measured by urinary volume, sodium, potassium and chloride).

B. Furosemide

(a) Azapropazone

Ten healthy subjects had no change in their urinary excretion in response to furosemide 40 mg daily when they were also given azapropazone 600 mg twice daily. The furosemide did not antagonise the uricosuric effects of the azapropazone.

(b) Celecoxib and other Coxibs

In a placebo-controlled study, 7 patients with cirrhosis and ascites were given a single 40-mg intravenous dose of furosemide before and after receiving celecoxib 200 mg twice daily for 5 doses. It was found that this short-term use of celecoxib did not reduce the natriuretic or diuretic effects of furosemide.

Two patients with a history of chronic heart failure, taking furosemide 40 or 80 mg daily, developed acute renal failure when they started to take celecoxib 100 or 200 mg twice daily. Neither patient showed any sign of decompensated heart failure on admission (which can in itself cause renal failure) and both recovered on stopping the celecoxib and furosemide combination. One patient was also taking enalapril, and the combination of the enalapril with furosemide was restarted without any changes in renal function. The same authors also described two other patients taking furosemide who developed renal failure when they started to take rofecoxib. Other cases have occurred in patients taking furosemide, often with ACE inhibitors, after they started rofecoxib.

(c) Diclofenac

A study in patients with heart failure and cirrhosis found that diclofenac 150 mg daily reduced the furosemide-induced excretion of sodium by 38%, but the excretion of potassium was unaltered.

(d) Diflunisal

A study in 12 healthy subjects found that diflunisal 500 mg twice daily reduced sodium excretion in response to furosemide by 59%, but potassium excretion remained unchanged. In patients with heart failure and cirrhosis taking furosemide, diflunisal 500 to 700 mg daily decreased the sodium excretion by 36% and the potassium excretion by 47%. However, another study found no interaction between diflunisal and furosemide.

(e) Flurbiprofen

A study in healthy subjects found that a single 200-mg dose of flurbiprofen did not affect the overall furosemide diuresis, but the diuretic effect was slightly delayed.

(f) Flurbiprofen

A study in 7 healthy subjects found that the increase in renal osmolar clearance of a standard water load in response to furosemide 40 mg orally or 20 mg intravenously fell from 105% to 19% and from 140% to 70%, respectively, after flurbiprofen 100 mg was given. A single-dose study in 10 healthy subjects found that flurbiprofen 100 mg reduced the urinary volume, urinary sodium and urinary potassium, in response to oral furosemide 80 mg by 10%, 9%, and 12%, respectively.

(g) Ibuprofen

An elderly man with heart failure taking digoxin, isosorbide dinitrate and furosemide 80 mg daily, developed symptomatic congestive heart failure with ascites when given ibuprofen 400 mg three times daily. His serum urea and creatinine levels rose and no diuresis occurred, even when the furosemide dosage was doubled. Two days after withdrawing the ibuprofen, brisk diuresis took place, renal function returned to normal, and his condition improved steadily. Another elderly patient similarly had a poor response to furosemide (and later to metolazone as well) until he stopped taking ibuprofen 600 mg four times daily and at least two aspirin daily (for headache). This was due to hypotenaemic hypovolaemia brought on by the drug combination.

In a small, placebo-controlled, crossover study in 8 healthy subjects, ibuprofen 400 mg and 800 mg three times daily for 3 days significantly reduced the glomerular filtration rate and the diuresis produced by a single 20-mg intravenous dose of furosemide, but did not alter sodium excretion.

(h) Indomethacin

A study in 4 healthy subjects and 6 patients with essential hypertension found that furosemide 80 mg three times daily reduced the mean blood pressure by 13 mmHg, but when indomethacin 50 mg four times daily was also given the blood pressures returned to virtually pre-treatment levels. Moreover, the normal urinary sodium loss induced by the furosemide was significantly reduced.

A study in healthy subjects and patients with congestive heart failure given furosemide found that indomethacin 100 mg reduced the urinary output by 53% and also reduced the excretion of sodium, potassium, and chloride by 64%, 49%, and 62%, respectively. A study in 14 patients...
with ascites secondary to liver cirrhosis found that indometacin 50 mg every 6 hours for 2 doses significantly reduced the urinary volume and the natriuretic response to furosemide, by 82% and 69%, respectively, but produced only a small, non-significant reduction in creatinine clearance.24

Another study found that indometacin reduced the urinary output in response to furosemide by 20 to 30%.25 There are other case reports and studies confirming the interaction between furosemide and indometacin.21,26-31

(i) Ketoprofen

A study in 12 healthy subjects given furosemide 40 mg daily found that ketoprofen 100 mg twice daily reduced the 6-hour urine output by 67 mL, and the 24-hour urine output by 651 mL on the first day of treatment. However no significant differences were seen after 5 days of treatment.32

(ii) Ketorolac

Twelve healthy subjects were given oral ketorolac 30 mg four times daily, and then a single 30-mg intramuscular dose of ketorolac 30 minutes before a 40-mg intravenous dose of furosemide. No precise figures are given, but the maximum serum level of the furosemide, its diuretic effect, and the electrolyte loss were said to be significantly reduced by the ketorolac.33

Another study in healthy elderly subjects found that when they were given oral ketorolac 120 mg, then, on the following day, intramuscular ketorolac 30 mg, followed 30 minutes later by furosemide 40 mg, the urinary output fell by 16% and the sodium output fell by 26% over the next 8 hours, when compared with furosemide alone.34

(iii) Lornoxicam

A study in 12 healthy subjects found that lornoxicam 4 mg significantly antagonised the diuretic and natriuretic effects of furosemide, but this was not quantified.35

(iv) Meloxicam

Meloxicam 15 mg daily for 3 days had no significant effect on the pharmacokinetics of furosemide 40 mg in 12 healthy subjects. The furosemide-induced diuresis was unchanged, and although the cumulative urinary electrolyte excretion was somewhat lower, but this was not considered to be clinically significant.36 A similar study in patients with heart failure taking an ACE inhibitor also found no clinically significant pharmacokinetic or pharmacodynamic interaction between furosemide and meloxicam.37

(v) Metamizole sodium (Dipyrone)

A study in 9 healthy subjects found that metamizole sodium 3 g daily for 3 days, reduced the clearance of intravenous furosemide 20 mg from 175 to 141 mL/minute but the diuretic effects of the furosemide were unchanged.38

(vi) Mofebutazone

A study in 10 healthy subjects found that mofebutazone 600 mg had no effect on the diuretic effects of furosemide 40 mg. The urinary volume and excretion of sodium, potassium and chloride were unchanged.39

(vii) Naproxen

Two elderly women with congestive heart failure did not respond to treatment with furosemide and digoxin until the naproxen they were taking was withdrawn.40 A single-dose study in patients with heart failure found that the volume of urine excreted in response to furosemide was reduced about 50% by naproxen.41 In a placebo-controlled study, 6 patients with cirrhosis and ascites were given a single 40-mg intravenous dose of furosemide before and after naproxen 500 mg twice daily for 5 doses. It was found that this short-term use of naproxen reduced the glomerular filtration rate and the natriuretic and diuretic effects of furosemide.42

(viii) Nimesulide

A study in 8 healthy subjects found that nimesulide 200 mg twice daily attenuated the effects of furosemide 40 mg twice daily. Subjects who had initially lost weight when taking furosemide regained weight, diuresis was slightly reduced, and the glomerular filtration rate was reduced.43

(ix) Piroxicam

A 96-year-old woman with congestive heart failure did not adequately respond to furosemide until the dosage of piroxicam she was taking was reduced from 20 to 10 mg daily.44

In one study in 9 hypertensive patients with a creatinine clearance of less than 60 mL/minute, who were taking furosemide, piroxicam 20 mg daily for 3 days produced a significant reduction in the natriuretic and kaliuretic effects of an additional single 40-mg dose of furosemide. However, in 13 other patients, with a creatinine clearance of greater than 60 mL/minute, who were taking a thiazide diuretic, piroxicam did not alter the effects of a single 40-mg dose of furosemide. In a third group of 8 healthy subjects, the same dose of piroxicam reduced the natriuretic effects, but not the kaliuretic effects, of a single 40-mg dose of furosemide.45

(j) Sulindac

A study in 5 healthy subjects found that pre-treatment with two 150-mg doses of sulindac reduced the urinary volume and urinary sodium following an intravenous furosemide 80 mg by 25% and 37.5%, respectively. In patients with cirrhosis and ascites, sulindac 150 mg reduced the urinary volume, urinary sodium, and urinary potassium following an 80-mg intravenous dose of furosemide by 38%, 52%, and 8%, respectively.46 In another placebo-controlled study in 15 healthy women, sulindac 200 mg twice daily for 5 days produced a similar but slightly smaller reduction in the natriuretic effect of a single 40-mg intravenous dose of furosemide, when compared with indometacin.31

(k) Tenoxicam

A study in 12 patients found that tenoxicam 20 to 40 mg daily had no significant effect on the urinary excretion of sodium or chloride due to furosemide 40 mg daily, and blood pressure, heart rate and body-weight also were not affected.47

C. Piretanide

(a) Indometacin

A comparative study into the pharmacological mechanisms underlying the way drugs interfere with the actions of loop diuretics found that indometacin reduced the peak fractional renal excretion of sodium in response to a single 6-mg dose of piretanide. The clinical importance of this change was not studied.

(b) Pirprofen

A comparative study into the pharmacological mechanisms underlying the way drugs interfere with the actions of loop diuretics found that piroxicam 20 mg twice daily for 2 days did not significantly affect the peak fractional excretion of sodium in response to a single 6-mg dose of piretanide.45

D. Torasemide

A study in healthy subjects suggested that indometacin did not affect the natriuretic effects of torasemide, but on the basis of later study the same workers suggest that pathological factors in patients may allow an interaction similar to that with furosemide and indometacin to occur.48

Mechanism

Uncertain and complex. It is likely that a number of different mechanisms come into play. One probable mechanism involves the synthesis of renal prostaglandins, which occurs when the loop diuretics cause sodium excretion. If this synthesis is blocked by drugs such as the NSAIDs, then renal blood flow and diuresis will be altered.49 NSAIDs cause fluid and salt retention, which would antagonise the effects produced by diuretics.

Importance and management

NSAIDs can cause renal impairment, particularly in patients in whom prostaglandins are playing an important role in maintaining renal function. Such patients include those taking diuretics, the elderly and those with concurrent conditions such as congestive heart failure and ascites. Hence the combination of diuretics and NSAIDs may increase the nephrotoxicity of NSAIDs.50,51

The antihypertensive and diuretic effects of the loop diuretics are reduced by NSAIDs. This interaction is very well documented between furosemide and indometacin, and of clinical importance, whereas less is known about the interactions with other NSAIDs, although the interaction should be anticipated with all of them. Use of an alternative non-NSAID analgesic should always be considered if possible. However, in cases where concurrent use cannot be avoided, the loop diuretic dosage may need to be raised (according to clinical response), but the effects on renal function and electrolytes, as well as efficacy, should be closely monitored.

Patients at greatest risk of an adverse interaction include the elderly and patients with cirrhosis, cardiac failure and/or renal impairment, and NSAIDs should usually be used with caution in these patient groups regardless of concurrent use of diuretics. Note that a retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) with NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use. The most common
NSAIDs taken by this cohort of patients were diclofenac, ibuprofen, indometacin and naproxen. Much less is known about the interactions of NSAIDs with bumetanide, and even less about those with piretanide and torasemide, but the evidence suggests that they probably interact in the same way as furosemide and indometacin. It would therefore seem prudent to be alert for interactions with any of the NSAIDs with which furosemide interacts. See also ‘Loop diuretics + Aspirin’, p.948, for a discussion of the interactions between aspirin and bumetanide or furosemide.

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, including diuretics, and the findings of these are summarised in ‘Table 23.2’, (p.862).

---

**Loop diuretics + Probenecid**

Probenecid decreases the renal clearance of furosemide, but it appears not to alter its overall diuretic effect. Probenecid reduces the natriuretic effects of piretanide, but the clinical relevance of this is not known. Probenecid does not appear to significantly affect bumetanide diuresis.

### Clinical evidence, mechanism, importance and management

**(a) Bumetanide**

Probenecid 1 g did not affect the response of healthy subjects to 500 micrograms or 1 mg of intravenous bumetanide. Another study reported a fall in natriuresis and in the clearance of bumetanide, but this was of minimal clinical importance.

**(b) Furosemide**

The concurrent use of furosemide and probenecid has been closely studied to determine the renal pharmacological mechanisms of loop diuretics. One study in patients given furosemide 40 mg daily found that the addition of probenecid 500 mg twice daily for 3 days reduced their urinary excretion of sodium by about 36% (from 56.3 to 35.9 mmol daily). Other studies have also found some changes in overall diuresis (a fall, a rise, and no change in some studies), and a reduction of 35 to 80% in the renal clearance of furosemide. Other study found that probenecid 1 g increased the half-life of furosemide by 70% and decreased its oral clearance by 65%. Probenecid-associated renal impairment was identified in a large general internal medicine practice.

---

**Piretanide**

A comparative study into the pharmacological mechanisms underlying the way drugs interfere with the actions of loop diuretics found that probenecid 1 g reduced the peak fractional excretion of sodium produced by a 6-mg dose of oral piretanide by 65%. Another study confirmed that probenecid reduces the natriuretic effects of piretanide. The clinical importance of these changes was uncertain, but probably small.

**Potassium-sparing diuretics + H₂-receptor antagonists**

Although minor interactions occasionally occur between potassium-sparing diuretics and the H₂-receptor antagonists, none of these have been shown to be of clinical significance. The combinations that have been studied are; amiloride or triamterene with cimetine, and triamterene with ranitidine.

**Clinical evidence, mechanism, importance and management**

(a) Amiloride

A study in 8 healthy subjects given amiloride 5 mg daily found that cimetine 400 mg twice daily for 12 days reduced the renal clearance of amiloride by 17% and reduced its urinary excretion from 65% to 53%. Amiloride also reduced the excretion of cimetine from 43% to 32%, and the AUC was reduced by 14%.2 No changes in the diuretic effects (urinary volume, sodium or potassium excretion) occurred. It seems that each drug reduces the gastrointestinal absorption of the other drug by as yet unidentified mechanisms. The overall plasma levels of the amiloride remain unchanged because the reduced absorption is offset by a reduction in its renal excretion. These mutual interactions do not seem to be clinically significant.2

(b) Triamterene

A study in 6 healthy subjects given triamterene 100 mg daily for 4 days found that cimetine 400 mg twice daily increased the AUC of triamterene by 22%, reduced its metabolism (hydroxylation) by 32%, and reduced its renal clearance by 28%. There also appeared to be a reduction in the absorption of triamterene. However, the loss of sodium in the urine was not significantly changed, and the potassium-sparing effects of triamterene were not altered.2 Because the diuretic effects of triamterene are minimally changed, this interaction is unlikely to be clinically important.2

In 8 healthy subjects ranitidine 150 mg twice daily for 4 days roughly halved the absorption (as measured by renal clearance) of triamterene 100 mg daily. Its metabolism was also reduced, with the total effect being a 21% reduction in the AUC. As a result of the reduced plasma triamterene levels, the urinary sodium loss was reduced to some extent but potassium excretion remained unchanged.3 Overall the diuretic effects of triamterene were only mildly affected. Another study found that a 22% reduction in the AUC of triamterene is unlikely to result in a significant change in its diuretic effects.2 No clinically significant interaction is anticipated.1

**Potassium-sparing diuretics + NSAIDs**

The concurrent use of triamterene and indometacin has, in several cases, rapidly lead to acute renal failure. An isolated case of renal impairment with diclofenac has been reported in a patient taking triamterene plus a thiazide. A case of exercise-induced acute renal failure has also been reported in a patient taking ibuprofen with triamterene plus a thiazide. Indometacin reduced the diuretic effect of spironolactone.

**Clinical evidence**

(a) Spironolactone with Indometacin

A study in healthy subjects found that indometacin 150 mg daily reduced the natriuretic effect of spironolactone 300 mg daily by 54%.1

(b) Triamterene with Diclofenac

A patient receiving triamterene 100 mg plus trichlormethiazide 2 mg daily was given intramuscular diclofenac 75 mg before admission to hospital with breast pain. On admission serum creatinine was 91 micromol/L and after 2 days it had increased to 248 micromol/L, but it returned to normal over 2 weeks. Subsequent oral diclofenac produced no adverse effects. The observed deterioration in renal function was attributed to an interaction between triamterene and diclofenac.2

(c) Triamterene with Diflunisal

Diflunisal had no effects on the pharmacokinetics of triamterene in healthy subjects, but the plasma AUC of an active metabolite, p-hydroxy-triamterene was increased by more than fourfold.1

(d) Triamterene with Ibuprofen

A 37-year-old patient developed acute renal failure after strenuous exercise while taking hydrochlorothiazide/triamterene 50/75 mg daily and ibuprofen (800 mg 12 hours and 2 hours before the exercise, and 800 mg 24 hours after). A renal biopsy showed acute tubular necrosis.4

(e) Triamterene with Indometacin

A study in 4 healthy subjects found that indometacin 150 mg daily given with triamterene 200 mg daily over a 3-day period reduced the creatinine clearance in 2 subjects by 62% and 72%, respectively. Renal function returned to normal after a month. Indometacin alone caused an average 10% fall in creatinine clearance, but triamterene alone caused no consistent change in renal function. No adverse reactions were seen in 18 other subjects treated in the same way with indometacin and furosemide, hydrochlorothiazide or spironolactone.3,5 Five patients are reported to have rapidly developed acute renal failure after receiving indometacin and triamterene, either concurrently or sequentially.6,9,10

**Mechanism**

Uncertain. One suggestion is that triamterene causes renal ischaemia, for which the kidney compensates by increasing prostaglandin (PG_E₂) production, thereby preserving renal blood flow. Indometacin opposes this by inhibiting prostaglandin synthesis, so that the damaging effects of triamterene on the kidney continue unchecked. Increases in pharmacologically active metabolites of triamterene may occur due to competition for renal excretory pathways but the clinical significance is uncertain.

As prostaglandins may contribute to the natriuretic effects of spironolactone, the NSAIDs may exert their effects by blocking prostaglandin synthesis. See also ‘Loop diuretics + NSAIDs’, p.949.

**Importance and management**

Information is limited to these reports, but the interaction with indometacin is established. The incidence is uncertain. Since acute renal failure can apparently develop unpredictably and very rapidly it would seem prudent to use triamterene and indometacin cautiously, or avoid it altogether. The authors of the report with diclofenac suggest caution with the use of any NSAID with triamterene.2 Strenuous exercise can reduce renal blood flow, and the author of the case report with ibuprofen notes that although renal failure secondary to this is rare, patients taking medication that also reduces renal blood flow are more at risk of this complication.4 A retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) and NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use, although the relative risk (1.4) with potassium-sparing diuretics was less than that when combined with a thiazide (2.9). The most common NSAIDs taken by this cohort of patients were diclofenac, ibuprofen, indometacin and naproxen.11 The European Society of Cardiology (ESC) Task Force and the joint American College of Cardiology/American Heart Association guidelines on the management of chronic heart failure both recommend that NSAIDs, including coxibs, should be avoided, if possible, with aldosterone antagonists (such as eplerenone or spironolactone),...
as this increases the risk of developing hyperkalaemia and renal failure.\textsuperscript{12,13} For a discussion of the interaction of spironolactone with aspirin, see ‘Spironolactone + Aspirin’, p.954.

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, including diuretics, and the findings of these are summarised in ‘Table 23.2’, (p.862).

Potassium-sparing diuretics + Potassium compounds

The concurrent use of spironolactone or triamterene and potassium supplements can result in severe and even life-threatening hyperkalaemia. Amiloride and eplerenone are expected to interact similarly. Potassium-containing salt substitutes can be as hazardous as potassium supplements.

Clinical evidence

In a retrospective analysis of hospitalised patients who had received spironolactone, hyperkalaemia had developed in 5.7% of patients taking spironolactone alone and in 15.4% of those also taking a potassium chloride supplement. The incidence was 42% in those with severe azotaemia given spironolactone and potassium chloride.\textsuperscript{1} A retrospective survey of another group of 25 patients taking spironolactone and oral potassium chloride supplements found that half of them had developed hyperkalaemia.\textsuperscript{2} Another patient developed severe hyperkalaemia and cardiotoxicity as a result of treatment with spironolactone and a potassium supplement.\textsuperscript{3} Three patients taking furosemide and spironolactone became hyperkalaemic\textsuperscript{4,5} because they took potassium-containing salt substitutes (\textit{No Salt} in one case)\textsuperscript{6}. Two developed cardiac arrhythmias.\textsuperscript{3}

The pacemaker of a patient failed because of hyperkalaemia caused by the concurrent use of triamterene/hydrochlorothiazide (Dyazide) and potassium chloride (Slow-K).\textsuperscript{6}

Mechanism

The effects of these potassium-sparing diuretics and potassium compounds are additive, which can result in hyperkalaemia.

Importance and management

The interaction with spironolactone is established and of clinical importance. A case has also been reported with triamterene; amiloride and eplerenone would be expected to behave similarly. Avoid potassium compounds in patients taking potassium-sparing diuretics except in cases of marked potassium depletion and where the effects can be closely monitored. Warn patients about the risks of salt substitutes containing potassium, which may increase the potassium intake by 50 to 60 mmol daily.\textsuperscript{2}

The signs and symptoms of hyperkalaemia include muscular weakness, fatigue, paraesthesia, flaccid paralysis of the extremities, bradycardia, shock and ECG abnormalities, which may develop slowly and insidiously.

Potassium-sparing diuretics + Total parenteral nutrition

Metabolic acidosis occurred in two patients receiving total parenteral nutrition, which was attributed to the use of triamterene or amiloride.

Clinical evidence, mechanism, importance and management

Metabolic acidosis developed in two patients receiving total parenteral nutrition associated with the concurrent use of triamterene or amiloride. The cases were complicated by a number of pathological and other factors, but it was suggested that the major reason for the acidosis was because the diuretics prevented the kidneys from responding normally to the acid load. Caution is advised during concurrent use.\textsuperscript{1}

Potassium-sparing/Thiazide diuretics + Trimethoprim

Excessively low sodium levels have been seen in a few patients taking hydrochlorothiazide with amiloride or triamterene when they were given trimethoprim or co-trimoxazole. Trimethoprim may cause hyperkalaemia and this may be additive with potassium-sparing diuretics, including the aldosterone antagonists.

Clinical evidence

A 75-year-old woman with multiple medical conditions taking methyl dopa, levothyroxine and co-amilozide (hydrochlorothiazide with amiloride) developed nausea and anorexia, and was found to have hyponatraemia (plasma sodium 107 mmol/L), within 4 days of starting to take trimethoprim 200 mg twice daily. The problem resolved when the diuretics and trimethoprim were stopped. When re-challenged 4 months later with trimethoprim, hyponatraemia did not occur, but it developed rapidly when co-amilozide was also restarted.\textsuperscript{4} The authors of this report say that they have seen several other patients who developed hyponatraemia within 4 to 12 days of starting trimethoprim or co-trimoxazole, all of whom were elderly and all but one of whom were taking a diuretic \textit{un}named.\textsuperscript{4}

Another report describes hyponatraemia in two other patients after co-trimoxazole was added to treatment with co-amilozide or co-triamterene (hydrochlorothiazide with triamterene).\textsuperscript{2}

Mechanism

Not established. Thiazide diuretics combined with potassium-sparing diuretics are said to be particularly liable to cause hyponatraemia.\textsuperscript{2} Trimethoprim can also cause hyperkalaemia\textsuperscript{2}, by blocking amiloride-sensitive sodium channels in the collecting duct (this produces a similar effect to that of a potassium-sparing diuretic). It seems likely that these adverse effects can be additive with the effects of other drugs.
The antihypertensive effects of spironolactone in patients with hypertension were unaffected by anti-inflammatory doses of aspirin in one small study, although there is evidence that these doses of aspirin reduce the spironolactone-induced loss of sodium in the urine.

Clinical evidence
(a) Effects on blood pressure
Five patients with low-renin essential hypertension, well-controlled for 4 months or more with spironolactone 100 to 300 mg daily, took part in a crossover study. Aspirin 2.4 to 4.8 g daily given over 6-week periods had no effect on blood pressure, serum electrolytes, body-weight, blood-urea-nitrogen or plasma renin activity.1

(b) Effects on natriuresis
A study in 10 healthy subjects given single 25-, 50- and 100-mg doses of spironolactone, found that a single 600-mg dose of aspirin reduced the urinary excretion of sodium in response to spironolactone.2 In a further study in 7 of these subjects, the effectiveness of the spironolactone was reduced by 70%, and the overnight sodium excretion was reduced by one-third when they were given spironolactone 25 mg four times daily for one week followed by a single 600-mg dose of aspirin.2 Reductions in sodium excretion are described in other studies of this interaction.3,4 In one of these the sodium excretion brought about by spironolactone was completely abolished when aspirin was given 90 minutes after the spironolactone, but when the drugs were given in the reverse order the inhibition of sodium excretion, which was caused by aspirin, was not completely reversed by spironolactone.4

In another study in 7 patients with ascites due to liver cirrhosis, pre-treatment with two doses of aspirin 900 mg reduced the natriuretic effect of spironolactone 300 mg daily by 33%. However, there was no significant change in urinary output.5

Mechanism
Uncertain. There is evidence that the active secretion of carboxen (the active metabolite of spironolactone) is blocked by aspirin, but the significance of this is not entirely clear.3

Importance and management
An adequately but not extensively documented interaction. Despite the results of the studies showing a reduced natriuretic effect, the small study in hypertensive patients shows that the blood pressure-lowering effects of spironolactone might not be affected by anti-inflammatory doses of aspirin. In general, concurrent use need not be avoided, but if the diuretic response to spironolactone is less than expected consider this interaction as a cause.

None of these studies looked at the effects of low-dose aspirin on spironolactone. Nevertheless, it is likely that the proven protective cardiovascular benefits of low-dose aspirin in patients with hypertension and/or coronary artery disease would usually outweigh the possible reduction in the efficacy of spironolactone. However, note that, when spironolactone is being used for congestive heart failure, the European Society of Cardiology (ESC) and American College of Cardiology/American Heart Association (ACC/AHA) heart failure guidelines say that the prophylactic use of aspirin in patients with heart failure has not been proven unless the patient has underlying ischaemic heart disease6,7 and should be avoided in patients with recurrent hospital admissions for worsening heart failure.6 See also ‘Potassium-sparing diuretics + NSAIDs’, p.952, for a discussion of the interactions of spironolactone with NSAIDs.

Spironolactone + Colestyramine
A few case reports have described hyperchloraemic metabolic acidosis, which was associated with the use of colestyramine and spironolactone.

Clinical evidence
Four case reports describe the development of hyperchloraemic metabolic acidosis in patients with liver cirrhosis taking colestyramine (up to about 25 g daily), who were also taking spironolactone 75 mg or 100 mg daily.1-4 One patient developed significant hyperkalaemia (potassium 8 mmol/L),1 and 2 patients developed mild renal impairment.1,3 One patient had recently recovered from a respiratory tract infection, which the authors suggested may have contributed to the acidosis.1 Acidosis resolved when the colestyramine was stopped.

Mechanism
Bicarbonate has been shown to compete in vitro with bile acids for binding sites on the colestyramine resin.1,3 The chloride ions in the colestyramine resin may cause an anion exchange of not only the bile salts, as is the intention, but also bicarbonate in the small bowel. This removal of bicarbonate from the body can predispose to the development of a hyperchloraemic metabolic acidosis and hyperkalaemia. This might be exacerbated by the bicarbonate-losing and hyperkalaemic effects of spironolactone.1-4

Importance and management
In healthy subjects with normal renal function, acidosis does not usually occur, as the kidneys correct it by increasing the excretion of chloride and production of bicarbonate.1,4 However, in patients with renal impairment, volume depletion (e.g. secondary to diuretics) or concurrent conditions that predispose to acidosis, this interaction may be significant. It has been suggested that electrolytes should be closely monitored when patients who are at risk of an interaction are taking colestyramine and spironolactone, although note that the interaction appears to be rare.

Spironolactone + Dextropropoxyphene
(Propoxyphene)

A single case report describes the development of gynaecomastia and a rash when a man taking spironolactone was given dextropropoxyphene.

Clinical evidence, mechanism, importance and management

A patient who had been taking spironolactone uneventfully for 4 years developed swollen, tender breasts and a rash on his chest and neck a fortnight after starting to take Darvon Compound (dextropropoxyphene, aspirin, phenacetin and caffeine). The problem disappeared when both drugs were withdrawn but the rash reappeared when the Darvon Compound alone was given and disappeared when it was withdrawn. No problems occurred when the spironolactone was given alone, but both the rash and the gynaecomastia recurred when the Darvon Compound was again added.1 The reasons for this reaction are not understood. Gynaecomastia is a known adverse effect of spironolactone (incidence 1.2%), but the authors considered it unlikely that it should spontaneously develop after so many years of treatment. Consequently they attribute the reaction to an interaction with Darvon Compound, but say they cannot be sure which of the components is responsible. This is an isolated case, and would therefore not be expected to be of general relevance.

Spironolactone + Food

Food may increase the plasma levels of spironolactone, but this did not alter antihypertensive efficacy in one long-term study.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects food increased the AUC of canrenone (the major active metabolite of spironolactone) by about 30% after a single 100-mg dose of spironolactone, when compared to the fasted state.1 However, the same research group later found that the steady-state canrenone levels did not differ when spironolactone 100 mg daily was taken at least 30 minutes before eating for 60 days, compared with immediately after eating for 60 days. Furthermore, in a crossover study in 10 hypertensive patients, the antihypertensive efficacy of spironolactone was not altered by food. They suggest that the difference is due to a more specific drug interaction within the gut. Even so, a one-third reduction in the absorption of spironolactone is likely that they will interact similarly. Note that it is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine and 1 hour before or 4 hours after colestipol.

Thiazide diuretics + Calcium and/or Vitamin D

Hypercalcaemia and possibly metabolic alkalosis can develop in patients who are given high doses of vitamin D and/or large amounts of calcium if they are also given diuretics such as the thiazides, which can reduce the urinary excretion of calcium. One case of hypercalcaemia has been reported in a patient using a high-strength topical tacalcitol with a thiazide diuretic.

Clinical evidence

(a) Calcium and vitamin D

An elderly woman taking hydrochlorothiazide 25 mg and triamterene 50 mg daily became confused, disoriented and dehydrated 6 months after starting to take vitamin D3 50 000 units and calcium 1.5 g daily (as calcium carbonate) for osteoporosis. Her serum calcium level had risen to about 3.5 mmol/L (normal range about 2 to 2.6 mmol/L).1

A young woman with osteoporosis taking 3 mg of vitamin D2 and calcium 2 g daily (as lactate) became hypercalcaemic 3 days after starting to take hydrochlorothiazide 500 mg every 6 hours.2

(b) Calcium carbonate

A 47-year-old man was admitted to hospital complaining of dizziness and general weakness, which had begun 2 months previously. He was taking hydrochlorothiazide 500 mg daily for hypertension, ‘thyroid’ 120 mg daily for hypothyroidism and calcium carbonate 7.5 to 10 g daily for heartburn. On examination he was found to have metabolic alkalosis with respiratory compensation, a total serum calcium concentration of 3.4 mmol/L (range given as 2.15 to 2.6 mmol/L) and an abnormal ECG. He was diagnosed as having the milk-alkali syndrome. Recovery was rapid when the thiazide and calcium carbonate were withdrawn and a sodium chloride infusion, furosemide and oral phosphates were given.3

An elderly woman with normal renal function taking hydrochlorothiazide 50 mg daily developed hypercalcaemia about 3 weeks after increasing her dose of calcium carbonate from 2.5 g daily to 7.5 g daily.4

In both cases the thiazide diuretic was thought to be implicated as the levels of calcium ingestion were in the region of the normally recommended doses.

(c) Oral vitamin D

In a group of 12 patients treated for hypoparathyroidism with vitamin D (dihydrotachysterol or ergocalciferol), 5 patients became hypercalcaemic.

Mechanism

Hydrochlorothiazide becomes bound to these non-absorbable anionic exchange resins within the gut, and less is available for absorption.

Importance and management

Established interactions of clinical importance. The best dosing schedule would appear to be to give hydrochlorothiazide 4 hours before colestyramine to minimise mixing in the gut. Even so, a one-third reduction in thiazide absorption occurs and the possibility of this interaction should be considered in patients taking colestyramine or colestipol who have a reduced response to a thiazide diuretic. The optimum time-interval with colestipol has not been investigated but it would be reasonable to take similar precautions. Information about other thiazides is lacking although it seems likely that they will interact similarly.

Thiazide diuretics + Bile-acid binding resins

The absorption of hydrochlorothiazide (and probably chlorothiazide) can be reduced by more than one-third if colestipol is given concurrently. Colestyramine also reduces the absorption of hydrochlorothiazide by more than two-thirds.

Clinical evidence

In 6 healthy subjects the plasma levels of hydrochlorothiazide were reduced by about two-thirds by colestyramine 8 g, taken 2 minutes before and 6 and 12 hours after a single 75-mg oral dose of hydrochlorothiazide. Total urinary excretion of hydrochlorothiazide fell by 83%. In a parallel study with colestipol 10 g, the blood levels of hydrochlorothiazide fell by about 14% and the total urinary excretion fell by 31%.1 A further study found that giving the colestyramine 4 hours after the hydrochlorothiazide reduced the effects of the interaction but the absorption was still reduced by one-third.2 In another study colestipol, given simultaneously or one hour after chlorothiazide, reduced the urinary excretion of chlorothiazide by 58% and 54%, respectively.3

Mechanism

Hydrochlorothiazide becomes bound to these non-absorbable anionic exchange resins within the gut, and less is available for absorption.

Importance and management

Established interactions of clinical importance. The best dosing schedule would appear to be to give hydrochlorothiazide 4 hours before colestyramine to minimise mixing in the gut. Even so, a one-third reduction in thiazide absorption occurs and the possibility of this interaction should be considered in patients taking colestyramine or colestipol who have a reduced response to a thiazide diuretic. The optimum time-interval with colestipol has not been investigated but it would be reasonable to take similar precautions. Information about other thiazides is lacking although it seems likely that they will interact similarly. Note that it is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine and 1 hour before or 4 hours after colestipol.

Thiazide diuretics + Calcium and/or Vitamin D

Hypercalcaemia and possibly metabolic alkalosis can develop in patients who are given high doses of vitamin D and/or large amounts of calcium if they are also given diuretics such as the thiazides, which can reduce the urinary excretion of calcium. One case of hypercalcaemia has been reported in a patient using a high-strength topical tacalcitol with a thiazide diuretic.

Clinical evidence

(a) Calcium and vitamin D

An elderly woman taking hydrochlorothiazide 25 mg and triamterene 50 mg daily became confused, disoriented and dehydrated 6 months after starting to take vitamin D3 50 000 units and calcium 1.5 g daily (as calcium carbonate) for osteoporosis. Her serum calcium level had risen to about 3.5 mmol/L (normal range about 2 to 2.6 mmol/L).1

A young woman with osteoporosis taking 3 mg of vitamin D2 and calcium 2 g daily (as lactate) became hypercalcaemic 3 days after starting to take chlorothiazide 500 mg every 6 hours.2

(b) Calcium carbonate

A 47-year-old man was admitted to hospital complaining of dizziness and general weakness, which had begun 2 months previously. He was taking hydrochlorothiazide 500 mg daily for hypertension, ‘thyroid’ 120 mg daily for hypothyroidism and calcium carbonate 7.5 to 10 g daily for heartburn. On examination he was found to have metabolic alkalosis with respiratory compensation, a total serum calcium concentration of 3.4 mmol/L (range given as 2.15 to 2.6 mmol/L) and an abnormal ECG. He was diagnosed as having the milk-alkali syndrome. Recovery was rapid when the thiazide and calcium carbonate were withdrawn and a sodium chloride infusion, furosemide and oral phosphates were given.3

An elderly woman with normal renal function taking hydrochlorothiazide 50 mg daily developed hypercalcaemia about 3 weeks after increasing her dose of calcium carbonate from 2.5 g daily to 7.5 g daily.4

In both cases the thiazide diuretic was thought to be implicated as the levels of calcium ingestion were in the region of the normally recommended doses.

(c) Oral vitamin D

In a group of 12 patients treated for hypoparathyroidism with vitamin D (dihydrotachysterol or ergocalciferol), 5 patients became hypercalcaemic.
mic when they took bendroflumethiazide or methyclothiazide. A significant rise in plasma calcium levels occurred in 7 patients given vitamin D and methyclothiazide or chlorothiazide, and hypercalcaemia developed in 3 of them. A study in 12 children taking calcitriol (31 nanograms/kg daily) found that the addition of hydrochlorothiazide (1 to 2 micrograms/kg daily) reduced the urinary excretion of calcium caused by the calcitriol. Another study in 7 patients with vitamin D-induced calciuria found that the addition of hydrochlorothiazide and amiloride reduced the urinary excretion of calcium due to the calcitriol to a greater extent than hydrochlorothiazide alone. Moreover, the addition of amiloride helped to prevent adverse effects associated with the use of hydrochlorothiazide, such as hypokalaemia and alkalosis.

(d) Topical vitamin D analogues

A case of asymptomatic hypercalcaemia has been reported in a patient taking trichloromethiazide 6 mg daily and using 10 g of a high-strength topical tacalcitol ointment (20 micrograms/g) daily for psoriasis as part of a clinical study. His calcium level reached a peak of 3.55 mmol/L 28 days after starting the tacalcitol ointment and it fell back to within the normal range within 7 days of stopping the ointment.

Mechanism

The thiazide diuretics (and triamterene) can cause calcium retention by reducing its urinary excretion. This, added to the increased intake of calcium, resulted in excessive calcium levels. Alkalosis (the milk-alkali syndrome, associated with hypercalcaemia, alkalosis, and renal impairment) may also occur in some individuals because the thiazide limits the excretion of bicarbonate.

Importance and management

An established interaction. The incidence is unknown but the reports cited suggest that it can be considerable if the intake of vitamin D and calcium are high. Concurrent use need not be avoided; thiazides have been used clinically to reduce vitamin-D induced hypercalciuria, but the serum calcium levels should be regularly monitored to ensure that they do not become excessive. Patients should be warned about the ingestion of very large amounts of calcium carbonate (readily available without prescription) if they are taking thiazide diuretics.

The case of hypercalcaemia with the use of a topical vitamin D analogue is rare and the strength of the preparation of tacalcitol used was fivefold higher than the current licensed preparation of 4 micrograms/g (Curatoderm). However, bear this case in mind should a patient taking thiazides with a topical vitamin D analogue develop hypercalcaemia.

Thiazide and related diuretics + NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, including diuretics, although some studies have not found the increase to be clinically relevant. The concurrent use of NSAIDs with thiazide diuretics may exacerbate congestive heart failure and increase the risk of hospitalisation.

Clinical evidence

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, and the findings of these are summarised in ‘Table 23.2’. In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAIDs. In two meta-analyses, the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between indometacin and sulindac in one analysis. Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis, the effect was greatest for piroxicam, indometacin, and ibuprofen, intermediate for naproxen, and least for sulindac and flurbiprofen. In the other meta-analysis, ibuprofen was the single largest drug, and was more effective in another meta-analysis for piroxicam, and least for ibuprofen and sulindac. An attempt was also made in one study to evaluate the effect of antihypertensive agents on blood pressure. The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual clinical and pharmacological studies that have studied the effects of specific NSAIDs on diuretics are outlined in the subsections below and in ‘Table 26.2’. In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAIDs. In two meta-analyses, the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between indometacin and sulindac in one analysis. Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis, ibuprofen was the single largest drug, and was more effective in another meta-analysis for piroxicam, and least for ibuprofen and sulindac. An attempt was also made in one study to evaluate the effect of antihypertensive agents on blood pressure. The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

**Abbreviations:** ARF = acute renal failure; CHF = congestive heart failure; GFR, glomerular filtration rate; N/S = non-significant
one month did not alter the antihypertensive effect of the combinations of hydrochlorothiazide 25 mg daily with fosinopril 10 to 40 mg daily,14 or lisinopril 10 to 40 mg daily.8

(d) Indometacin

A controlled study in 7 patients with hypertension taking amiloride 5 to 10 mg with hydrochlorothiazide 50 to 100 mg, found that indometacin 100 mg daily for 3 weeks raised their blood pressure by 13/9 mmHg when lying and by 16/9 mmHg when standing. Body-weight increased by 1.1 kg.3 A later study in patients taking hydrochlorothiazide found a 6/3 mmHg blood pressure rise after they took indometacin for 2 weeks, but this had gone after 4 weeks.15 A blood pressure rise of only 5/1 mmHg was seen in another study in hypertensive patients taking hydrochlorothiazide with indometacin 100 mg daily.16 Indometacin also attenuated the hypotensive effect of hydrochlorothiazide (given with amiloride) in anoth-
er study.6

In other studies indometacin had no effect on blood pressure in healthy subjects,7 no effect on the sodium excretion caused by hydrochlorothiazide,18 and did not affect the pharmacokinetics of hydrochlorothi-
azide.17,18

(e) Kebuzone

A mean systolic blood pressure rise of 18 mmHg (from 171 to 189 mmHg) occurred in 15 patients taking hydrochlorothiazide 50 mg daily, when they were given kebuzone 750 mg daily. This rise represents about a 35% reduc-
tion in the antihypertensive effect of hydrochlorothiazide.19

(f) Naproxen

One study found that naproxen had no clinically relevant interaction with hydrochlorothiazide alone,5 while another found that naproxen attenuated the antihypertensive efficacy of hydrochlorothiazide taken with timolol, but how much of the attenuation is due to an interaction with the diuretic is unclear.20

(g) Phenylbutazone

A mean systolic blood pressure rise of 18 mmHg (from 171 to 189 mmHg) occurred in 15 patients taking hydrochlorothiazide 50 mg daily, when they were given phenylbutazone 750 mg daily. This rise represents about a 35% reduc-
tion in the antihypertensive effect of hydrochlorothiazide.19

(h) Piroxicam

One study found that piroxicam attenuated the antihypertensive efficacy of hydrochlorothiazide taken with timolol, but how much of the attenua-
tion is due to an interaction with the diuretic is unclear.20

(i) Sulindac

Sulindac does not appear to reduce either the hypotensive or diuretic ef-
fects of hydrochlorothiazide, and may even slightly enhance the antihyp-
ertensive effects.6,7,15,16,20,21 Another study found that sulindac did not alter the antihypertensive efficacy of hydrochlorothiazide/amiloride given with beta blockers.22 Similarly, sulindac 200 mg twice daily for one month did not alter the antihypertensive effect of the combinations of hydrochlorothiazide 25 mg daily with fosinopril 10 to 40 mg daily,14 or lisinopril 10 to 40 mg daily.8

D. Metolazone

Indometacin was found to reduce the urinary sodium excretion due to me-
tolazone by 34% in 6 healthy subjects.21 The excretion of total potassium fell by 30%.

(f) Sulindac

Sulindac was found to reduce the urinary sodium excretion due to metola-
zone by 19% in 6 healthy subjects.23 The excretion of total potassium fell by 16%.

E. Unspecified

Not understood. NSAIDs can cause salt and water retention, which antag-
onises the effects of diuretics. Prostaglandins have a role to play in renal

Mechanism

Not understood. NSAIDs can cause salt and water retention, which antag-
onises the effects of diuretics. Prostaglandins have a role to play in renal

function and drugs such as the NSAIDs, which inhibit prostaglandin syn-
thesis, would therefore be expected to have some effect on the actions of diuretics, whose venodilatory effects also depend on the activity of the prostaglandins. A study in rats suggested that indometacin may oppose the effects of the thiazides by reducing chloride delivery to the site of thi-
azide action in the distal tubule.25

Importance and management

Overall, the evidence suggests that some patients taking thiazide diuretics can have a rise in blood pressure when given NSAIDs, but this may not always be clinically relevant. Some consider that the use of NSAIDs should be kept to a minimum in patients taking antihypertensives.26 The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with high salt intake.25 However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggest-
ed.27 While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if pa-
tients in primary care have inadequate control of blood pressure, other rea-
sons may be more likely than any effect of concurrent NSAIDs.27 There is insufficient data at present to clearly differentiate between NSAIDs, al-
though there is some evidence that the effects of indometacin are greatest and sulindac least. Further study is needed. A retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) with NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use. The most common NSAIDs taken by this cohort of patients were diclofenac, ibuprofen, indometacin and naproxen.28 The European Society of Cardiology (ESC) Task Force and the joint American College of Cardiology/American Heart Associa-
tion both recommend avoiding NSAID use, if possible, in patients with congestive heart failure.29,30

For the effects of NSAIDs on other antihypertensive drug classes see ‘ACE inhibitors’, (p.28), ‘beta blockers’, (p.835) and ‘calcium-channel blockers’, (p.861).

### Thiazide diuretics + Propantheline

**Propantheline can slightly increase the absorption of hydrochlorothiazide.**

**Clinical evidence, mechanism, importance and management**

In 6 healthy fasting subjects the absorption of hydrochlorothiazide 75 mg was delayed and increased (AUC increased by 23% and urinary recovery increased by 36%) by propantheline 60 mg. It is suggested that this occurs because propantheline causes a slower delivery of the hydrochlorothiazide to its areas of absorption.1 This small increase is unlikely to be clinically important.

The various gastrointestinal drug groups covered in this section are listed in ‘Table 27.1’, (see below). ‘Drug absorption interactions’, (p.3) discusses how absorption interactions occur and contains more detailed information on some of the mechanisms of interaction covered in this section.

**Metabolism of proton pump inhibitors**

The main metabolic pathway for esomeprazole, lansoprazole, omeprazole, pantoprazole, and to a lesser extent rabeprazole, is through the cytochrome P450 isoenzyme CYP2C19. This isoenzyme is subject to genetic polymorphism,1 (see ‘Genetic factors’, (p.4), for a further explanation of polymorphism). The poor metaboliser phenotype for CYP2C19 is found in approximately 1 to 6% of Caucasians, 1 to 7.5% of Blacks and 12 to 23% of Oriental and Indian Asians.2

Therefore most patients will be extensive CYP2C19 metabolisers, and their major route for the metabolism of these PPIs will be through this isoenzyme. As a consequence, the levels of PPIs in these patients are likely to be affected by drugs that inhibit or induce CYP2C19, such as ‘fluvoxamine’, (p.973).2 Patients of the extensive metaboliser phenotype have also been shown in some studies to have a poorer clinical outcome, when compared with poor metabolisers e.g. in the eradication of *H. pylori*, as they tend to have lower therapeutic levels of PPIs.2-4

Poor metabolisers, who lack CYP2C19 metabolising capacity, use alternative pathways to metabolise PPIs, and this is mainly CYP3A4. Because poor metabolisers are more dependent on CYP3A4 for metabolism of the PPIs the levels of PPIs may be raised in these patients when they are given CYP3A4 inhibitors, such as ‘clarithromycin’, (p.971), and ‘ketoconazole’, (p.218).

Omeprazole and esomeprazole are also inhibitors of CYP2C19, and therefore they may increase the levels of drugs that are metabolised by CYP2C19, such as diazepam. Other CYP2C19 substrates are listed in ‘Table 1.3’, (p.6).1,2 Particular care may be required when giving drugs that are CYP2C19 inhibitors to patients in those ethnic groups who have a higher percentage of poor CYP2C19 metabolisers, such as Indian Asians.1,2

**Antacids + Milk**

Hypercalcaemia, alkalosis and renal insufficiency (milk-alkali syndrome) can develop in patients taking antacids with calcium-containing substances, including dairy products.

### Clinical evidence

A man presented with nausea, vomiting, constipation, polyuria and polydipsia, which was diagnosed as milk-alkali syndrome, due to daily treatment with 6 tablets of **Caved-S** and 3.5 pints of milk, for dyspepsia related to a peptic ulcer. This dose of **Caved-S** meant he was taking 600 mg of aluminium hydroxide, 1200 mg of magnesium carbonate, 600 mg of sodium bicarbonate and 2280 mg of deglycyrrhizinised liquorice daily. Another case report describes a 42-year-old man who presented with confusion, agitation, involuntary movements of his limbs, severe dehydration, and metabolic and respiratory alkalosis. He had taken large amounts of a **calcium/magnesium carbonate**-containing antacid preparation (Rennies) and had also consumed at least 3 litres of dairy products a day for upper abdominal complaints. Milk-alkali syndrome was diagnosed and he was successfully treated with isotonic saline and potassium. A pregnant woman developed vomiting, drowsiness, abdominal pain and acute pancreatitis after excessive antacid use. She had been taking up to 10 tablets of Rennies antacid (**calcium/magnesium carbonate**), containing about 3 g of elemental calcium with up to 3 glasses of milk a day. In a study in 125 patients with non end-stage renal disease, milk-alkali syndrome was found to be the cause of hypercalcaemia in 11 (8.8%) of the patients, 9 of whom had severe hypercalcaemia (serum calcium greater than 3.5 mmol/L). Several other cases have been reported in recent years involving excessive use of non-prescription calcium carbonate, one of which was in a pregnant woman.

### Mechanism

High intake and absorption of calcium can suppress the parathyroid hormone, which leads to bicarbonate retention by the kidneys, leading to metabolic and respiratory alkalosis. The alkalosis also causes reduced excretion of calcium by the kidneys. Hypermagnesaemia may also have a part to play.

### Importance and management

The milk-alkali syndrome was a common adverse effect of antacid use when it was the primary treatment of peptic ulcer disease, but has become very uncommon with the advent of H2-blockers and proton pump inhibitors. However, the above cases illustrate that while taking antacids, even well within the recommended dosage range, as in the first case, it is still possible to develop a serious and potentially life-threatening reaction if the intake of calcium is high. This should be borne in mind in patients who take both prescribed or non-prescription medications containing calcium, such as antacids or supplements for the prophylaxis of osteoporosis, and also consume large quantities of dairy products in their diet. Chronic milk-alkali syndrome can lead to the formation of calcification and kidney damage, which may be irreversible. The quantity of calcium ingested does not appear to be directly correlated to either the development or severity of milk-alkali syndrome, which has been reported with an intake of between 4 g to 60 g of calcium carbonate. However, a safe maximum calcium intake of 1.2 to 1.5 g of elemental calcium (3 to 3.75 g of calcium carbonate) has been suggested.

---

---

**Bismuth compounds + H2-receptor antagonists**

Ranitidine possibly causes an increase in the absorption of bismuth from tripotassium dicitratobismuthate, but not bismuth salicylate or bismuth subnitrate. Any increase is considered unlikely to be clinically relevant with recommended short courses for *H. pylori* eradication. Other H2-receptor antagonists would be expected to interact similarly.

### Clinical evidence, mechanism, importance and management

The AUC of a single 240-mg dose of tripotassium dicitratobismuthate (TDB, *De Nolabs*), was increased fourfold in 12 healthy subjects given two 300-mg doses of ranitidine (one the night before and one 2 hours before the bismuth compound). The maximum serum levels were approximately doubled. The same regimen of ranitidine had no significant effect on the absorption of bismuth from bismuth salicylate (Pepato-Bismol) or bismuth subnitrate (Roter tablets).

The authors suggest that the reduction in gastric acidity maintains the considered “toxic range” for bismuth. Other H2-receptor antagonists, and other drugs that reduce gastric acidity would be expected to interact similarly (see also ‘Bismuth compounds + Proton pump inhibitors’, p.961).

However, the manufacturers of TDB say that the toxic range of bismuth is arbitrary and a small increase in absorption is not clinically relevant, except perhaps in patients with renal failure, in whom this bismuth compound should be avoided in any case. Note that a complex of ranitidine with bismuth and citrate (ranitidine bismuth citrate) is available in many countries and is a recommended constituent in one of the triple therapy regimens for *H. pylori* eradication. As with all bismuth compounds, it is recommended that this is used only for limited periods: a maximum of 16 weeks (two 8-week courses or four 4-week courses) in a 12-month period.

---

---

**Bismuth compounds + Proton pump inhibitors**

Omeprazole markedly increases the absorption and bioavailability of bismuth from tripotassium dicitratobismuthate and bismuth biskalciurate. Other proton pump inhibitors are expected to interact similarly. However, this is probably unlikely to be clinically relevant.

### Clinical evidence

Thirty-four healthy subjects were randomised to receive a triple therapy capsule *Helizide* (containing bismuth biskalciurate 140 mg, metronidazole 125 mg, and tetracycline 125 mg) at a dose of three capsules four times daily with or without omeprazole 20 mg twice daily for 6 days. Omeprazole increased the maximum serum levels and AUC of bismuth by about threefold. However, the maximum serum level achieved was 25.5 micrograms/L, which was still well below 50 micrograms/L, a level reported to be highly unlikely to cause toxicity. The authors also state that in clinical trials of *Helizide* with omeprazole for 10 days in several hundred patients, no patient showed signs of encephalopathy, a notable adverse effect of bismuth.

In an earlier single-dose study in 6 healthy subjects, a single 240-mg dose of tripotassium dicitratobismuthate was taken 1 hour after the last dose of a 1-week course of omeprazole 40 mg daily. Omeprazole increased the AUC of bismuth fourfold, and increased the maximum serum levels from 36.7 to 86.7 micrograms/L, which the authors pointed out approaches the considered “toxic range” for bismuth (100 micrograms/L and above).
Mechanism

The solubility and absorption of some bismuth compounds are known to be increased by decreased acidity of the stomach, see also 'Bismuth compounds + H₂-receptor antagonists', p.961).

Importance and management

The authors of the single-dose study recommended that the dosage of tripotassium dichromatobismuthate be halved when given with omeprazole because of the possibility of systemic bismuth toxicity. However, an increased risk of toxicity has not been seen in subsequent studies using bismuth biskalcitrate for up to 10 days. The manufacturers of tripotassium dichromatobismuthate say that the toxic range of bismuth is arbitrary and the small increase in absorption is not clinically relevant, except perhaps in patients with renal failure, in whom this bismuth compound should be avoided in any case. No clinically significant effect would be expected if combined treatment is limited to the recommended 2-week regimen for resistant Helicobacter pylori infection. As this interaction is due to changes in gastric pH other proton pump inhibitors would be expected to interact similarly.

2. O’Morain C, Borody T, Farley A, De Boer WA, Dallaire C, Schuman R, Piotrowski J, Fallone CA, Tytgat G, Megraud F, Spénard J. Efficacy and safety of single-tripotassium bismuth compounds + H₂-receptor antagonists, was found to be ap-

Carbenoxolone + Antacids

There is some evidence that antacids may possibly reduce the bioavailability of carbenoxolone liquid.

Clinical evidence, mechanism, importance and management

The bioavailability of carbenoxolone, in a liquid formulation, when given with aluminium/magnesium hydroxide antacids, was found to be approx-imately half that of carbenoxolone in granular and capsule formula-
tions. The extent to which antacids might reduce the ulcer-healing ability of carbenoxolone liquid seems not to have been assessed, but the possibility of a reduction should be borne in mind.

Carbenoxolone + Phenytoin

A single 100-mg dose of phenytoin had no significant effect on the hal-life of a single 100-mg dose of carbenoxolone in 4 healthy subjects. This limited evidence would seem to suggest that there is no reason for avoiding concurrent use.

1. Thornton PC, Papouchado M, Reed PI. Carbenoxolone interactions in man - preliminary re-

Carbenoxolone + Antihypertensives

Carbenoxolone causes fluid retention and raises blood pressure in some patients. This may be expected to oppose the effects of antihypertensive drugs. The potassium-depleting effects of carbenoxolone and diuretics such as the thiazides or loop diuretics can be additive. Spironolactone or amiloride can oppose the ulcer-healing effects of carbenoxolone.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives (unnamed)

Carbenoxolone can raise blood pressure. Five out of 10 patients taking carbenoxolone 300 mg daily, and 2 out of 10 patients taking carbenoxolone 150 mg daily, had a rise in diastolic blood pressure of 20 mmHg or more. Other reports confirm that fluid retention and hypertension occur in those taking carbenoxolone, with the reported incidence of hypertension varying from as low as 4% to as high as 50%, and fluid retention occurring in 0% to 46% of patients. The reason for the blood pressure rise is that carbenoxolone has mineralocorticoid-like activity and therefore causes sodium and water retention. There appear to be few direct reports of adverse interactions between antihypertensives and carbenoxolone. Patients taking carbenoxolone should have regular checks on their weight and blood pressure, and carbenoxolone should be used with caution, if at all, in those with cardiac disease such as hypertension or congestive heart failure (see also Diuretics, below).

(b) Diuretics

Thiazide diuretics have been used to control the oedema and hypertension caused by carbenoxolone, but spironolactone (an aldosterone antagonist) and amiloride are best avoided because they oppose its ulcer-healing effects. If thiazides or other potassium-depleting diuretics (see ‘Table 26.1’, (p.944)) are used it should be remembered that the potassium-losing effects of the carbenoxolone and the diuretic will be additive, so that a potassium supplement may be needed to prevent hypokalaemia. For example, rhabdomyolysis and acute tubular necrosis associated with severe hypokalaemia occurred in a patient given carbenoxolone and chlortalidone, without a potassium supplement. Laryngospasm and stridor have been reported in a patient secondary to hypokalaemia and alkalosis caused by long-term use of furosemide and a carbenoxolone-containing antacid (Pyrogastrone). Possible alternatives to carbenoxolone are the H₁-receptor antagonists, or the proton pump inhibitors, which do not appear to interact with antihypertensives.

Carbenoxolone + Sulphonylureas

Chlorpropamide appears to reduce the serum levels of carbenox-

Clinical evidence, mechanism, importance and management

A single 500-mg dose of tolbutamide had no significant effect on the half-life of a single 100-mg dose of carbenoxolone in 4 healthy subjects. A single 250-mg dose of chlorpropamide delayed the absorption of carbenoxolone and reduced its plasma levels in 6 patients taking
carbonoxolone 100 mg three times daily. The clinical importance of this latter interaction is uncertain.

### Cimetidine + Dimeticone

The pharmacokinetics of a 200-mg dose of cimetidine were not significantly changed by dimeticone 2.25 g in 11 healthy subjects. For the effect of antacids containing dimeticone, see ‘H2-receptor antagonists + Antacids’, p. 966.

### Cimetidine + Phenobarbital

Phenobarbital modestly reduces the AUC of cimetidine, although this is probably not clinically relevant.

**Clinical evidence, mechanism, importance and management**

Phenobarbital 100 mg daily for 3 weeks reduced the AUC of a single 400-mg oral dose of cimetidine in 8 healthy subjects by 15%, and the time during which the plasma concentrations of the cimetidine exceeded 0.5 micrograms/mL (regarded as therapeutically desirable) was reduced by 11%. Phenobarbital apparently stimulates the enzymes in the gut wall so that the metabolism of the cimetidine is increased. Thus the amount of cimetidine absorbed and released into the circulation is reduced.

Direct information is very limited, but the effect of phenobarbital on cimetidine is small and unlikely to be clinically important. No special precautions seem to be necessary.

### Cimetidine + Rifampicin (Rifampin)

Antituberculous treatment with rifampicin, isoniazid and ethambutol has been shown to increase the non-renal clearance of cimetidine by about 50%. This is probably due to enzyme induction caused by rifampicin. However, the total clearance is unchanged and so this interaction would appear to be of little clinical importance.

### Cisapride + Miscellaneous

Ketoconazole, erythromycin, and clarithromycin can cause a marked rise in serum cisapride levels, increasing the risk of serious and life-threatening ventricular arrhythmias including torsade de pointes. Nefazodone and protease inhibitors are also predicted to have this effect. Although there do not appear to be any specific reports, cisapride should not be used with other drugs that prolong the QT interval (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p. 257). No clinically relevant interactions with cisapride are apparent when it is given with antacids, cimetidine, esomeprazole, fluoxetine or pantoprazole, but two isolated reports attribute cardiac toxicity to the concurrent use of cisapride and ranitidine or diltiazem. Cisapride increases the rate of absorption of bromperidol, ciclosporin, diazepam, disopyramide, and nifedipine, but appears to have no important effect on doxigou, morphine, paracetamol (acetaminophen) or propranolol. The effects of anticoagulants may be altered by cisapride.

**Clinical evidence, mechanism, importance and management**

In many countries cisapride has been withdrawn from the market, or is only available for restricted use because of its potential to cause torsade de pointes arrhythmias, especially when cisapride serum levels are elevated. This can lead to cardiac arrest and sudden death. The interactions of cisapride and their importance and management are summarised in ‘Table 27.2’, (p. 964).

### Enteral feeds + Aluminium compounds and/or Sucralfate

Aluminium-containing antacids and sucralfate can interact with high-protein liquid enteral feeds to produce an obstructive plug.

**Clinical evidence**

(a) Aluminium-containing antacids

Three patients, who were being fed with a liquid high-protein nutrient (Fresubin liquid) through an enteral tube, developed an obstructing protein-aluminium-complex oesophageal plug when intermittently given an aluminium/magnesium hydroxide antacid (Alucol-Gel). Another report also describes blockage of a nasogastric tube in a patient treated with aluminium hydroxide (Aludrox) and Nutrition.

(b) Sucralfate alone or with aluminium-containing antacids

A number of reports describe the development of hard putty-like or creamy precipitations and encrustations that have blocked the oesophagus or stomach of patients given sucralfate with enteral feeds (Ensure Plus, Fresubin plus F or Osmalite). Another patient developed this precipitate when treated with Isocal and sucralfate with aluminium/magnesium hydroxide. Similarly, a patient receiving Pulmocare nasogastric feed, sucralfate and aluminium hydroxide gel also developed an oesophageal bezoar, which was analysed and found to contain components of both the drugs and the enteral feed.

Data from the French Pharmacovigilance system database found 16 adults and 5 newborn babies who developed bezoars while taking sucralfate, and identified nasogastric feeding as a risk factor.

**Mechanism**

It seems that a bezoar (a relatively insoluble complex) forms between the protein in the enteral feeds, and the aluminium from the antacids or sucralfate (sucralfate is about 18% aluminium). It thickens when the pH falls.

**Importance and management**

An established and clinically important interaction that can result in the blockage of enteral or nasogastric tubes. The authors of one report say that high molecular protein solutions should not be mixed with antacids or followed by antacids, and if an antacid is needed, it should be given some time after the nutrients and the tube should be vigorously flushed beforehand. The authors of another report say that they feed for 18 hours daily and then give the sucralfate overnight without problems. The manufacturers recommend separating the administration of sucralfate suspension and enteral feeds given by nasogastric tube by one hour.

H₂-receptor antagonists + Antacids

The absorption of cimetidine, famotidine, nizatidine, and ranitidine may possibly be reduced to some extent by antacids, but it seems doubtful if this significantly reduces their effects. Separating the dosages by 1 to 2 hours minimises any interaction. Roxatidine absorption appears not to be affected by antacids. Cimetidine appears not to interfere with the effectiveness of Gaviscon (sodium alginate compound).

Clinical evidence

(a) Cimetidine

When 12 healthy subjects were given oral cimetidine 300 mg four times daily for 5 doses, with and without 30 mL of Mylanta II (aluminium/magnesium hydroxide mixture), the absorption of cimetidine was unaffected.¹ No interaction was found in other single-dose studies using aluminium phosphate²–⁵ or aluminium/magnesium hydroxide⁶–¹⁰ antacids.

In contrast, a number of other single-dose studies indicated that antacids reduce the absorption of cimetidine. The AUCs of 200- to 800-mg doses of cimetidine were reduced by an average of 19 to 34% by 10 to 45 mL of a variety of aluminium/magnesium-containing antacids.⁶–¹⁰ When the antacids were given 1 to 3 hours after cimetidine ‘marginal’ or insignificant reductions occurred in the AUCs.⁷,¹¹,¹²

Gaviscon (sodium alginate/antacid) is an anti-reflux preparation that needs a small amount of gastric acid to be present in order for the alginic acid ‘raft’ to form. A study in 12 healthy subjects designed to find out if an H₂-receptor antagonist would alter the effectiveness of Liquid Gaviscon found that cimetidine 400 mg four times daily for 7 days caused some slight changes in gastric emptying, but the distribution of the Gaviscon in the fundus of the stomach was not altered.¹³

(b) Famotidine

Mylanta II (aluminium/magnesium hydroxide with simeticone) was found to reduce the absorption of famotidine by 19%, a difference that was considered unimportant.¹⁰ Two chewable tablets of Mylanta II were found to have no effect on the pharmacokinetics or pharmacodynamics of famotidine 10 or 20 mg in 18 healthy subjects.¹⁶

(c) Nizatidine

Mylanta Double Strength (aluminium/magnesium hydroxide with simeticone) reduced the absorption of nizatidine by 12%, which was considered clinically insignificant.¹⁰ In a study in 11 healthy subjects a single 30-mL dose of Gelusil (aluminium/magnesium hydroxide with simeticone) reduced the mean AUC and maximum serum levels of nizatidine (given simultaneously) by 13 and 17%, respectively.¹⁷ Another study found that the pharmacokinetics of nizatidine were not affected by an aluminium/magnesium hydroxide antacid (Maalox) although a non-significant reduction in the AUC of 8% and an increase in the time to peak effect of nizatidine were seen.¹⁸

(d) Ranitidine

Mylanta II (aluminium/magnesium hydroxide mixture) 30 mL reduced the ranitidine peak serum levels and AUC after a single 150-mg dose by about one-third in 6 healthy subjects.¹⁹ Mylanta Double Strength (aluminium/magnesium hydroxide with simeticone) reduced the absorption of ranitidine by 26%, which was not thought to be clinically significant.¹⁶

Reductions of up to 59% were found in another study.⁹ Yet another study showed that aluminium phosphate reduced the bioavailability of ranitidine by 30%.²⁰ In contrast, another study found no significant changes in the pharmacokinetics of ranitidine given with an aluminium/magnesium hydroxide antacid (Maalox).¹⁸

(e) Roxatidine

In an open-label crossover study, 24 healthy subjects were given roxatidine 150 mg with 10 mL of Maalox (aluminium/magnesium hydroxide) four times daily. The pharmacokinetics of roxatidine were unchanged, apart from a clinically insignificant lengthening of the half-life.²¹

Mechanism

Not fully understood. Changes in gastric pH caused by the antacid, and retarded gastric motility have been suggested as potential mechanisms. An in vitro study showed no absorption interaction occurred between cimetidine and antacids.⁹

Importance and management

A modest reduction in the bioavailability of cimetidine, famotidine, nizatidine and ranitidine can occur with some antacids although this appears to be more likely when larger doses of antacids are used. None of these interactions are well established and evidence that the effects of the H₂-receptor antagonists are reduced seems to be lacking. If the antacids are given 1 to 2 hours before or after the H₂-receptor antagonist (if fasting), or 1 hour after (if the H₂-receptor antagonist is taken with food), no reduction in bioavailability should occur.¹⁴,¹⁵,¹⁶,¹⁷,¹⁸ Evidence suggests thatroxatidine is unaffected. Given the evidence available it seems unlikely that a clinically significant interaction will occur between any H₂-receptor antagonist and standard doses of an antacid. The action of Gaviscon (sodium alginate) does not appear to be compromised by cimetidine.¹³

References

H2-receptor antagonists + Probenecid

Probenecid markedly decreases the renal clearance of famotidine and modestly reduces the renal clearance of cimetidine. However, these effects are not expected to result in adverse clinical effects.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study 6 healthy subjects were given probenecid 500 mg every 6 hours for 13 doses, with a single 300-mg intravenous dose of cimetidine 3 hours after the last probenecid dose. Probenecid reduced the renal clearance of cimetidine by 22%, without affecting overall clearance. Probenecid 1.5 g increased the AUC of a single 20-mg dose of famotidine in 8 healthy subjects by 81%, and reduced the renal tubular clearance by 89%. It has been suggested that probenecid inhibits the renal secretion of cimetidine and famotidine, thereby reducing their loss from the body. This is consistent with the way that probenecid affects some other drugs. The effects of famotidine would be expected to be increased, but this was not observed. The effects of cimetidine are unlikely to be significantly altered. There would therefore seem to be no reason for avoiding concurrent use. Other H2-receptor antagonists are also renally excreted and therefore they may behave similarly.

H2-receptor antagonists + Sucralfate

Most in vitro and human studies have found that sucralfate does not affect the absorption of either cimetidine, ranitidine, or oxanditidine, but two studies found 22 to 29% reductions in ranitidine bioavailability due to concurrent use of sucralfate. There is no clear reason for avoiding concurrent use.

H2-receptor antagonists + Tobacco or Nicotine

Smoking may reduce the plasma levels of cimetidine and ranitidine, but does not appear to affect famotidine. Cimetidine, and to a lesser extent ranitidine, reduce the clearance of nicotine from the body in non-smokers, but there is some evidence to suggest that cimetidine has no effect on nicotine clearance in smokers.

Clinical evidence

(a) Nicotine

Cimetidine 600 mg twice daily for one day, given before intravenous nicotine (1 microgram/kg per minute given intravenously for 30 minutes), reduced the nicotine clearance in 6 healthy non-smokers by 27 to 30%.

Ranitidine (300 mg twice daily taken for one day) reduced the clearance of nicotine by about 7 to 10%. See also tobacco smoking, below.

(b) Tobacco

In one study, tobacco smokers were given single oral doses of either ranitidine 150 mg or cimetidine 200 mg on two separate days. On one of the days they were allowed to smoke as normal and on the other they were not allowed to smoke. Peak levels for both drugs occurred sooner and were higher on the smoking day than on the non-smoking day. However, the plasma levels of the H2-receptor antagonists after peak levels were achieved were lower. No effect was seen when intravenous cimetidine or ranitidine were given.

A study in heavy smokers (more than 20 cigarettes per day for at least 1 year) given cimetidine 400 mg three times daily for 2 weeks found no reduction in the clearance of nicotine or in the number of cigarettes smoked, when compared with placebo.

There was no difference in the pharmacokinetics and gastric acid-lowering effect of famotidine between 12 healthy smokers and 8 non-smokers.

Mechanism, importance and management

The authors of one of the above studies noted that tobacco smoking induces nicotine metabolism and that this may have been a factor in the lack of effect of cimetidine on nicotine clearance compared with their previous study in non-smokers. On balance cimetidine and other H2-receptor antagonists probably have little effect on nicotine replacement therapy or tobacco smoking.

The healing of duodenal ulcers in patients taking H2-receptor antagonists such as cimetidine, nizatidine and ranitidine is slower and ulcer recurrence is more common in smokers than in non-smokers. It is quite possible that this is due to smoking being a risk factor for the occurrence of duodenal ulcers rather than a significant interaction between smoking and H2-receptor antagonists.

Loperamide + Colestyramine

An isolated report, supported by an in vitro study, indicates that the effects of loperamide can be reduced by colestyramine.

Clinical evidence, mechanism, importance and management

A man who had undergone extensive surgery to the gut, with the creation of an ileostomy, needed treatment for excessive fluid loss. His fluid loss was observed to be “substantially less” when he took loperamide 2 mg every 6 hours alone, than when he took loperamide in combination with colestyramine 2 g every 4 hours. The probable reason is that the colestyramine interacts with other drugs. It has been suggested that the two drugs should be separated as much as possible to prevent mixing in the gut, or that the loperamide dosage should be increased. It is a standard recommendation that other drugs should be given 1 hour before or 4 to 6 hours after colestyramine.

**Mesalazine (Mesalamine) + Ispaghula, Lactitol, or Lactulose**

On theoretical grounds, formulations designed to release mesalazine in response to the higher pH in the colon should not be given with lactulose, lactitol or other preparations that lower the colonic pH. However, neither ispaghula nor lactulose appear to affect the bioavailability of mesalazine.

**Clinical evidence, mechanism, importance and management**

Asacol is a preparation of mesalazine coated with an acrylic based resin (Eudragit S) that disintegrates above pH 7 and thereby releases the mesalazine into the terminal ileum and colon. Since the disintegration depends upon this alkaline pH, the UK manufacturers of Asacol say that the concurrent use of preparations that lower the pH in the lower part of the gut should be avoided. Salofalk is another preparation of mesalazine with a pH-dependent enteric coating.

The pH in the colon can be lowered by lactulose and lactitol, which are metabolised by gut bacteria to a number of acids (e.g. acetate, butyrate, propionate, and lactic acid). In healthy subjects, lactulose 30 to 80 g daily has been found to cause slight falls in colonic pH; from about 6 to 5 in the right colon and from 7 to 6.7 in the left colon. Lactitol 40 to 180 g daily can cause similar falls in pH. Ispaghula can also lower colonic pH (from 6.5 to 5.8 in the right colon, and from 7.3 to 6.6 in the left colon). However, a study in patients given mesalazine found that despite this colonic acidification by ispaghula husk (Fybogel), the release of mesalazine appeared not to be affected, as 24-hour faecal and urinary excretion of mesalazine metabolites were unchanged. Similarly, another study in 14 healthy subjects given delayed-release mesalazine (Asacol) 400 mg three times daily found that lactulose (15 mL increased to 30 mL twice daily) did not affect urinary or faecal excretion of mesalazine and its metabolites.

Thus, although on theoretical grounds ispaghula husk and lactulose might be expected to reduce the effects of mesalazine, no interaction of clinical importance seems to occur, and there have been no reports as yet that a clinically important interaction occurs with either ispaghula husk, lactulose or lactitol. Also note that this interaction is not mentioned by the US manufacturers of Asacol.

**Loperamide + Co-trimoxazole**

**Clinical evidence, mechanism, importance and management**

Co-trimoxazole 960 mg twice daily was given to healthy subjects for 24 hours before and then 48 hours after they took a single 4-mg dose of loperamide (12 subjects) or loperamide oxide (a prodrug of loperamide, 10 subjects). The co-trimoxazole increased the loperamide AUC by 89% and doubled its maximum plasma levels. The loperamide oxide AUC was raised by 54% and its maximum plasma levels were raised by 41%. It is thought that co-trimoxazole inhibits the metabolism of loperamide, possibly by reducing its first pass metabolism. However, despite these rises, because loperamide has a very wide margin of safety, it is thought unlikely that any dosage changes are needed.

The clinical relevance of the decrease in loperamide bioavailability with ritonavir alone or tipranavir/ritonavir is unknown.

**Loperamide + Protease inhibitors**

Ritonavir increases the plasma levels of loperamide. Tipranavir, alone and combined with ritonavir, reduces the bioavailability and plasma levels of loperamide and its metabolites. No central opioid adverse effects are seen when loperamide is given with ritonavir alone, tipranavir alone, or tipranavir/ritonavir.

**Clinical evidence**

In a double-blind, placebo-controlled study, 12 healthy subjects were given a single 600-mg dose of ritonavir with either loperamide 16 mg or placebo. The loperamide AUC and maximum plasma level were increased threefold and 17%, respectively, by ritonavir, but no additional CNS adverse effects were seen. Another study in 20 healthy subjects looked at the pharmacokinetics and pharmacodynamics of a single 16-mg dose of loperamide taken with either tipranavir 750 mg twice daily, ritonavir 200 mg twice daily or both drugs together. (Note that this dose of tipranavir is higher than the usual ritonavir-boosted dose of 500 mg twice daily.) Tipranavir alone reduced the maximum concentration and AUC of loperamide by 58% and 63%, respectively, whereas ritonavir increased these parameters by 93% and 121%, respectively. The combination of tipranavir/ritonavir, as is usual clinical practice, resulted in a net reduction in the maximum concentration and AUC of loperamide by 61% and 51%, respectively, similar to the effect seen with tipranavir alone. The maximum concentration and AUC of the metabolites of loperamide were also reduced. There were no clinically significant loperamide adverse effects on respiration or pupil contractility with either ritonavir alone, tipranavir alone, or the combination.

**Mechanism**

Loperamide is primarily metabolised by cytochrome P450 isoenzyme CYP3A4, and is thought to lack CNS effects because it is a substrate for P-glycoprotein, which transports drugs out of the cells at the blood-brain barrier, thereby restricting CNS penetration. The increase in loperamide levels with ritonavir alone is thought to be due to ritonavir inhibiting CYP3A4. The lack of an increase in loperamide CNS effects suggests that ritonavir alone does not inhibit P-glycoprotein. The reduction in loperamide levels with tipranavir alone or tipranavir/ritonavir is not thought to be via effects on CYP3A4, but is due to induction of gastrointestinal P-glycoprotein by tipranavir, resulting in decreased systemic bioavailability of loperamide.

**Importance and management**

Despite the increases seen in loperamide plasma levels seen in both studies with ritonavir alone, a lack of central opioid effects with loperamide (such as pupillary constriction, respiratory depression and also analgesic effects) was demonstrated. This suggests that the combination of loperamide with ritonavir is potentially safe to use as an anti-diarrhoeal for protease inhibitor-induced diarrhoea.

**Mesalazine (Mesalamine) + Proton pump inhibitors**

Omeprazole does not affect the release of mesalazine from a delayed-release preparation (Asacol).
Clinical evidence, mechanism, importance and management

Asacol is a preparation of mesalazine coated with an acrylic based resin (Eudragit S) that disintegrates above pH 7 and thereby releases the mesalazine into the terminal ileum and colon. The release is rapid at pH values of 7 and above, but it can also occur between pH 6 and 7. Since the proton pump inhibitors can raise the pH in the stomach to 6 and above, the potential exists for the premature release of mesalazine from Asacol. However, a study in 6 healthy subjects given Asacol 400 mg three times daily for 3 weeks found that when they were also given omeprazole 20 mg daily during the second week, and omeprazole 40 mg daily during the third week, the steady-state pharmacokinetics of the mesalazine remained unchanged.1 Had mesalazine been released earlier, the absorption characteristics would have changed. There would therefore appear to be no reason for avoiding the concurrent use of Asacol and omeprazole in doses of up to 40 mg daily. On the basis of this study, it seems likely that other proton pump inhibitors will behave similarly at equivalent doses.

2. Mihara K, Svensson USH, Tybring G, Hai TN, Bertilsson L, Ashton M. Stereospecific analysis of the enantiomers of a single 20-mg dose of omeprazole to the same extent, and increased the oral bioavailability of omeprazole by about threefold.2 The clinical significance of this interaction is unclear.

Omeprazole + Artemisinin

Artemisinin modestly increases the metabolism of omeprazole, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that the AUC of a single 20-mg dose of omeprazole was reduced by 35% by artemisinin 250 mg twice daily for 7 days. The pharmacokinetics of the omeprazole metabolites were unchanged, but the ratio of hydroxyomeprazole/omeprazole increased 2.2-fold in those of an extensive CYP2C19 metabolisers phenotype (see ‘metabolism of proton pump inhibitors’, p.960). This suggests that artemisinin affects the pharmacokinetics of omeprazole by inducing the cytochrome P450 isoenzyme CYP2C19, an enzyme involved in its metabolism, although other isoenzymes may also be involved. A single 250-mg dose of artemisinin had no effect on the pharmacokinetics of omeprazole, which supports the proposed mechanism of enzyme induction.1 A subsequent study in 8 healthy subjects who were of the extensive CYP2C19 metaboliser phenotype similarly found that artemisinin 500 mg daily for 7 days decreased the AUC of both the S- and R-enantiomers of a single 20-mg dose of omeprazole to the same extent, and increased the oral clearance of both enantiomers by about threefold.2 The clinical significance of this interaction is unclear.

Omeprazole + Disulfiram

An isolated case describes a catatonic reaction in a patient given omeprazole and disulfiram.

Clinical evidence, mechanism, importance and management

A patient who had been taking omeprazole 40 mg daily for 7 months was also given disulfiram 500 mg daily. Six days later he gradually developed confusion, which progressed to a catatonic state with muscle rigidity and trismus (spasm of the muscles used to chew food) after 15 days. Both drugs were withdrawn and he gradually recovered. Some months later while taking disulfiram 250 mg daily, he again developed confusion, disorientation and nightmares within 72 hours of starting to take omeprazole 40 mg each morning. Again he recovered when both drugs were stopped.1

The reason for this reaction is not understood, but the authors of the report suggest that the omeprazole may have allowed the accumulation of one of the metabolites of disulfiram, carbon disulphide, which could have been responsible for the toxic effects.1

This is the first and only report of a possible interaction between omeprazole and disulfiram. Other patients given both drugs are said not to have shown adverse effects.2 The general importance of this adverse interaction is therefore uncertain, but it seems likely to be small.

Pirenzepine + Antacids

Mylanta reduces the bioavailability of pirenzepine by about 30%. Another antacid, Trigastril, modestly increases the bioavailability of pirenzepine, but these changes are probably of little clinical importance.

Clinical evidence, mechanism, importance and management

The AUC of a single 50-mg dose of pirenzepine was reduced by about 30% in 20 healthy subjects by 30 mL of Mylanta (aluminium/magnesium hydroxide and simeticone). The antacid reduced the peak plasma levels of pirenzepine by about 45%.1 Another study in 10 healthy subjects found that the AUC of a single 50-mg dose of pirenzepine was increased by almost 25% by 10 mL of an antacid (Trigastril, aluminium/magnesium hydroxide, calcium carbonate).2 In practical terms these modest changes in bioavailability are probably too small to matter.

Pirenzepine + Cimetidine

The pharmacokinetics of pirenzepine and cimetidine are not affected by the presence of the other drug, but pirenzepine increases the cimetidine-induced reduction in gastric acid secretion, which is an apparently advantageous interaction.1

Pirenzepine + Food

Food reduces the bioavailability of pirenzepine by about 30%, but this is probably of little clinical importance.

Clinical evidence, mechanism, importance and management

The AUC of a single 50-mg dose of pirenzepine was reduced by about 30% in 20 healthy subjects when pirenzepine was taken half-an-hour before food, or with food. Peak plasma levels were reduced by about 30% and 45%, respectively. The time to achieve peak levels was also reduced.1 In practical terms this modest change in bioavailability is probably too small to matter. The authors of this report suggest taking it with food because compliance is better if associated with a convenient daily ritual.1

Proton pump inhibitors + Antacids

Maalox does not appear to alter the pharmacokinetics of omeprazole, pantoprazole or rabeprazole. Antacids may cause a slight reduction in the bioavailability of lansoprazole. This is probably not clinically relevant but can be accommodated by separating their administration by one hour. There is no interaction between sodium alginate and omeprazole.
Clinical evidence, mechanism, importance and management

(a) Lansoprazole
In a study in 12 healthy subjects a single 30-mL dose of Maalox (aluminium/magnesium hydroxide) slightly reduced the AUC of a 30-mg dose of lansoprazole by 13% (not statistically significant), and reduced the maximum plasma level by 27%. However, no changes were seen when the lansoprazole was given 1 hour after the antacid. Note that in this study, the bioavailability of lansoprazole was highly variable between subjects (the AUC varied by a factor of 6), and the effect of ‘food’, (below), was greater than the effect of the antacid. In another study, magaldrate had no effect on the AUC of lansoprazole, and slightly reduced the maximum level (28%), but this change was not considered clinically relevant. Nevertheless, the manufacturer recommends that antacids should not be taken within one hour of lansoprazole, but this seems to be an overcautious recommendation.

(b) Omeprazole
Two single-dose studies have shown that Maalox suspension (aluminium/magnesium hydroxide) did not affect the absorption or disposition of omeprazole from an enteric-coated formulation. Similar findings were reported for Maalox suspension in another single-dose study. In contrast, this study found that Maalox granules modestly reduced the AUC of omeprazole-enteric-coated tablets by 26% and reduced its plasma levels. A randomised, crossover study in healthy subjects given omeprazole capsules 20 mg daily for 3 days, with two Gaviscon tablets (aluminium hydroxide, magnesium trisilicate and sodium alginate) on day 3, found that omeprazole did not significantly affect the alginate raft formation or the length of time the raft stayed in the stomach. Another study in healthy subjects, concurrent use of Gaviscon Advance (sodium alginate) 10 mL four times daily and omeprazole (Losec MUPS) 20 mg daily for 3 days did not affect the pharmacokinetics of omeprazole, although it was noted that Gaviscon Advance, unlike Gaviscon, does not contain any antacid. No special precautions appear to be necessary if pantoprazole is given with these antacids.

(c) Pantoprazole
Pantoprazole 40 mg daily was given to 24 healthy subjects with and without 10 mL of Maalox (aluminium/magnesium hydroxide). The AUC, maximum serum levels, and the half-life of the pantoprazole were unchanged by the antacid. No special precautions would seem necessary on concurrent use.

(d) Rabeprazole
In a single-dose study, 12 healthy subjects were, on separate occasions, given 20 mg of rabeprazole with, without, and 1-hour after a dose of aluminium/magnesium hydroxide antacid (Maalox). The antacid had no effect on the pharmacokinetics of rabeprazole, so no special precautions would seem necessary on concurrent use.

Proton pump inhibitors + Food or Drinks

Food modestly reduces the bioavailability of lansoprazole and esomeprazole, but not omeprazole, pantoprazole, or rabeprazole.

Foods such as apple sauce, apple or orange juice, and yoghurt do not seem to significantly affect the bioavailability of the contents of lansoprazole or omeprazole capsules, and apple sauce did not alter the bioavailability of the contents of esomeprazole capsules.

Clinical evidence, mechanism, importance and management

(a) Esomeprazole
In a crossover study in fasting healthy subjects, the bioavailability of the contents of an esomeprazole capsule mixed with one tablespoonful of apple sauce were similar to those of an intact esomeprazole capsule taken with water. Apple sauce was chosen because it is acidic and would therefore be unlikely to affect the enteric coat of the esomeprazole granules from the capsule. An in vitro study found that esomeprazole enteric-coated granules from an opened capsule were stable when mixed with 100 mL tap water, yoghurt, orange juice or apple juice. The authors suggest that it is likely that esomeprazole could be mixed with these juices or other soft acidic foods in patients who cannot swallow a capsule. Nevertheless, for patients unable to swallow, the UK manufacturers recommend dispersing esomeprazole tablets in non-carbonated water only to avoid dissolving the enteric coating. They also note that food delays and decreases the absorption of esomeprazole tablets, but that this has little effect on the efficacy of the gastric acidity. The US manufacturers say that because the AUC of esomeprazole can be reduced by 43 to 54% by food, esomeprazole capsules and oral suspension should be taken at least one hour before meals.

(b) Lansoprazole
A study found that food (a standard meal) reduced lansoprazole bioavailability by 27%. Another study found a 50% reduction in lansoprazole bioavailability with food (a standard breakfast). The authors of both these studies therefore recommended that lansoprazole should not be given with food. The maximum serum levels and AUC of lansoprazole are reduced by 50 to 70% when it is given 30 minutes after food. No significant effect was found when lansoprazole was given before meals. The manufacturers recommend, to achieve optimal efficacy, lansoprazole should be given in the morning at least 30 minutes before food. However, in a crossover study in fasting healthy patients the bioavailability of the contents of a lansoprazole 30 mg capsule mixed with either orange juice, tomato juice, or one tablespoonful of strained pear was comparable to that of an intact capsule given with water. This study suggests that, for patients who are unable to swallow or who have difficulty swallowing, mixing the capsule contents with these specific juices or soft foods is acceptable. The US manufacturers also say that the intact contents of the delayed-release capsules may be mixed in with a small volume (60 mL) of apple sauce, Ensure pudding, cottage cheese, or yoghurt. However, the soluble tablets may only be dispersed in water, and, if given via a nasogastric tube, the tube should be flushed with water before and after administration. The suspension may only be mixed with water and must not be given through a nasogastric tube.

(c) Omeprazole
In a study in healthy subjects, giving omeprazole with breakfast delayed its absorption, but did not affect the total amount absorbed. Similarly, in another study in healthy subjects, a standardised breakfast did not affect the bioavailability or maximum concentration of omeprazole enteric-coated tablets, when compared to the fasting state, or when taken immediately before a meal, although an increase in time to maximum concentration was seen. Omeprazole may therefore be taken without regard to the timing of meals. For patients unable to swallow, the manufacturers recommend mixing the intact contents of the opened capsule with non-carbonated water, apple, orange or pineapple juice, yoghurt or apple sauce.

(d) Pantoprazole
The manufacturers state that food has no effect on the bioavailability of pantoprazole. The US manufacturers recommend that the tablet is swallowed whole with water with or without food, whereas the UK manufacturers recommend taking it before a meal.

(e) Rabeprazole
A high-fat meal may delay the absorption of rabeprazole but does not alter the AUC and maximum serum levels and so rabeprazole may be taken with or without food. The UK manufacturers note that, although food

---

has no effect on the activity of rabeprazole, for once daily regimens they recommend taking it in the morning, before breakfast, to aid compliance.5,6

6. Bergstrand R, Grind M, Nyberg G, Olofsson B. Decreased oral bioavailability of lansa- 

Proton pump inhibitors + Grapefruit juice

Grapefruit juice has little effect on the AUC of lansoprazole or omeprazole, but modestly reduces the formation of the sulphone metabolites, which is unlikely to be clinically relevant.

Clinical evidence

(a) Lansoprazole

In a randomised, crossover study 21 subjects were given a single 60-mg dose of lansoprazole with either 200 mL of water or freshly-squeezed grapefruit juice. The AUC of lansoprazole was slightly increased by 18%, and the formation of the sulphone metabolite was reduced by the grapefruit juice. Metabolism to the hydroxyl metabolite was not significantly affected.1

(b) Omeprazole

In a single-dose study in 12 healthy subjects, grapefruit juice 300 mL had no significant effect on the AUC or half-life of omeprazole 20 mg: the results were similar in both CYP2C19 metaboliser phenotypes, as indicated by renal clearance of hydroxyomeprazole. However, there was a 20% reduction in AUC of omeprazole sulphone.2

Mechanism

From the studies above1,2 it appears that grapefruit juice may have a minor inhibitory effect on the metabolism of omeprazole and lansoprazole by the cytochrome P450 isoenzyme CYP3A4 (which results in the sulphone me- 

Findings and management

These appear to be the only studies examining the effects of Gingko biloba and St John’s wort on proton pump inhibitors. However, the reduction in the AUCs of omeprazole seen (about 40%) suggest that there is a possibility that omeprazole will be less effective in patients taking these herbal medicines. As all PPIs are metabolised by CYP2C19 in all subjects (by 49% in extensive metabolisers and 41% in poor metabolisers), and also increased the levels of hydroxyomeprazole by 35% in those who were extensive metabolisers. It was concluded that Gingko biloba increases the metabolism (hydroxylation) of omeprazole by inducing the cyto- 

Proton pump inhibitors + Herbal medicines

Both Gingko biloba and St John’s wort induce the metabolism of omeprazole, and this might result in reduced efficacy. Other pro- 

Clinical evidence and mechanism

(a) Gingko biloba

In one study, 18 healthy Chinese subjects were given a single 40-mg dose of omeprazole before and after a 12-day course of a standardised extract of Gingko biloba 140 mg twice daily. The subjects were divided into three groups: homozygous extensive CYP2C19 metabolisers (6 subjects), het- erozygous extensive CYP2C19 metabolisers (5) and poor CYP2C19 me- 

Impact and management

These appear to be the only studies examining the effects of Gingko biloba and St John’s wort on proton pump inhibitors. However, the reduction in the AUCs of omeprazole seen (about 40%) suggest that there is a possibility that omeprazole will be less effective in patients taking these herbal medicines. As all PPIs are metabolised by CYP2C19 to varying extents, it is likely that the effects of Gingko biloba and St John’s wort seen in these studies will be similar with other PPIs. There is insufficient evidence to suggest that these herbs should be avoided in patients taking PPIs. However, the potential reduction in the efficacy of the PPI should be borne in mind, particular where the consequences may be serious, such as in pa-

(b) St John’s wort (Hypericum perforatum)

In a crossover study 12 healthy subjects (6 of the extensive CYP2C19 metaboliser phenotype and 6 of the poor CYP2C19 metaboliser phenotype) were given St John’s wort 300 mg three times daily or placebo for 14 days, followed by a single 20-mg dose of omeprazole on day 15. St John’s wort modestly decreased the AUC of omeprazole in all subjects (by 49% in extensive metabolisers and 41% in poor metabolisers), and also increased the levels of hydroxyomeprazole by 35% in those who were extensive metabolisers. It was concluded that St John’s wort increases the metabolism of omeprazole by inducing both CYP2C19 and CYP3A4.

Proton pump inhibitors + Macrolides

Clarithromycin approximately doubles the serum levels of esome- prazole, lansoprazole and omeprazole, but has no effect on panto-

The small changes in lansoprazole and omeprazole pharmacokinetics are not clinically relevant, so it appears that they may be taken with grapefruit juice. See also ‘Proton pump inhibitors + Food or Drinks’, p.970, for the finding that other fruit juices had no effect on lansoprazole or omeprazole bioavailability.

levels, without significantly altering its effects. Lansoprazole and omeprazole do not appear to affect the pharmacokinetics of roxithromycin.

Clinical evidence

(a) Clarithromycin

When 11 healthy subjects taking omeprazole 40 mg daily were also given clarithromycin 500 mg every 8 hours for 5 days, the maximum serum levels of clarithromycin rose by 30% and its AUC rose by 89%, but the effect of omeprazole on gastric pH was unchanged. The maximum serum clarithromycin levels rose by 11% and the AUC increased by 15%. In a similar study, approximately twofold increases in the AUC of omeprazole were reported. In another study in 8 subjects (all extensive metabolisers of CYP2C19), clarithromycin 500 mg twice daily for 7 days induced a similar twofold increase in the AUC of omeprazole 20 mg twice daily but did not affect the AUC of pantoprazole 40 mg twice daily. The levels of clarithromycin itself were not affected.

The AUC of a single 60-mg dose of lansoprazole was raised 1.55-fold to 1.8-fold by clarithromycin 500 mg twice daily for 6 days in both extensive and poor metabolisers of CYP2C19. In another study in healthy subjects, the AUC of lansoprazole 30 mg twice daily was increased by just 25% by clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily for 4 days. The AUC of the hydroxyl metabolite of clarithromycin was also increased by about 25%.

In a study in 18 healthy subjects the AUC, maximum serum levels and half-life of esomeprazole 40 mg once daily were increased by 70%, 18% and 35%, respectively, when taken with clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily for 7 days. When the study was repeated in 19 healthy subjects with esomeprazole 20 mg the AUC, maximum serum levels and half-life of esomeprazole were increased by 127%, 39% and 40%, respectively. All subjects were of the CYP2C19 extensive metaboliser phenotype. Similar increases in esomeprazole levels (e.g. AUC doubled) were seen in a further 6 subjects who were of the CYP2C19 poor metaboliser phenotype. In these studies, esomeprazole did not alter clarithromycin levels.

See also ‘Proton pump inhibitors + Penicillins’, below, for information on case reports of glossitis, stomatitis and a black tongue with lansoprazole and antibacterial regimens including clarithromycin.

(b) Erythromycin

A study was undertaken in a patient to confirm the in vitro findings that erythromycin inhibits the metabolism of omeprazole. After taking 500 mg of erythromycin base and 20 mg of omeprazole daily for 8 weeks, it was found that the AUC of omeprazole was increased almost fourfold, and the metabolite of omeprazole was undetectable. These raised omeprazole levels might have been expected to increase its effectiveness, but in this patient the time during which gastric pH was less than 4 decreased by 22%.

(c) Roxithromycin

A study of roxithromycin 300 mg twice daily with omeprazole 20 mg twice daily or with lansoprazole 30 mg twice daily, for 6 days found that neither PPI significantly affected the pharmacokinetics of roxithromycin.

Mechanism

Clarithromycin appears to inhibit the metabolism of esomeprazole, lansoprazole, and omeprazole by the cytochrome P450 isoenzyme CYP3A4, one of the enzymes involved in their metabolism. Pantoprazole is metabolised by CYP2C19 only and was therefore not affected by the inhibition of CYP3A4. See ‘Gastrointestinal drugs’, (p.960) for an overview of the metabolism of PPIs and the role of CYP2C19 polymorphism. Erythromycin interacts similarly, whereas roxithromycin has only weak effects on CYP3A4.

Importance and management

The pharmacokinetic interactions between clarithromycin and omeprazole, esomeprazole and lansoprazole are established. However, none of the changes reported represents an adverse interaction, but they may help to explain why concurrent use is valuable in the eradication of Helicobacter pylori. Erythromycin is likely to interact similarly, whereas roxithromycin does not. Pantoprazole is not affected by macrolides.

Clinical evidence and mechanism

(a) Pharmacokinetic interactions

A study in 12 healthy subjects found no significant changes in the pharmacokinetics of amoxicillin 1 g twice daily when it was given with lansoprazole 30 mg twice daily and clarithromycin 500 mg twice daily for 4 days. Other randomised, crossover studies in a total of 36 healthy subjects also found no changes in the bioavailability or half-life of amoxicillin 1 g twice daily when it was given with clarithromycin 500 mg twice daily and either esomeprazole 20 mg twice daily or 40 mg once daily for 7 days.

In other studies amoxicillin caused a few small changes in the pharmacokinetics of bacampicillin and amoxicillin, but their bioavailabilities were not reduced, and the use of amoxicillin with omeprazole had a synergistic effect on Helicobacter pylori eradication. Similarly, in another study, omeprazole 40 mg twice daily for 5 days did not affect the pharmacokinetics of amoxicillin 750 mg twice daily for 5 days, although the mean serum concentration of amoxicillin was 12% lower and intragastric pH was slightly lower with the combination than with omeprazole alone. This was felt to be partly due to suppression of H. pylori.

Omeprazole has no clinically significant effect on the pharmacokinetics of oral or intravenous metronidazole.

Clinical evidence, mechanism, importance and management

The plasma pharmacokinetics of a single oral dose of metronidazole were unaffected by 5 days pre-treatment with omeprazole 20 mg twice daily in 14 healthy subjects. Similar results were found in another study with oral and intravenous metronidazole, but when the gastric juice was further studied it was found that the transfer of metronidazole into the gastric juice following an intravenous dose dropped from 15.5 to 2.6% in the presence of omeprazole. The significance of these findings is unclear, but the clinical relevance seems small.

See also ‘Proton pump inhibitors + Penicillins’, below, for case reports of glossitis, stomatitis and a black tongue with lansoprazole and antibacterial regimens including metronidazole.

Esomeprazole, lansoprazole and omeprazole do not alter the pharmacokinetics of amoxicillin, and omeprazole does not alter bacampicillin bioavailability. Isolated reports describe glossitis, stomatitis and a black tongue with lansoprazole and antibacterial regimens including metronidazole.

(b) Proton pump inhibitors + Penicillins
Six cases of glossitis, stomatitis and/or black tongue were reported to the Sicilian Regional Pharmacovigilance Centre in patients on lansoprazole, when combined with antibiotics used to treat H. pylori infections. All 6 patients had been given daily doses of lansoprazole 60 mg with clarithromycin 1 g and either metronidazole 1 g (3 patients) or amoxicillin 2 g (3 patients) for one week, after which the antibacterials were stopped. The lansoprazole continued at 30 mg for periods of up to 3 weeks. The glossitis (1 patient), black tongue (3 patients) and stomatitis (2 patients) developed between days 2 and 19 of the courses of treatment. In one small randomised study, nine cases of glossitis occurred when lansoprazole was given with amoxicillin but none occurred with lansoprazole alone.

Importance and management
The incidence of glossitis, stomatitis and black tongue reported with lansoprazole and antibacterials appears to be rare and no new cases appear to have been published since these reports, whereas these drug combinations are commonly used for the eradication of H. pylori. Just why these drugs cause these adverse effects, and whether they are due to just one drug or to an interaction is not understood. Noted that the CSM in the UK have received reports of stomatitis, glossitis and a black, hairy tongue or discoloration with each of the reported drugs individually. The CSM in the UK have received reports of 4 cases of stomatitis, one case of glossitis and one case of a black hairy tongue with sole use of lansoprazole, but these are rare effects.

The pharmacokinetics of amoxicillin do not appear to be affected by concurrent use of esomeprazole, lansoprazole and omeprazole, and omeprazole was not affected by amoxicillin.

Mechanism
All proton pump inhibitors are primarily metabolised by the cytochrome P450 isoenzyme CYP2C19, which is subject to genetic polymorphism, see ‘Gastrointestinal drugs’ (p.960). As fluvoxamine inhibits CYP2C19, it can increase the levels of PPIs in patients who are extensive CYP2C19 metabolisers, but does not significantly affect the metabolism of PPIs in patients who are poor metabolisers.

Importance and management
An established interaction. The increased levels of these PPIs seen in extensive metabolisers taking fluvoxamine are similar to those seen in poor metabolisers not taking fluvoxamine, and are unlikely to lead to an increase in adverse effects because of the wide therapeutic margin of PPIs.

Some studies have shown that CYP2C19 genotype is a factor in the success of PPI-based eradication regimens, as poor metabolisers of CYP2C19 appear to have higher H. pylori eradication rates with these regimens than extensive metabolisers. Therefore, treatment of H. pylori is likely to be more successful in patients who are extensive metabolisers and are also taking an inhibitor of CYP2C19 such as fluvoxamine (see ‘Table 1.3’, (p.6)). However, the addition of fluvoxamine to improve PPI-based eradication regimens is not clinically appropriate because of the risk of fluvoxamine adverse effects.

Proton pump inhibitors + SSRIs
Fluvoxamine markedly inhibits the metabolism of the proton pump inhibitors lansoprazole, omeprazole and rabeprazole in those of the CYP2C19 extensive metaboliser phenotype, producing levels comparable to those in poor metabolisers. However, these increases are probably of little clinical relevance. Theoretically escitalopram may have the same effect. Omeprazole may increase escitalopram levels.

Clinical evidence
(a) Eslicotoram
Omeprazole 30 mg daily caused a 50% increase in the plasma levels of eslicotoram. This is only a moderate increase, but the manufacturer suggests that caution is warranted and a dose adjustment of the escitalopram may be needed.

(b) Fluvoxamine
Several studies in healthy subjects have investigated the effects of fluvoxamine (a CYP2C19 inhibitor) on the metabolism of PPIs. In these studies, fluvoxamine 25 mg twice daily for 6 days had significant effects on the pharmacokinetics of three different PPIs in patients who were of the extensive CYP2C19 metaboliser phenotype (the most common phenotype) as follows:
- **Lansoprazole**: Fluvoxamine increased the AUC and elimination half-life of a single 40-mg dose of lansoprazole by 3.8-fold and 3-fold, respectively.
- **Omeprazole**: Fluvoxamine increased the AUC, half-life and maximum plasma concentration of a single 40-mg dose of omeprazole by 6-fold, 2.6-fold and 3.7-fold, respectively.
- **Rabeprazole**: Fluvoxamine increased the AUC, elimination half-life and maximum plasma concentration of a single 20-mg dose of rabeprazole by 2.8-fold, 2.4-fold and 2-fold, respectively.

However, these pharmacokinetic changes essentially had the effect of turning the extensive metabolisers into poor metabolisers. In contrast, in patients who were of the CYP2C19 poor metabolisers phenotype, fluvoxamine did not have any significant effect on the pharmacokinetics of either of these three PPIs.

In an earlier study in 12 healthy subjects (7 extensive metabolisers and 5 poor metabolisers of CYP2C19) given fluvoxamine 10 to 50 mg daily for 7 days, with a single 20-mg dose of omeprazole on day 7, the AUC of omeprazole was increased by nearly threefold by fluvoxamine 10 to 20 mg and by over fourfold by fluvoxamine 25 to 50 mg (all subjects combined).

**Sulphasalazine + Antibacterials**
Ampicillin and rifampicin markedly reduce the colonic release of 5-aminosalicylate (the active drug) from sulphasalazine. Metronidazole appears not to interact adversely with sulphasalazine.
Clinical evidence

(a) Ampicillin
In a study in 5 healthy subjects the conversion and release of the active metabolite of sulfasalazine, 5-aminosalicylic acid was reduced by one third when a single 2-g dose of sulfasalazine was given after a 5-day course of ampicillin 250 mg four times daily.1

(b) Metronidazole
A study in 10 patients (7 with Crohn’s disease and 5 with ulcerative colitis) taking long-term sulfasalazine 2 to 4 g daily found that no statistically significant changes in serum sulfapyridine levels occurred while they were also taking metronidazole 400 mg twice daily for 8 to 14 days.2

(c) Rifampicin (Rifampin)
A crossover trial in 11 patients with Crohn’s disease receiving long-term treatment with sulfasalazine found that rifampicin 10 mg/kg daily and ethambutol 15 mg/kg daily reduced the plasma levels of both 5-aminosalicylic acid and sulfapyridine by about 60%.3 A similar study in patients taking sulfasalazine 1.5 to 4 g daily found that the plasma sulfapyridine levels were reduced by 57% when patients were taking rifampicin 10 mg/kg and ethambutol 15 mg/kg daily, when compared with placebo. They also noted an increase in the erythrocyte sedimentation rate (ESR) during antibacterial treatment.4

Mechanism
The azo link of sulfasalazine is split by anaerobic bacteria in the colon to release sulfapyridine and 5-aminosalicylic acid, the latter being the active metabolite that acts locally in the treatment of inflammatory bowel disease. Antibacterials that decimate the gut flora can apparently reduce this conversion and this is reflected in lower plasma levels. Rifampicin also possibly increases the metabolism of the sulfapyridine.

Importance and management
Information is limited, but the interaction appears to be established. However, the extent to which these antibacterials actually reduce the effectiveness of sulfasalazine in the treatment of Crohn’s disease or ulcerative colitis seems not to have been assessed, but be alert for evidence of a reduced effect if ampicillin, rifampicin or any other oral antibacterial is given. Neomycin, which also affects the activity of the gut microflora, has been seen to interact similarly in animal studies, but limited evidence suggests metronidazole does not interact.5

Sulfasalazine + Colestyramine
Animal studies show that colestyramine can bind with sulfasalazine in the gut, thereby reducing its activity, but it is not known if this also occurs in clinical use.

Clinical evidence, mechanism, importance and management
A study in rats found that colestyramine binds with sulfasalazine so that the azo-bond is protected against attack by the bacteria within the gut. As a result the active 5-aminosalicylic acid is not released and the faecal excretion of intact sulfasalazine increases 30-fold.1 It seems possible that this interaction could also occur in humans, but confirmation of this is lacking. Separating the drug dosages to prevent their admixture in the gut has proved effective with other drugs that bind with colestyramine. Standard advice is to avoid other drugs for one hour before, and 4 to 6 hours after colestyramine.

Sulfasalazine + Iron compounds
Sulfasalazine and iron appear to bind together in the gut, but whether this reduces the therapeutic response to either drug is uncertain.

Clinical evidence, mechanism, importance and management
Ferrous iron 400 mg reduced the peak serum levels of a single 50-mg/kg dose of sulfasalazine by 40% in 5 healthy subjects. The reasons are not known, but it seems likely that the sulfasalazine chelates with the iron in the gut and thereby interferes with its absorption.1 The extent to which this suggested chelation affects the ability of the intestinal bacteria to split the sulfasalazine and release its locally active metabolite 5-aminosalicylic acid seems not to have been studied. Therefore the effect of this interaction on the clinical response to sulfasalazine is unclear.

Sulfasalazine + Zileuton
No pharmacokinetic interaction appears to occur between sulfasalazine and zileuton.

Clinical evidence, mechanism, importance and management
In a randomised, double-blind, placebo-controlled study, 14 healthy subjects were given sulfasalazine 1 g every 12 hours for 8 days, with zileuton 800 mg or a placebo every 12 hours on days 3 to 8. It was found that the pharmacokinetics of the sulfasalazine and its metabolites (sulphapyridine and N-acetyl sulphapyridine) were not significantly changed. The study did not directly look at the pharmacokinetics of the zileuton but the parameters measured were similar to those seen in a previous study.1 There would seem to be no reason for special precautions if both drugs are used.

Sulfasalazine + Cimetidine
Cimetidine does not interact with sulfasalazine.

Clinical evidence, mechanism, importance and management
In a study, 5 patients with rheumatoid arthritis were given sulfasalazine alone, and another 9 patients were given cimetidine 400 mg three times daily for 18 weeks as well as their usual sulfasalazine. On comparing the two groups, it was found that cimetidine did not affect the plasma or urinary levels of sulfasalazine and there were no changes in blood cell counts or haemoglobin levels. It was concluded that no clinically important interaction occurs between these two drugs.1

---

The oral contraceptives are of two main types: the combined hormonal contraceptives containing both an oestrogen and a progestogen (monophasic, biphasic, triphasic, or sequential), available as tablets or a patch, and the progestogen-only contraceptives, which are available as tablets (sometimes called ‘mini’ pills), parenteral preparations (implants, depot injections) and intrauterine devices.

The oestrogen most commonly used in combined hormonal contraceptives is ethinylestradiol, in a usual daily dose of 20 to 50 micrograms, though higher doses of ethinylestradiol may be used with liver enzyme-inducing drugs such as rifampicin. Mestranol (a pro-drug of ethinylestradiol) is used only rarely (daily dose 50 micrograms). The progestogens used in both combined and progestogen-only oral contraceptives are commonly those derived from 19-nortestosterone and can be subdivided into first generation (e.g. etynodiol diacetate, lynestrenol, norethisterone), second generation (levonorgestrel, norgestrel) and third generation (e.g. desogestrel, drospirenone, gestodene, norgestimate). Note that drospirenone is an analogue of spironolactone and has antiandrogenic and antimineralocorticoid effects. A patch containing ethinylestradiol and norelgestromin is also available. The progestogens used in parenteral progestogen-only contraceptives are either 19-nortestosterone derivatives (e.g. etonogestrel, norethisterone) or derived from progesterone (e.g. medroxyprogesterone acetate). Those in intra-uterine devices are 19-nortestosterone derivatives (e.g. levonorgestrel).

Combined oral preparations are most usually taken for 21 days, followed by a period of 7 days during which withdrawal bleeding occurs. Some of them include 7 inert tablets to be taken at this time so that the daily routine of taking a tablet is not broken. The combined patch is applied weekly for 3 weeks followed by a patch-free week. The oestrogenic and progestogenic components of these contraceptives act together to consistently suppress ovulation. The progestogen-only oral contraceptives are taken continuously; the implants, injections or intra-uterine devices slowly release the progestogen over an extended period of time. They do not inhibit ovulation reliably in all cycles and probably act mainly by increasing the viscosity of the cervical mucus so that the movement of the sperm is retarded. They may also cause changes in the endometrium, which inhibit successful implantation.

Interactions

(a) Combined hormonal contraceptives

Almost all of the interactions of the hormonal contraceptives described in this publication involve the combined hormonal contraceptives. Most of the clinically important interactions with the combined hormonal contraceptives involve increased metabolism. The major route for hepatic metabolism of ethinylestradiol is hydroxylation by the cytochrome P450 isoenzyme CYP3A4, and progestogens are also substrates for this enzyme. Thus, inducers of this enzyme can increase the clearance of the contraceptive steroids and possibly increase breakthrough bleeding and decrease contraceptive efficacy (see ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985). The drugs that have been shown to induce the metabolism of hormonal contraceptives are listed in ‘Table 28.1’, (see below). Conversely, inhibitors of CYP3A4 may increase the incidence of adverse effects such as nausea, breast tenderness, headaches, and potentially more serious complications such as thromboembolic events, although the latter has yet to be demonstrated.

Some of the conjugated metabolites of ethinylestradiol undergo enterohepatic recirculation, and certain antibacterials are postulated to reduce this by inhibiting gut flora, thereby possibly decreasing contraceptive efficacy, although this is unproven (see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981). Low-dose combined oral contraceptives may be more susceptible to drug interactions than standard-dose or high-dose preparations, but evidence to support this is scant. When considering any pharmacokinetic interactions, it should be noted that there is a large interindividual variation in plasma levels of ethinylestradiol and progestogens.

(b) Progestogen-only contraceptives

There is very little direct information about interactions with the progestogen-only contraceptives (oral, parenteral, and intrauterine). It is unwise to uncritically assume that interactions known to occur with the combined oral contraceptives also occur with these. However, it seems probable that an increased risk of failure with the oral and parenteral progestogen-only contraceptives is likely with drugs that cause enzyme induction (listed in ‘Table 28.1’, (see above)), which results in an increased clearance of the progestogen, with an accompanying loss of efficacy. The progestogen-releasing intrauterine system is thought to have a primarily local effect, and may not be affected by enzyme-inducers (see ‘Progestogen-only contraceptives + Enzyme inducers’, p.1007). However, much more study is needed to clarify the situation.

(c) Emergency hormonal contraceptives

It is not known whether interacting drugs are likely to affect the emergency hormonal contraceptives, although it is common practice that women taking enzyme-inducing drugs (see ‘Table 28.1’, (see above)) are given an increased dosage to accommodate the increased rate of metabolism by the liver (see ‘Emergency hormonal contraceptives + Enzyme inducers’, p.977). The efficacy of progestogen-only emergency hormonal contracept-
tives is not affected by antibacterials that do not induce liver enzymes (see ‘Emergency hormonal contraceptives + Antibacterials’, p.977).

(d) Hormone replacement therapy (HRT)

The preparations used for HRT contain oestrogens, either alone or combined with progestogens. They differ from the hormonal contraceptives as the most commonly used oestrogens in HRT are natural oestrogens such as estradiol and conjugated oestrogens, and their dosages are generally lower than equivalent doses of ethinylestradiol used in combined hormonal contraceptives. There are only a few reports of interactions with HRT preparations, but generally they are expected to behave very much like the combined oral contraceptives.

(e) Other preparations

Cyproterone acetate combined with ethinylestradiol (co-cyprindiol) is intended for use in women with androgen-dependent skin conditions, but it also acts as an oral contraceptive and is therefore predicted to interact like conventional oestrogen-containing oral contraceptives (see ‘Co-cyprindiol (Cyproterone/Ethinylestradiol) + Miscellaneous’, p.977).

General references

Co-cyprindiol is a mixture of the anti-androgenic progestogen, cyproterone acetate 2 mg, with ethinylestradiol 35 micrograms. It is used for the treatment of acne and moderately severe hirsutism in women who may also wish to use it as an oral contraceptive, and its contraceptive efficacy is expected to be reduced by the same hepatic enzyme inducers (see Table 28.1). Co-cyprindiol also interacts with minocycline to increase facial pigmentation.

Clinical evidence, mechanism, importance and management

Co-cyprindiol has the potential to cause hyperkalaemia and may have additive effects with other potassium-sparing drugs.

Clinical evidence, mechanism, importance and management

Drospirenone has the potential to cause hyperkalaemia and may have additive effects with other potassium-sparing drugs.

Emergency hormonal contraceptives + Enzyme inducers

The efficacy of both the progestogen-only and combined emergency hormonal contraceptive is likely to be reduced by enzyme inducers such as rifampicin and some antiepileptics.

Emergency hormonal contraceptives + Antibacterials

There is a theoretical possibility that the emergency contraceptive efficacy of norgestrel/ethinylestradiol could be affected by antibacterials that do not induce liver enzymes, such as the penicillins and tetracyclines. The efficacy of levonorgestrel given for emergency contraception is not likely to be affected by these antibacterials.

Clinical evidence, mechanism, importance and management

The manufacturer has stated that the efficacy of norgestrel/ethinylestradiol (Schering PC4) may be reduced by ampicillin and other antibacterials. Co-cyprindiol is expected to interact with enzyme inducers in a similar manner to the combined oral contraceptives, and therefore the risk of contraceptive failure is increased. Like combined oral contraceptives, there may be rare cases of contraceptive failure with broad-spectrum antibacterials. There is some evidence that co-cyprindiol also interacts with minocycline to increase facial pigmentation.

Drospirenone + Potassium-sparing drugs

Drospirenone has the potential to cause hyperkalaemia and may have additive effects with other potassium-sparing drugs.

Clinical evidence, mechanism, importance and management

Drospirenone is an analogue of spironolactone and has antimineralocorticoid and potassium-sparing effects, and therefore may increase the risk of hyperkalaemia if it is given to patients with conditions that predispose to hyperkalaemia (e.g. renal failure), and/or with potassium supplements or other drugs that may increase potassium levels such as ACE inhibitors, angiotensin II receptor antagonists, ciclosporin, heparin, NSAIDs (uncommon), potassium-sparing diuretics (such as amiloride, triamterene) and other aldosterone antagonists (such as spironolactone and eplerenone). Note that the US manufacturer notes that hyperkalaemia did not occur in a study where drospirenone was given with enalapril 10 mg twice daily, but subject developed hyperkalaemia (defined as serum potassium greater than 5.5 mmol/L). It is generally recommended that serum potassium is measured during the first cycle of treatment with drospirenone.

combined oral contraceptives (see individual monographs). This would also be expected when they are used as postcoital emergency contraceptives. However, it is difficult to envisage a study design that would show whether this reduced metabolism results in reduced efficacy of emergency contraception (e.g. indicators of ovulation do not necessarily indicate likely reduced efficacy).

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit notes that there appears to be no good evidence on how to manage this interaction, but current clinical practice is to increase the contraceptive dose by approximately 50%. The British National Formulary recommends giving a dose of levonorgestrel 1.5 mg immediately followed by another 1.5-mg dose 12 hours later, although this is unlicensed. A copper IUD may also be used as an effective alternative. In the UK it is possible to buy emergency hormonal contraception without a prescription; however, it has been advised that patients taking enzyme inducers should not be supplied the emergency hormonal contraceptive but should be referred to a doctor or family planning service. Given the potential consequences of an unwanted pregnancy, these seem sensible precautions.

Gestrinone + Enzyme inducers

The manufacturer says that rifampicin and antiepileptics may reduce the effects of gestrinone.

Clinical evidence, mechanism, importance and management

The manufacturer suggests that rifampicin and antiepileptics (not named, but by implication those that are enzyme-inducers, see Table 28.1, (p.975)) can accelerate the metabolism of gestrinone thereby reducing its effects. However, there appear to be no reports that this actually occurs. Good monitoring is advisable if any of these drugs are given concurrently, with dosage adjustments if necessary.

Hormonal contraceptives + Antacids

Despite in vitro evidence that some antacids might reduce the availability of norethisterone acetate, evidence from healthy women indicates that no interaction occurs. This also appears to be true for ethinylestradiol and levonorgestrel.

Clinical evidence, mechanism, importance and management

An in vitro study found that a 1% suspension of magnesium trisilicate in water adsorbed about 80% of mestranol and 50% of norethisterone, but minimal amounts of ethinylestradiol. Similarly, another in vitro study reported reduced dissolution of norethisterone acetate from combined oral contraceptive tablets in the presence of magnesium trisilicate, kaolin mixture, and aluminium hydroxide. In contrast, a single dose study in 12 healthy women given a combined oral contraceptive (ethinylestradiol 30 micrograms and either norethisterone acetate 1 mg or levonorgestrel 150 micrograms) with magnesium trisilicate 500 mg and aluminium hydroxide 250 mg showed that the AUC and peak levels of all three steroids were unchanged. This is in line with common experience. There do not appear to be any reports of contraceptive failure with antacids and norethisterone acetate or mestranol-containing combined oral contraceptives. No special precautions seem to be necessary.

Hormonal contraceptives + Anthelmintics

The use of praziquantel or metrifonate does not appear to alter the pharmacokinetics of combined oral contraceptives. The manufacturer of albendazole recommends that women should use effective methods of contraception during and for one month after stopping the drug. This is because albendazole is teratogenic in some animal species.

Clinical evidence, mechanism, importance and management

(a) Albendazole

The manufacturer recommends that women taking albendazole should use effective methods of contraception during and for one month after stopping the drug. This is because albendazole is teratogenic in some animal species.

(b) Metrifonate and Praziquantel

A study in 25 women with early active schistosomiasis (S. haematobium or S. mansoni) without signs of liver disease showed that neither the disease itself nor the concurrent use of antischistosomal drugs (a single 40-mg/kg dose of praziquantel, or metrifonate in three doses of 10 mg/kg at fortnightly intervals) had any effect on the plasma levels of steroids from a combined oral contraceptive (ethinylestradiol/levonorgestrel 50/500 micrograms). Moreover, in another study there was no evidence that women with early active schistosomiasis without signs of liver disease were at any greater risk of hepatic impairment while using combined oral contraceptives. No special precautions would therefore appear necessary in women with early active schistosomiasis taking oral contraceptives and praziquantel or metrifonate. Note that oral contraceptives are considered contraindicated in schistosomiasis with liver involvement.

Hormonal contraceptives + Antibacterials; Cephalosporins

A few anecdotal cases of combined oral contraceptive failure have been reported with cefalexin, cefalexin with clindamycin, and unspecified cephalosporins. The interaction (if such it is) appears to be very rare indeed.

Clinical evidence

Two pregnancies were attributed to the use of cephalosporins (unspecified) and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (61 cases were attributed to other antibacterials). One case of contraceptive failure has been attributed to cefalexin, and one to cefalexin used with clindamycin. In a case-control study, 356 women were who had received oral contraceptives and antibacterials (said to be cephalosporins, penicillins, tetracyclines) were identified over a 5-year period in 3 dermatological practices. The contraceptive failure rate in these women (1.6% per year; 2 pregnancies occurred in women taking a cephalosporin and 3 in women taking minocycline) was indistinguishable from the failure rate seen in control patients taking oral contraceptives and no antibacterials (1% per year).

Mechanism

Suppression of intestinal bacteria, which results in reduced enterohepatic recirculation of ethinylestradiol and a fall in serum levels, is the suggested
Importance and management

The interaction between the combined hormonal contraceptives and cephalosporins that are summarised here are all that have been identified in the literature. These interactions are not adequately established and the whole issue remains very controversial.\(^5\) Bearing in mind the extremely wide use of both groups of drugs, any increased incidence of contraceptive failure above that normally seen is clearly very low indeed. On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that patients taking antibacterials that do not induce liver enzymes should use a second form of non-hormonal contraception, such as condoms, while taking a short course of less than 3 weeks of a cephalosporin, and also for 7 days after the antibiotic has been stopped. This advice applies to both the oral and patch form of the combined contraceptive.\(^5\) For further comment and advice see also ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981.

\(^{2}\) DeSano EA, Hurley SC. Possible interactions of antihistamines and antibiotics with oral contraceptives + Antibacterials, p.1007, or the progestogen-only contraceptives, see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.

\(^{3}\) The macrolides such as erythromycin might possibly be expected to suppress the bacteria responsible for the enterohepatic recycling of ethinyloestradiol, but good evidence that this is clinically important is scant (see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981). Erythromycin is also not considered to cause failure of combined oral contraceptives. The UK Family Planning Association considered that it only isolated reports of pregnancies with this drug, coupled with its known enzyme-inhibiting properties, suggest that it is unlikely to cause contraceptive failure. The UK Family Planning Association considered that it was almost certain that erythromycin did not interact with combined oral contraceptives.\(^{11}\) Information on the other macrolides seems to be limited to the studies cited, on the basis of which no interaction appears to be likely with clarithromycin, roxithromycin and telithromycin. Dirithromycin also appears unlikely to cause oral contraceptive failure. No cases of contraceptive failure with these newer macrolides appear to have been reported. (See the section on contraceptive failure with spiramycin.)

Mechanism

Information about erythromycin is very limited, but the fact that there are only isolated reports of pregnancies with this drug, coupled with its known enzyme-inhibiting properties, suggest that it is unlikely to cause contraceptive failure. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure with the macrolides, they recommend that additional contraceptives, such as condoms, should be used for short courses of antibacterials, see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981, for more detailed information. This advice has usually been applied to only broad-spectrum antibacterials that do not induce liver enzymes, but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be ‘broad-spectrum’, and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include the macrolides. This applies to both the oral and the patch form of the combined hormonal contraceptive. Note that antibacterials that do not induce liver enzymes do not affect the reliability of the progestogen-only contraceptives, see ‘Progestogen-only contraceptives + Antibacterials, p.1007), or the emergency hormonal contraceptive, see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.

Hormonal contraceptives + Antibacterials; Macrolides

The macrolides clarithromycin, dirithromycin, roxithromycin and telithromycin appear unlikely to cause combined hormonal contraceptive failure. Erythromycin is also not considered to cause failure of combined hormonal contraceptives, but isolated anecdotal cases have been reported. An isolated case has also been reported with spiramycin.

Clinical evidence

(a) Clarithromycin

Ten women taking a combined oral contraceptive (ethinylestradiol with levonorgestrel or desogestrel) showed a very slight but not statistically significant rise in serum ethinylestradiol levels while taking clarithromycin 250 mg twice daily for 7 days. No changes in levonorgestrel levels occurred, but levels of the active metabolite of desogestrel were increased. Ovulation did not occur (progesterone levels remained suppressed, and FSH and LH levels were reduced). These hormonal changes suggest that clarithromycin may even increase the efficacy of combined oral contraceptives.\(^1\)

(b) Dirithromycin

Fifteen women taking a triphasic combined oral contraceptive (ethinylestradiol/norethisterone) were given dirithromycin 500 mg daily for 14 days starting on day 21 of the cycle. A small but statistically significant decrease of 7.6% occurred in the mean ethinylestradiol AUC, but no woman ovulated (as assessed by ultrasound and ovarian hormone levels).\(^2\)

(c) Erythromycin

Isolated cases of contraceptive failure have been attributed to erythromycin, and two pregnancies were attributed to the use of erythromycin and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (61 cases were attributed to other antibacterials).\(^3\) Another survey of oral contraceptive failure identified 1 failure due to erythromycin (48 of 209 pill failures were attributed to antibacterials),\(^4\) and break-through bleeding due to erythromycin has also been described in 2 cases.\(^5\) Conversely, in 2 studies of contraceptive failures in dermatology patients, no pregnancies were identified in a total of 74 women taking erythromycin and an oral contraceptive.\(^6,7\)

(d) Roxithromycin

While taking roxithromycin 150 mg twice daily, the anti-ovulatory effects of a triphasic combined oral contraceptive (ethinylestradiol/levonorgestrel) remained unchanged during one cycle in 21 healthy women. Efficacy was measured by monitoring ovulation, which was assessed by ultrasound and progesterone levels.\(^8\)

(e) Spiramycin

One case of contraceptive failure has been attributed to concurrent treatment with spiramycin.\(^9\)

(f) Telithromycin

Telithromycin 800 mg once daily for 10 days had no effect on the pharmacokinetics of ethinylestradiol, but increased the plasma levels of levonorgestrel in 38 healthy women taking a triphasic combined oral contraceptive. None of the women ovulated, as assessed by progesterone levels.\(^10\)

Importance and management

When clarithromycin, roxithromycin and telithromycin appear unlikely to cause combined hormonal contraceptive failure, the macrolides clarithromycin, dirithromycin, roxithromycin and telithromycin appear unlikely to cause combined hormonal contraceptive failure. Erythromycin is also not considered to cause failure of combined hormonal contraceptives, but isolated anecdotal cases have been reported. An isolated case has also been reported with spiramycin. Information about erythromycin is very limited, but the fact that there are only isolated reports of pregnancies with this drug, coupled with its known enzyme-inhibiting properties, suggest that it is unlikely to cause contraceptive failure. The UK Family Planning Association considered that it was almost certain that erythromycin did not interact with combined oral contraceptives. Information on the other macrolides seems to be limited to the studies cited, on the basis of which no interaction appears to be likely with clarithromycin, roxithromycin and telithromycin. Dirithromycin also appears unlikely to cause oral contraceptive failure. No cases of contraceptive failure with these newer macrolides appear to have been reported. If one accepts the theory that the there are an as yet unidentified small group of women for whom enterohepatic recirculation of ethinyloestradiol is important, then additional contraceptive precautions should be taken. However, if one is led to the theory that the other macrolides discussed here, also inhibit the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of the contraceptive steroids. Therefore they might be expected to increase rather than reduce contraceptive efficacy. This would be expected to offset any possible reduced enterohepatic recycling.
For a discussion of the adverse hepatic interaction between oral contraceptives and the macrolide troleandomycin, see ‘Hormonal contraceptives + HRT + Antibacterials; Troleandomycin’, p.984.

**Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives, **see ‘Progestogen-only contraceptives + Antibacterials’, p.1007, or the progestogen-only emergency hormonal contraceptive, **see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.**

### Hormonal contraceptives + Antibacterials: Metronidazole

**Isolated cases of combined oral contraceptive failure have been reported with metronidazole. The interaction (if such it is) appears to be very rare indeed. In a controlled study, metronidazole did not affect contraceptive steroid levels.**

**Clinical evidence, mechanism, importance and management**

In 10 women taking a combined oral contraceptive metronidazole 400 mg three times daily for 6 to 8 days had no effect on the AUC of ethinylestradiol and norethisterone. However, 2 of the 10 women had a rise in plasma progesterone levels suggesting that ovulation may have occurred. One of a further 15 women taking metronidazole and a combined oral contraceptive also appeared to ovulate. Of the 3 women who ovulated one also ovulated during the cycle while not taking metronidazole. Another similar study in 10 women found that none ovulated while taking metronidazole and a combined oral contraceptive (ethinylestradiol/norethisterone). Only 3 reports of pregnancies were identified in women who took metronidazole and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. A survey of oral contraceptive failure identified one failure due to metronidazole (48 of a total of 209 cases were attributed to antibacterials) and a follow-up study identified one further case. Another survey found one contraceptive failure in a woman taking metronidazole, but she was also taking doxycycline (see ‘Hormonal contraceptives + Antibacterials; Tetracyclines’, p.983). It is possible that these cases represent chance associations. The interaction between metronidazole and combined oral contraceptives is not established, and the whole issue of any interaction with broad-spectrum antibacterials remains very controversial. Bearing in mind the extremely wide use of both metronidazole and combined oral contraceptives, any increased incidence of contraceptive failure above that seen in general usage is clearly very low indeed. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with combined hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure, they recommend that additional form of contraception, such as condoms, should be used for short courses of antibacterials, see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981, for more detailed information. This applies to both the oral and the patch form of the combined contraceptive. This advice has usually been applied to only broad-spectrum antibacterials that do not induce liver enzymes but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be ‘broad-spectrum’, and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include metronidazole.**

One or two cases of combined oral contraceptive failure have been reported in patients given chloramphenicol, clindamycin (used with cefalexin), dapson, fusidic acid, isoniazid, nitrofurinol and nitrofurantoin. These isolated cases are anecdotal and unconfirmed, and the interaction (if such it is) appears to be very rare indeed. The combination of aminosaliclylic acid, isoniazid and streptomycin does not appear to affect contraceptive efficacy.

**Clinical evidence, mechanism, importance and management**

One woman taking a combined oral contraceptive was briefly reported to have developed breakthrough bleeding and to have become pregnant while taking chloramphenicol. One or two cases of contraceptive failure have been briefly attributed to clindamycin (used with cefalexin), dapson, fusidic acid, isoniazid, nitrofurinol and nitrofurantoin. Breakthrough bleeding, due to clindamycin in one case and chloramphenicol in another case, have also been reported. Conversely, no evidence of ovulation or of changes in plasma ethinylestradiol and norethisterone levels were seen in a study of 8 women taking a combined oral contraceptive with aminosalicylic acid, isoniazid and streptomycin.

The interactions between the oral contraceptives and antibacterials summarised here are all that have been identified in the literature involving the drugs cited. These interactions are not established, and given the few anecdotal cases with each drug, could just be coincidental. With isoniazid in particular, there is evidence that the drug does not cause contraceptive failure when used in combination antitubercular therapy (without rifampicin). On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that women taking combined hormonal contraceptives should routinely use an additional form of contraception, such as condoms, while taking a short course of antibacterials that do not induce liver enzymes, and for 7 days after the antibiotic has been stopped. This advice applies to both the oral and patch form of the combined hormonal contraceptives. For further details of this advice see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981. Although this advice has previously been applied to only broad-spectrum antibacterials that do not induce liver enzymes, the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be ‘broad-spectrum’, and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes. Note that antibacterials that do not induce liver enzymes do not affect the reliability of the progestogen-only contraceptives, see ‘Progestogen-only contraceptives + Antibacterials’, p.1007, or the progestogen-only emergency hormonal contraceptive, see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.

---

Hormonal contraceptives and Sex hormones

 Mechanism

Not understood. The oestrogen component of the contraceptive undergoes enterohepatic recirculation (i.e. it is repeatedly secreted in the bile as sul- fate and glucuronide conjugates, which are hydrolysed by the gut bacteria before reabsorption). One idea is that if these bacteria are suppressed by the use of an antibacterial, the steroid conjugates are not hydrolysed and are therefore only poorly reabsorbed, resulting in lower than normal concentrations of circulating oestrogen in some women. This may result in inadequate suppression of ovulation.2 However, although the penicillins reduce urinary oestrogen secretion in pregnant women,2,5,10 no marked changes in serum ethinylestradiol levels have been found in controlled studies in women taking an oral contraceptive with ampicillin or any other broad-spectrum antibacterial (see ‘tetracyclines’, (p.983), ‘macrolides’, (p.979), ‘quinolones’, (p.982)). It may be that the enterohepatic recirculation of ethinylestradiol is not clinically important: note that women with an ileostomy have normal serum contraceptive steroid levels.20 Alternatively, it may be that the proportion of women for whom enterohepatic recirculation is important is extremely small.22 The progestogens do not take part in enterohepatic recirculation in their active forms.

Importance and management

The interaction between combined hormonal contraceptives and penicillins is inadequately established and controversial. Almost all of the evidence is anecdotal with no controls. The total number of failures is extremely small when viewed against the number of women worldwide using combined hormonal contraceptives (estimated at 70 million in 1996 by WHO41), so most women are apparently not at risk.

On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that women taking combined hormonal contraceptives should routinely use a second form of contraception, such as condoms, while taking a short course of less than 3 weeks of an antibacterial,24 and for 7 days after the antibacterial has been stopped.25 In addition, the FFPRHC recommends that if fewer than 7 active pills are left in the pack after the antibacterial has been stopped, the new packet should be started without a pill-free break, omitting any of the inactive tablets. For patients using the combined contraceptive patch, if the 7 days after the antibacterial has been stopped runs into the usual 7 day patch-free period, a new patch should be applied when it is due to be changed and the patch-free week delayed by 7 days.22 Although this advice has previously only been applied to broad-spectrum antibacterials that do not induce liver enzymes the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be ‘broad-spectrum’, and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include penicillins.22 However, others contend that these instructions may confuse patients, and complicate pill taking, and could have the opposite effect of increasing the failure rate of oral contraceptives.23 The FFPRHC also says that after 3 weeks of treatment the gut flora becomes resistant to the antibacterial. Therefore women taking a long-term antibacterial that does not induce liver enzymes (for example, for acne) no longer need additional contraceptive protection after the initial 3 weeks of concurrent use. However, if the antibacterial is changed or another antibacterial is started, additional contraceptive cover is required. Women who have already been taking long-term antibacterials that do not induce liver enzymes, who start a combined hormonal contraceptive, do not require additional contraception, unless the antibacterial is changed.22 Note that antibacterials that do not induce liver enzymes do not affect the reliability of the progestogen-only contraceptives, see ‘Progestogen-only contraceptives + Antibacterials’, p.1007, or the progestogen-only emergency hormonal contraceptive, see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.

Combined oral contraceptive failure has been attributed to ampicillin, amoxicillin, flucloxacillin, oxacillin, phenoxymethylpenicillin, pivampicillin and talampicillin. However, the interaction (if such it is), appears to be very rare. Controlled studies have not shown any effect of ampicillin on contraceptive steroid levels and ovarian suppression.

Clinical evidence

A case report describes 3 women taking an oral contraceptive who became pregnant when given ampicillin.1 One woman had two unwanted pregnancies while taking a combined oral contraceptive (ethinylestradiol/norethisterone). On both occasions conception occurred when she was being treated with ampicillin for tonsillitis.2 Another woman taking ethinylestradiol/norethisterone for 5 years with no history of breakthrough bleeding, lost a quantity of blood similar to a normal period loss within a day of starting to take ampicillin (exact dose unknown). There was no evidence of diarrhoea or vomiting in either case.2 Two other case reports attributed contraceptive failure to oxacillin,3 and to an intramuscular injection of benzathine penicillin, procaine penicillin and benzylpenicillin.4 The use of a penicillin (unspecified) was implicated in 32 pregnancies in women taking an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a further 31 cases were attributed to other antibacterials).5 In an earlier review, the penicillins in 15 cases of contraceptive failure were named as ampicillin (alone or with fusidic acid, tetracycline or flucloxacillin), amoxicillin, talampicillin, phenoxymethylpenicillin (one also with oxytetracycline) and ‘penicillin’.6 A survey of contraceptive failure described failures due to amoxicillin (16 cases), flucloxacillin, phenoxymethylpenicillin, pivampicillin (5 cases) and amoxicillin with phenoxymethylpenicillin (1 case),7 and a follow-up survey identified 9 further cases involving amoxicillin and one with ‘penicillin’.8 Another similar survey described a total of 17 cases with amoxicillin and 5 cases with ‘penicillin’,9 and a follow-up survey identified 8 further cases with amoxicillin and 1 case with ‘penicillin’.10 In contrast, 3 controlled studies have provided evidence that ampicillin does not alter the plasma levels of contraceptive steroids nor reduce their anti-ovulatory effects.11-13 In the first study, ampicillin 250 mg four times daily for 16 days was given to women taking ethinylestradiol/etynodiol.11 No women ovulated, as assessed by FSH, LH and progesterone levels. Two women had breakthrough bleeding while receiving ampicillin, and one had spotting while receiving placebo.11 In another study in 7 patients and 6 healthy women, amoxicillin 500 mg three times daily for 8 days had no significant effect on the plasma levels of ethinylestradiol and levonorgestrel. However, one woman had a large fall in ethinylestradiol levels. Despite this, none of the women ovulated, as assessed by progesterone levels.12 The third study in 6 women found that ampicillin 1 g twice daily had no effect on the plasma levels of ethinylestradiol and norethisterone, and ovulation did not occur.13 A crossover study involving 16 healthy women also found that a 10-day course of amoxicillin 875 mg twice daily did not affect etonogestrel or ethinylestradiol released from the NuvaRing vaginal contraceptive ring.14

Hormonal contraceptives + Antibacterials; Penicillins

Hormonal contraceptives + Antibacterials; Quinolones

Ciprofloxacin, moxifloxacin and ofloxacin have been shown not to affect the pharmacokinetics of combined oral contraceptives in controlled studies. No cases of contraceptive failure appear to have been reported, and ovarian suppression is not affected. The plasma levels of moxifloxacin may be modestly reduced by combined oral contraceptives.

Clinical evidence

(a) Ciprofloxacin

No ovulation occurred (as assessed by LH, FSH and estradiol levels) in 10 healthy women taking a combined oral contraceptive (ethinylestradiol plus desogestrel, gestodene or levonorgestrel) with ciprofloxacin 500 mg twice daily for 7 days (started on the first day of contraceptive intake). No breakthrough bleeding occurred. Another study in 24 healthy women taking a combined oral contraceptive (ethinylestradiol/desogestrel) found that ciprofloxacin 500 mg twice daily for 10 days had no effect on the pharmacokinetics of ethinylestradiol. In addition, no subject ovulated, as assessed by progesterone and estradiol levels. However, 2 of the subjects were potentially ovulatory while taking a placebo instead of ciprofloxacin, as detected by an ultrasound of ovarian activity. A further 4 subjects taking ciprofloxacin and 2 taking placebo had lesser indications of ovarian activity.

(b) Moxifloxacin

A placebo-controlled, crossover study in 29 young healthy women taking a combined oral contraceptive (ethinylestradiol/levonorgestrel) found that moxifloxacin 400 mg daily on cycle days 1 to 7 had no clinically relevant effect on the pharmacokinetics of either contraceptive steroid. The hormonal parameters measured (estradiol, progesterone, LH, FSH) were also unchanged by the presence of the quinolone, indicating that ovulation continued to be suppressed. Another study looking at the effects of combined oral contraceptives (unspecified) on the pharmacokinetics of a single 400-mg dose of moxifloxacin found that the total oral clearance of moxifloxacin was increased by 20% and its AUC and maximum plasma concentrations were reduced by approximately 15%. This was not considered to be clinically significant except in cases of borderline sensitivity of the bacteria to the drug.

(c) Ofloxacin

Ofloxacin had no effect on the suppression of ovulation in 19 women taking a combined oral contraceptive (ethinylestradiol/levonorgestrel). In this placebo-controlled, crossover study, two courses of ofloxacin 200 mg twice daily for 7 days were given on days 1 to 7 of two consecutive contraceptive cycles. Ovulation was assessed by ultrasound of the ovaries, and by measuring FSH, estradiol and progesterone levels. Four of the women showed signs of ovarian activity in both the placebo and ofloxacin cycles.

Mechanism

The fluoroquinolones are broad-spectrum antibacterials, and so might be expected to interrupt the enterohepatic recirculation of ethinylestradiol, but the evidence that this is clinically important is scant (for a more detailed discussion of this mechanism see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981).

Importance and management

The pharmacokinetic and pharmacodynamic data indicate a likely absence of interactions between combined oral contraceptives and these quinolones. In addition, reports of cases of contraceptive failure with these or any other quinolone antibacterial seem to be lacking. No special extra contraceptive precautions would therefore seem to be necessary during concurrent use. However, if one accepts the theory that there are an as yet unidentified tiny group of women for whom enterohepatic recirculation of ethinylestradiol is important, then it could be argued that insufficient patients were assessed in the above studies to include anyone from this group, and that the general precautions should be applied. However, if one tends to the theory that the anecdotal cases of contraceptive failure with broad-spectrum antibacterials are indistinguishable from the normal accepted failure rate, no special precautions are necessary with these quinolones, or indeed, any other antibacterials that do not induce liver enzymes. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure, they recommend that additional contraceptives, such as condoms, should be used for short courses of antibacterials, see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981, for more detailed information. This applies to both the oral and the patch form of the combined contraceptive. This advice has usually been applied to only broad-spectrum non-liver enzyme-inducing antibacterials but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be ‘broad-spectrum’, and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include the quinolones.

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the progestogen-only contraceptives, see ‘Progestogen-only contraceptives + Antibacterials, p.1007, or the progestogen-only emergency hormonal contraceptive, see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.

Co-trimoxazole (sulfamethoxazole/trimethoprim) increases ethinylestradiol levels. However, there are about 15 anecdotal cases on record of contraceptive failure attributed to co-trimoxazole. There are also isolated cases of contraceptive failure attributed to various sulfonamides and trimethoprim.
Clinical evidence

(a) Co-trimoxazole

In a study in 9 women taking a triphasic combined oral contraceptive (ethinylestradiol/levonorgestrel) the use of co-trimoxazole (trimethoprim/sulfamethoxazole) 960 mg twice daily for 7 days starting on day 10 of the cycle increased ethinylestradiol plasma levels by 30 to 50%. Levonorgestrel plasma levels remained unaltered. No subjects ovulated, as assessed by progesterone and FSH levels: FSH levels actually decreased, indicating increased suppression of ovulation.1

In contrast, 5 cases of oral contraceptive failure attributed to the use of co-trimoxazole were identified in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (58 cases were attributed to other antibacterials).2,3 Contraceptive failure has been reported in another 10 patients taking co-trimoxazole,4−8 and 3 further cases of contraceptive failure are attributed to the use of co-trimoxazole or trimethoprim.9

(b) Sulphonamides

One woman taking a combined oral contraceptive is briefly reported to have shown breakthrough bleeding and to have become pregnant while taking sulfamethoxypyridazine.10,11 One case of a pregnancy, in a woman who had taken a sulphonamide (unspecified) and an oral contraceptive (unspecified) was identified in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a total of 62 cases were attributed to other antibacterials).3 Three further cases of failure have been attributed to the use of sulfafurazole (sulfisoxazole) and a sulphonamide (unspecified).12

Mechanism

A possible explanation for the rise in ethinylestradiol levels is that co-trimoxazole inhibits the liver enzymes concerned with the metabolism of this oestrogen. Broad-spectrum antibacterials might be expected to interrupt the enterohepatic recirculation of ethinylestradiol leading to contraceptive failure, but the evidence that this is clinically important is scant (see also ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981).

Importance and management

Not established. The pharmacokinetic and pharmacodynamic evidence indicates that co-trimoxazole is not likely to reduce the effectiveness of combined oral contraceptives. Although there are a number of reports of contraceptive failure attributed to co-trimoxazole, these are anecdotal and unconfirmed, whereas the studies suggest increased contraceptive efficacy (but see below). It is possible that the cases are coincidental, and fit within the normal failure rate of combined oral contraceptives. The UK Family Planning Authority considered that it was almost certain that co-trimoxazole and sulphonamides did not interact with combined oral contraceptives.11 However, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure, they recommend that additional contraceptives, such as condoms, should be used for short courses of antibacterials, see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981, for more detailed information. This applies to both the oral and the patch form of the combined contraceptive. This advice has usually been applied to only broad-spectrum antibacterials that do not induce liver enzymes but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be ‘broad-spectrum’, and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include co-trimoxazole, sulfonamides and trimethoprim.

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the progestogen-only contraceptives, see ‘Progestogen-only contraceptives + Antibacterials, p.1007, or the progestogen-only emergency hormonal contraceptive, see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.

Aside from contraceptive failure the other aspect of using this drug combination is the potential for increased ethinylestradiol levels. The main concern is whether this would increase the risk of adverse effects of the contraceptive, but there are no data on the clinical significance of these modest (30 to 50%) increases on various contraceptive effects. It could be argued that a 40% increase would turn a standard-strength contraceptive (35 micrograms) into a high-dose contraceptive (50 micrograms). However, early studies showed that the interindividual variation in ethinylestradiol pharmacokinetics was greater than this anyway.2 Further study is needed on this issue.

Clinical evidence

8. Kakouros H, Kovacs GT. Co-trimoxazole: a potential contraceptive contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a total of 62 cases were attributed to other antibacterials). 5.

Hormonal contraceptives + Antibacterials; Tetracyclines

Contraceptive failure has been attributed to doxycycline, lymecycline, minocycline, oxytetracycline and tetracycline in about 40 reported cases, 7 of which specified long-term antibacterial use, but the interaction (if such it is) appears to be rare. Controlled studies have not shown any effect of tetracycline or doxycycline on contraceptive steroid levels.

Clinical evidence

A woman taking a combined oral contraceptive (ethinylestradiol with levonorgestrel) became pregnant, the evidence indicating that she had conceived during or in the week after taking tetracycline 500 mg every 6 hours for 3 days and then 250 mg every 6 hours for 2 days. There was no evidence of either nausea or vomiting, which might have been an alternative explanation for the contraceptive failure.1 A case of breakthrough bleeding attributed to tetracycline was also mentioned in this report.2 Two other case reports describe pregnancies in women taking a combined oral contraceptive and long-term tetracycline 500 mg daily3 or long-term minocycline 100 mg daily.4 The latter also briefly mentions 2 cases of contraceptive failure with doxycycline.5

Twelve reports of pregnancies were attributed to the use of tetracyclines (unspecified) and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (51 cases were attributed to other antibacterials).6 In an earlier report, the tetracyclines in 6 cases were named as tetracycline and oxytetracycline.7 A survey of oral contraceptive failure identified 7 failures due to doxycycline, lymecycline or minocycline (37 of a total of 163 cases were attributed to antibacterials),8 and a follow-up survey identified 3 further cases involving short courses of tetracycline.9 Similar surveys identified 5 contraceptive failures with tetracycline,10 and 2 failures with doxycycline.11 Breakthrough bleeding was attributed to doxycycline or oxytetracycline in 3 other cases.12

In a dermatological practice, of 124 women taking an oral contraceptive and antibacterials (mostly tetracyclines or erythromycin), 2 became pregnant, with a calculated failure rate of 1.2%. One patient was taking long-
term minocycline and ethinylestradiol/norethisterone, and one had taken a 5-day course of oxytetracycline while taking ethinylestradiol/levonorgestrel. This failure rate was reported to be sixfold higher than a normal failure rate of 0.2%. However, a rate of 0.2% represents perfect rather than typical use of combined oral contraceptives. In a similar analysis, one of 24 women became pregnant after taking long-term tetracycline and ethinylestradiol/norethisterone. This failure rate of 4.2% was not considered to be significantly different from a normal failure rate of 0.27%. In a larger, better-designed, case-control study, 356 women were identified who had received oral contraceptives and antibiotics (cephalosporins, penicillins, tetracyclines) over a 5-year period in 3 dermatological practices. The failure rate in these women (1.6% per year, 3 pregnancies occurred in women taking long-term minocycline and 2 taking a cephalosporin) was indistinguishable from the failure rate seen in control patients taking oral contraceptives and no antibiotics (1% per year). Moreover, two controlled studies have shown that tetracyclines do not affect the pharmacokinetics of contraceptive steroids. In the first, in 7 healthy women taking a combined oral contraceptive, tetracycline 500 mg every 6 hours for 10 days had no effect on the AUC of ethinylestradiol and norethisterone (measured on days 1, 5 and 10). Similarly, in 23 healthy women taking a combined oral contraceptive, doxycycline 100 mg twice daily for 7 days had no effect on the serum levels of ethinylestradiol and norethisterone (measured on days 5 to 7). In addition, ovulation did not occur, as assessed by progesterone levels, but 2 women did experience breakthrough bleeding. A further study has found no pharmacokinetic interaction between a combined contraceptive patch and tetracycline. A crossover study involving 16 healthy women also found that a 10-day course of doxycycline did not affect etonogestrel or ethinylestradiol released from the NuvaRing vaginal contraceptive ring.

The pharmacokinetics of tetracycline (4-hour AUC and peak level) were not significantly different between 7 healthy women taking a combined oral contraceptive (ethinylestradiol/norethisterone) and 4 healthy women not taking any medication. For reports of facial pigmentation due to minocycline and ethinylestradiol, see “Tetracyclines; Minocycline + Ethinylestradiol”, p.350.

Mechanism
Not understood. If an interaction occurs, suppression of intestinal bacteria resulting in a fall in enterobacterial recirculation of ethinylestradiol is the usual suggested explanation, but there is no evidence that this is clinically important. For a full discussion of this mechanism, see “Hormonal contraceptives + Antibacterials; Penicillins”, p.981.

Importance and management
The interactions between the oral contraceptives and tetracyclines summarised here are all that are identified in the literature. Much of the evidence is anecdotal with insufficient controls (if any). These interactions are not adequately established and the whole issue remains controversial. Bearing in mind the extremely wide use of both drugs, any increase in the incidence of contraceptive failure above the accepted failure rate is clearly very low indeed. On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that an additional form of contraception, such as condoms, should be used while taking a short course of antibiotics that do not induce liver enzymes, and for 7 days after the antibacterial has been stopped. See “Hormonal contraceptives + Antibacterials; Penicillins”, p.981, for more detailed information on how to manage this interaction. In the case of long-term use of tetracyclines for acne, at least 7 cases of contraceptive failure have been reported. Nevertheless, in statistical terms the only well-designed case-controlled study in dermatological practice indicated that the incidence of contraceptive failure due to this interaction could not be distinguished from the general and recognised failure rate of oral contraceptives.
The FFPRHC advise that additional contraceptive protection is not required in established users of the combined hormonal contraceptive patch taking tetracycline. This is in line with the findings of the study cited above.

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the progestogen-only contraceptives, see “Progestogen-only contraceptives + Antibacterials, p.1007, or the progestogen-only emergency hormonal contraceptive, see ‘Emergency hormonal contraceptives + Antibacterials’, p.977.

Hormonal contraceptives or HRT + Antibacterials; Troleandomycin

Severe pruritus and jaundice have been observed in women taking oral contraceptives shortly after starting treatment with troleandomycin. One case has also been reported with oestrogens for HRT.

Clinical evidence
A report describes 10 cases of cholestatic jaundice and pruritus in women taking oral contraceptives and troleandomycin. All had been using the contraceptive for 7 to 48 months and were given the antibacterial in daily doses of 1 to 3 g. The pruritus was intense, and started within 2 to 24 days of the first dose of troleandomycin, and preceding the jaundice. In 8 of the patients the pruritus and jaundice persisted for over a month. A later report and letter by the same authors describes a total of 24 cases of this reaction. There are numerous other reports of this adverse reaction in a total of over 40 other women. The adverse reactions (fatigue, anorexia, severe itching, jaundice) can begin very rapidly, sometimes even within 2 days of starting the troleandomycin, and may last up to 14 weeks or more. One report also describes a similar reaction in a 48-year-old woman taking oestrogens for HRT.

Mechanism
Uncertain. Hepatotoxicity has been associated with the use of both types of drug, but it is not common. The reaction suggests that their damaging effects on the liver may be additive or synergistic. Troleandomycin may cause an increase in levels of contraceptive steroids, since it is a liver enzyme inhibitor.

Importance and management
A well established, well documented and clinically important interaction. The incidence is unknown. Concurrent use should be avoided. Other mac-
Hormonal contraceptives + Anti-epileptics; Barbiturates or Phenotyin

Hormonal contraceptives are less reliable during the use of phenytoin and barbiturates such as phenobarbital and primidone. Intermenstrual breakthrough bleeding and spotting can take place, and pregnancies have occurred. Controlled studies have shown that phenytoin and phenobarbital can reduce contraceptive steroid levels.

Clinical evidence

An epileptic woman taking phenytoin 200 mg and sultiamine 50 mg daily (with ferrous gluconate and folic acid) became pregnant despite the regular use of a combined oral contraceptive (ethinylestradiol/norethisterone 50 micrograms/3 mg). Since this first report in 1972, at least 33 pregnancies have been reported in the literature in women taking a range of oral contraceptives (mostly combined) and a barbiturate (such as phenobarbital or primidone) and/or phenytoin (see ‘Table 28.2’, (p.986)). Note that most of these cases were with a combined oral contraceptive containing at least 50 micrograms of ethinylestradiol. In addition, between the years 1968 to 1984, a further 25 pregnancies in women who took phenytoin and an oral contraceptive, and 20 pregnancies in women who took phenobarbital and an oral contraceptive were reported to the CSM in the UK. However, it is unclear how many of these patients were receiving just the antiepileptic mentioned, since the authors note that some women were taking multiple antiepileptics (combinations not stated). Even so, the total number of unwanted pregnancies due to this interaction is fairly large. In this report, over half the cases of contraceptive failure with antiepileptics related to high-dose combined oral contraceptives (50 micrograms of oestrogen). Three were in women taking progestogen-only oral contraceptives.

In one study, breakthrough bleeding (which was regarded as loss of reliability of the contraceptive) occurred in 30 of 51 women taking a combined oral contraceptive (ethinylestradiol/norethisterone or mestranol/chlormadinone acetate given phenobarbital). In another study, 7 out of 11 patients taking phenobarbital and 1 of 2 patients taking phenytoin had breakthrough bleeding. The incidence of breakthrough bleeding was 90% with preparations containing ethinylestradiol 30 micrograms and 29% with preparations containing 75 micrograms of ethinylestradiol. Similarly, with preparations containing ethinylestradiol 50 micrograms, decreasing the dose of norgestrel from 500 to 125 micrograms increased breakthrough bleeding from 50% to 62%.

A pharmacokinetic study in 6 women taking a combined oral contraceptive found that the AUCs of ethinylestradiol 50 micrograms and levonorgestrel 250 micrograms were lowered by 49% and 42%, respectively, by phenytoin 200 to 300 mg daily for 8 to 12 weeks.

In another study, phenobarbital 30 mg twice daily did not significantly alter the plasma levels of contraceptive steroids in 4 women taking combined oral contraceptives (ethinylestradiol with norethisterone or norgestrel), but 2 of the women did have 54% and 60% falls, respectively, in their ethinylestradiol levels. These 2 women had breakthrough bleeding, but ovulation suppression was maintained.

Mechanism

The likeliest explanation for the unreliability and failure of oral contraceptives is that phenytoin and the barbiturates (known potent liver enzyme inductors) increase the metabolism and clearance of the contraceptive steroids from the body, thereby reducing their effects, and in some instances, allowing ovulation to occur.

Importance and management

The interactions between combined oral contraceptives and phenobarbital and phenytoin are clinically important and well documented. As primedone is metabolised to phenobarbital it would be prudent to assume that it will interact similarly. The risk of breakthrough bleeding and spotting is high (bleeding disturbances are usually regarded as an indication of reduced efficacy if cycles were previously regular). However, the actual incidence of contraceptive failure when combined oral contraceptives are given with these drugs is unknown. It appears that the incidence of unintended pregnancies is quite small: in one series, a failure rate of 3.1 per 100 woman years was calculated, compared with an expected 0.7 per 100 woman years. Note that this failure rate is still less than that seen with barrier methods such as condoms. Reliable contraception in most patients is said to be achievable with ethinylestradiol 80 to 100 micrograms daily. If these larger doses are required for good cycle control, there should be no increase in adverse effects because the enzyme-inducing effects of the antiepileptics reduce the blood levels of the steroids. However, note that many of the cases of unintended pregnancies were with products containing 50 micrograms of ethinylestradiol or more, and one review of contraceptive interactions suggested that women taking low-dose oestrogen contraceptives may not be at a greater risk of an interaction.

Nevertheless, the personal and ethical consequences of an unplanned pregnancy can be very serious, it is important to take the necessary practical steps to reduce this increased risk. Moreover, pregnancy in women with epilepsy should ideally be planned so that therapy can be reviewed to minimise the risks of foetal malformation. In this regard, it is of concern that some surveys have shown a lack of knowledge of these interactions and their management among prescribers, and the frequent use of enzyme-inducing antiepileptics with hormonal contraceptives containing less than 50 micrograms of ethinylestradiol or more, and one review of contraceptive interactions suggested that women taking low-dose oestrogen contraceptives may not be at a greater risk of an interaction.

14 This is of particular concern since progestogen-only oral contraceptives are not as effective as combined oral contraceptives. Some have suggested at least doubling the dose of the progestogen-only oral contraceptive. However, others consider that this is not an option as it tends to increase the rate of irregular bleeding (a common adverse effect of these contraceptives). They consider that progestogen-only oral contraceptives are not suitable for women taking enzyme-inducing antiepileptics. The use of an alternative, non-interacting antiepileptic drug should be considered in patients taking hormonal contraceptives. Note that ‘ethosuximide’, (p.987), ‘gabapentin’, (p.988), ‘lamotrigine’, (p.988), ‘levetiracetam’, (p.989), ‘sodium valproate’, (p.990), ‘tiagabine’, (p.990), and ‘vigabatrin’, (p.991) do not appear to interact with the hormonal contraceptives.

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit have issued guidance on the use of drugs that induce liver enzyme with hormonal contraceptives.

* Women taking combined oral contraceptives should use an ethinylestradiol dose of at least 50 micrograms daily. The dose may be increased further above 50 micrograms if breakthrough bleeding occurs. Omitting or reducing the pill-free interval has not been shown to reduce the risk of ovulation with liver enzyme inducers. Additional non-hormonal methods of contraception, such as condoms, should also be used by patients using combined hormonal contraceptives, both when taking the

</table>

Liver enzyme inducers and for at least 4 weeks after stopping the drug. Alternatives to all forms of combined hormonal contraceptives should be considered with long-term use of liver enzyme inducers.

- The combined contraceptive patch may be continued in the usual manner. Using more than one patch is not recommended. Additional, non-hormonal methods of contraception, such as condoms, should also be used by patients using the combined contraceptive patch, both when taking the liver enzyme inducers and for at least 4 weeks after stopping the drug.

- The progestogen-only implant may be continued with short courses of enzyme inducers. Additional non-hormonal methods of contraception, such as condoms, should also be used by patients using the progestogen-only implant, both when taking the liver enzyme inducers and for at least 4 weeks after stopping the drug. Alternatives to the progestogen-only implant should be considered with long-term use of liver enzyme inducers.

    - The progestogen-only pill is not recommended for use with liver enzyme inducers and alternative methods of contraception are advised.

- The effectiveness of the progestogen-only emergency hormonal contraceptive will be reduced in women taking liver enzyme inducers, see ‘Emergency hormonal contraceptives + Enzyme inducers’, p.977, for further guidance.

- Copper or levonorgestrel-releasing intrauterine devices (IUD) and depot progestogen-only injections may be used as alternative contraceptive methods, particularly for women requiring hormonal contracep-
Hormonal contraceptives + Antiepileptics; Carbamazepine or Oxcarbazepine

Hormonal contraceptives are less reliable during treatment with carbamazepine and oxcarbazepine. Breakthrough bleeding and spotting can take place, and unintended pregnancies have occurred with carbamazepine. Controlled studies have shown that carbamazepine and oxcarbazepine can reduce contraceptive sterility levels.

Clinical evidence

(a) Carbamazepine

In a pharmacokinetic study, carbamazepine 300 to 600 mg daily reduced the AUC of ethinylestradiol by 42% and levonorgestrel by 40% in 4 women given a single dose of a combined oral contraceptive (ethinylestradiol/levonorgestrel 50/250 micrograms) before and after 8 to 12 weeks of carbamazepine use. Another study compared the effects of topiramate or carbamazepine on a combined oral contraceptive containing norethisterone/ethinylestradiol 1 mg/35 micrograms (Ortho-Novum). In the 10 patients who received carbamazepine 600 mg daily, the AUC of norethisterone and ethinylestradiol were reduced by 58% and 42%, respectively.

In an early study, 6 of 12 women taking a combined oral contraceptive (ethinylestradiol/norethisterone) developed spotting or breakthrough bleeding while taking carbamazepine (this is regarded as a possible loss of reliability of the contraceptive). A similar study reported breakthrough bleeding in 4 of 6 patients taking carbamazepine and a combined oral contraceptive, and the same author later briefly reported 37 out of 59 patients had breakthrough bleeding while taking this combination.

One woman taking a low-dose combined oral contraceptive (not specified) conceived 6 weeks after starting carbamazepine, initially 200 mg daily then 600 mg daily. In two other cases the failure of a combined oral contraceptive containing ethinylestradiol 30 micrograms has been attributed to carbamazepine. Six pregnancies were identified in women who took carbamazepine and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. However, it is unclear how many of these 6 women were taking carbamazepine alone, as the authors note that some women were taking multiple antiepileptics. Two further pregnancies have been reported in women taking combined oral contraceptives and antiepileptics including carbamazepine and phenytoin, and one in a woman who was switched from phenytoin to carbamazepine.

(b) Oxcarbazepine

Preliminary observations revealed that 4 of 6 women receiving oxcarbazepine had breakthrough bleeding when they were given a combined oral contraceptive containing ethinylestradiol 30 micrograms. This resolved when two women when they took double the dose of ethinylestradiol.

In a pharmacokinetic study in 10 healthy women taking a triphasic combined oral contraceptive, oxcarbazepine 300 mg three times daily for 4 weeks reduced the AUCs of ethinylestradiol and levonorgestrel by 47% and 36%, respectively. Three women had menstrual bleeding disturbances. Similar results were reported in a later study with oxcarbazepine 1.2 g daily and a combined oral contraceptive (ethinylestradiol/levonorgestrel 50/250 micrograms). So far, no cases of unintended pregnancy have been reported.

Mechanism

The most likely explanation for these interactions is that both carbamazepine and oxcarbazepine reduce the levels of the contraceptive steroids, presumably by inducing their metabolism. This may result in loss of contraceptive efficacy.

Importance and management

The reduction in contraceptive steroid levels caused by carbamazepine and oxcarbazepine is well established. However, the actual incidence of contraceptive failure when oral contraceptives are given with these drugs is unknown. Given the few published reports, it appears that unintended pregnancies with carbamazepine are rare, and still less frequent than that seen with barrier methods such as condoms. No pregnancies have been reported in patients taking an oral contraceptive and oxcarbazepine. Nevertheless, given the personal and ethical consequences of an unwanted pregnancy, any reduction in contraceptive efficacy is of concern. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidelines on the management of patients taking liver enzyme inducers with hormonal contraceptives. These are discussed in further detail under ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’.

Hormonal contraceptives + Antiepileptics; Ethosuximide

Ethosuximide appears not to alter the efficacy of combined oral contraceptives.
Clinical evidence, mechanism, importance and management

Four pregnancies were identified in women who took ethosuximide and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. However, the authors note that in only one of the cases reported was ethosuximide the sole antiepileptic prescribed. Since ethosuximide is not an inducer of hepatic enzymes, it is likely that this one case is a chance association. Another case describes pregnancy in a woman who had been taking ethosuximide, phenytoin, and phenobarbital, with a combined oral contraceptive for 6 years. If indeed this case does represent an interaction, the known enzyme-inducers phenytoin and phenobarbital are more likely to be implicated than ethosuximide (see Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin, 1985). There do not appear to have been any pharmacokinetic or pharmacodynamic studies of the use of ethosuximide with oral contraceptives and no further case reports have been published. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that ethosuximide does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens. No special contraceptive precautions appear to be necessary on concurrent use.

Hormonal contraceptives + Antiepileptics; Lamotrigine

One study suggests that lamotrigine does not alter the contraceptive efficacy or plasma levels of combined oral contraceptives. Another study found a slight reduction in levonorgestrel levels but no evidence of ovulation, however, based on this, the manufacturer says that the possibility of reduced contraceptive efficacy cannot be ruled out. Hormonal contraceptives may reduce the levels of lamotrigine, which can lead to a decrease in seizure control.

Clinical evidence and mechanism

(a) Contraceptive efficacy

Preliminary results of a study showed that lamotrigine 150 mg daily for 10 to 14 days had no significant effect on the mean plasma levels of ethinylestradiol and levonorgestrel in women taking a combined oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms). No ovulation occurred (assessed by progesterone levels) and no changes in menstrual pattern were observed. Furthermore, lamotrigine did not induce hepatic enzymes (assessed by 6-β-hydroxy cortisol excretion). A study by the manufacturer in 16 healthy women taking the combined oral contraceptive Microgynon 30 (ethinylestradiol/levonorgestrel 30/150 micrograms) and given lamotrigine (titrated to 300 mg daily) found a slight but non-significant reduction in the AUC and the maximum serum concentration of levonorgestrel of 19% and 12%, respectively, compared with hormone levels before starting lamotrigine. Ethinylestradiol levels were not affected. Significant increases in FSH and LH were also seen, although there was no increase in the levels of progesterone, indicating that ovulation probably did not occur. Intermenstrual bleeding was reported in 32% of subjects when receiving lamotrigine.

(b) Lamotrigine efficacy

A case report describes 7 women in whom lamotrigine plasma levels were decreased by 41 to 64% by combined oral contraceptives (ethinylestradiol with desogestrel or norethisterone). Five had increased seizure frequency or recurrence of seizures after starting an oral contraceptive, and two had lamotrigine adverse effects on stopping the oral contraceptive. It was suggested that hormonal contraceptives can increase the glucuronidation of lamotrigine, thereby increasing its clearance. A subsequent study found a more than 50% reduction in lamotrigine levels in women taking the combined oral contraceptive. A study by the manufacturer in 16 healthy women taking the combined oral contraceptive Microgynon 30 (ethinylestradiol/levonorgestrel 30/150 micrograms) and lamotrigine (titrated to 300 mg daily) found that the maximum serum concentration and AUC of lamotrigine were decreased by approximately 39% and 52%, respectively, when compared with lamotrigine alone. A further study in 8 epileptic women found that lamotrigine plasma concentrations varied with hormonal contraceptive monthly cycles. The median lamotrigine plasma concentration was 15% higher during the hormonal contraceptive washout week than during the phase of hormonal contraceptive intake, although there was a wide interpatient variability.

Another study in 45 women found that a reduction in lamotrigine levels occurred with ethinylestradiol (given as a combined hormonal contraceptive in 11 subjects and a vaginal ring also containing etonogestrel in one subject) compared with 18 women using no hormonal contraception. However, lamotrigine serum concentrations were not affected in 16 women using a progestogen-only contraceptive (4 using oral desogestrel or norethisterone, 8 using subdermal etonogestrel or levonorgestrel, 1 using medroxyprogesterone, and 3 using intrauterine levonorgestrel).

Hormonal contraceptives + Antiepileptics; Felbamate

Felbamate increases the clearance of gestodene from a combined oral contraceptive but it is not known if this reduces contraceptive efficacy.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study 23 healthy women were given a combined oral contraceptive (ethinylestradiol/gestodene 30/75 micrograms) for 3 months or more. During months 1 and 2 they were also given either felbamate in a dose of up to 2.4 g daily, or a placebo, from day 15 of month 1 to day 14 of month 2. None of the women showed any evidence of ovulation during the entire 3 months, although one had intermenstrual spotting. However, felbamate reduced the gestodene AUC by 42% and the ethinylestradiol AUC by 13%. The reasons for this effect are not understood. What this means in terms of the reliability of the oral contraceptive is not known, but some reduction in its efficacy might be expected. More study is needed to assess the clinical relevance and to see whether other progestogens are similarly affected.

Hormonal contraceptives + Antiepileptics; Gabapentin

In a controlled study, gabapentin did not alter the levels of ethinylestradiol or norethisterone.

Clinical evidence, mechanism, importance and management

Gabapentin 400 mg every 8 hours for 7 days had no effect on the AUC of ethinylestradiol or norethisterone in 13 healthy women taking a combined oral contraceptive (ethinylestradiol/norethisterone 50 micrograms/2.5 mg). Ovulation suppression was not assessed. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that gabapentin does not induce liver enzymes responsible for the metabolism of contraceptive steroids and causes no reduction in ethinylestradiol or progestogens. Thus, no special contraceptive precautions appear to be required during concurrent use.

Hormonal contraceptives + Antiepileptics; Levetiracetam

Levetiracetam appears not to alter the contraceptive efficacy and plasma levels of ethinylestradiol and levonorgestrel given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a combined oral contraceptive (ethinylestradiol/levonorgestrel) were found not to be affected by levetiracetam 500 mg twice daily, nor was ovulation suppression altered (there were no changes in LH or progesterone levels). The pharmacokinetics of levetiracetam also remained unaffected.1 A placebo-controlled study in 18 subjects taking a combined oral contraceptive containing ethinylestradiol 30 micrograms and levonorgestrel 150 micrograms with levetiracetam 500 mg twice daily found that levetiracetam did not affect the serum levels of either steroid or alter the contraceptive efficacy of these drugs, as measured by progesterone and LH levels.2 The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of drug interactions with hormonal contraceptives state that levetiracetam does not induce liver enzymes and causes no reduction in ethinylestradiol or progesterone.2 These findings indicate that no special or additional precautions are needed if oral contraceptives and levetiracetam are used concurrently.

Hormonal contraceptives + Antiepileptics; Retigabine

Retigabine did not alter the plasma levels of ethinylestradiol or norgestrel given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

Preliminary results of a study show that retigabine 200 mg twice daily for 14 days had no effect on the pharmacokinetics of ethinylestradiol, desogestrel, or levonorgestrel, when compared with placebo, in women taking a combined oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms or ethinylestradiol/desogestrel 30/150 micrograms). Inhibition of ovulation was maintained (assessed by measurement of progesterone, FSH, and LH levels).1 It appears that no special contraceptive precautions are needed during concurrent use.

Remacemide appears not to interact with combined oral contraceptives.

Clinical evidence, mechanism, importance and management

Preliminary results of a study show that remacemide 200 mg twice daily for 14 days had no effect on the pharmacokinetics of ethinylestradiol, desogestrel, or levonorgestrel, when compared with placebo, in women taking a combined oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms or ethinylestradiol/desogestrel 30/150 micrograms). Inhibition of ovulation was maintained (assessed by measurement of progesterone, FSH, and LH levels).1 It appears that no special contraceptive precautions are needed during concurrent use.

Hormonal contraceptives + Antiepileptics; Rufinamide

Rufinamide caused a modest decrease in the plasma levels of ethinylestradiol and norethisterone given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

Preliminary results of a study show that rufinamide 800 mg twice daily for 14 days decreased the AUC of ethinylestradiol 35 micrograms by 22% and of norethisterone 1 mg by 14% in healthy women taking a combined oral contraceptive. Inhibition of ovulation was not assessed. These reductions in plasma levels of the contraceptive hormones are similar to those seen with topiramate (see ‘Hormonal contraceptives + Antiepileptics; Topiramate’, below), and their clinical relevance is unknown. However, given these findings, low-dose contraceptives (ethinylestradiol 20 micrograms) may be considered unsuitable for use with rufinamide. Further study is needed.

Hormonal contraceptives + Antiepileptics; Tiagabine

Tiagabine appears not to alter the contraceptive efficacy and plasma levels of combined oral contraceptives.

Clinical evidence, mechanism, importance and management

A study in 10 healthy women found that tiagabine 2 mg, four times daily from day 24 to day 7 of the next cycle, had no effect on the mean plasma levels of any of steroids in two combined oral contraceptives (ethinylestradiol/levonorgestrel or ethinylestradiol/desogestrel, both 30/150 micrograms). There was no evidence that the suppression of ovulation was altered in any way (no significant changes in the plasma concentrations of progesterone, FSH, or LH were seen between the first and second cycles, and progesterone levels remained in the non-ovulatory range). Tiagabine did not induce hepatic enzymes, as assessed by 6β-hydroxycortisol excretion. Two women did develop breakthrough bleeding, but given the above findings, this was not thought to represent reduced efficacy of the contraceptive. There would appear to be no reason for any special contraceptive precautions during concurrent use.

Hormonal contraceptives + Antiepileptics; Topiramate

The serum levels of ethinylestradiol may be reduced by topiramate, increasing the risk of breakthrough bleeding in women taking combined oral contraceptives. It is suggested that oral contraceptives with a higher dosage of oestrogen should be used.

Clinical evidence

Eleven epileptic women taking sodium valproate and a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) were also given three escalating doses of topiramate 100, 200 and 400 mg twice daily for 28-day periods. The mean AUC of the ethinylestradiol fell by 18%, 21%, and 30%, with the three doses respectively. Although no significant changes were found in the norethisterone AUC, the authors considered that the study was not sufficiently powered to detect small changes. No ovulation occurred, as assessed by progestogen levels, but one patient had breakthrough bleeding. A follow-up study evaluated the effect of lower doses of topiramate on the pharmacokinetics of a combined oral contraceptive containing ethinylestradiol/norethisterone 35 micrograms/1 mg (Ortho-Novum). Subjects were randomised to take daily doses of topiramate of 50 mg (11 subjects), 100 mg (10 subjects) or 200 mg (2 groups of 12 subjects). This study found a minor, non-significant change in the pharmacokinetics of both ethinylestradiol and norethisterone; this change was further reduced when the data from 2 subjects were excluded due to compliance issues. The authors noted that the difference between this study and the study cited above was due to the difference in the doses of topiramate used, as topiramate is a weak liver enzyme inducer, and this effect is dose-related.

Mechanism

Not understood. It is suggested that topiramate weakly induces enzymes in the liver, which increases the metabolism of the ethinylestradiol.

Importance and management

An established interaction but supported by limited evidence. The modest changes in pharmacokinetics of the combined oral contraceptive seen here are lower than those seen with other enzyme-inducing antiepileptics (see ‘Hormonal contraceptives + Antiepileptics; Carbamazepine or Oxcarbazepine’, p.987, and ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985) and may be dose-dependent. However, it is possible that they would be sufficient to cause failure of combined oral contraceptives in rare cases, particularly at high therapeutic doses of topiramate. As there is a risk of failure of contraception with the concurrent use of topiramate, and possibly more importantly, because topiramate is teratogenic, the manufacturer of topiramate advises the use of a non-hormonal contraceptive or a high-dose combined oral contraceptive (at least 50 micrograms of oestrogen), and also that patients should be told to report any changes in their bleeding patterns. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of liver enzyme inducers, including topiramate, with hormonal contraceptives, see ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985, for details of this guidance.

Hormonal contraceptives + Antiepileptics; Valproate

Sodium valproate and valproate semisodium do not appear to alter the efficacy of combined oral contraceptives. In one study, sodium valproate increased ethinylestradiol levels. Ethinylestradiol may reduce valproate levels but there appears to be only one case where this resulted in a loss of seizure control.

Clinical evidence and mechanism

(a) Contraceptive efficacy

In a series of 32 patients taking an oral contraceptive, none of 7 taking sodium valproate 600 mg to 1.8 g daily had breakthrough bleeding, whereas about two-thirds of those taking carbamazepine or phenobarbital had breakthrough bleeding (a sign of possible reduced contraceptive efficacy). Most of the 7 patients taking valproate were taking combined oral contraceptives containing 50 micrograms of ethinylestradiol; one was taking less than 50 micrograms, and one was using a progestogen-only oral contraceptive. One of the 7 patients had previously experienced breakthrough bleeding while taking phenobarbital, but this stopped when it was replaced with sodium valproate. Two further patients did not have breakthrough bleeding while taking sodium valproate and benzodiazepines, but breakthrough bleeding started when phenytoin was also given.

In a pharmacokinetic study, sodium valproate 200 mg twice daily had no effect on the AUC of a single dose of a combined oral contraceptive (ethinylestradiol/levonorgestrel 50/250 micrograms) given to women with epilepsy 8 to 16 weeks after they started sodium valproate. However, a 50% increase in the peak plasma levels of ethinylestradiol was noted. Conversely, one pregnancy was identified in a woman who took sodium valproate and an oral contraceptive (unspecified) in the adverse reactions
register of the CSM in the UK for the years 1968 to 1984. However, the authors consider this one case to be a chance association.3
(b) Valproate efficacy

A study in 9 women with epilepsy taking valproic acid found an increase in the apparent oral clearance of both total and unbound valproic acid during oral contraceptive intake compared with the pill-free period. The authors report that this may be due to induction of glucuronosyltransferase by ethinylestradiol and that the magnitude of this effect can differ between individuals.4 Reduced valproate levels and an increase in seizure frequency have been reported to occur in one patient taking a combined oral contraceptive during the active pill phase, when compared with the inactive 7-day period.5 No further cases appear to have been published.

Importance and management

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that valproate does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens.6 The manufacturers of sodium valproate and valproate semisodium state that valproate does not affect the efficacy of hormonal contraceptives.7 8 No special contraceptive precautions are required during concurrent use.

The significance of the reduction in valproate levels and the case report above is unclear.

Hormonal contraceptives + Antiepileptics; Vigabatrin

Vigabatrin appears not to alter the pharmacokinetics of ethinylestradiol or levonorgestrel given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

Vigabatrin 3 g daily had no statistically significant effect on the pharmacokinetics of ethinylestradiol and levonorgestrel in 13 healthy women given a single dose of a combined oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms); although 2 of the women had a 39% and a 50% fall in the AUC of ethinylestradiol. Vigabatrin did not induce hepatic enzymes as assessed by antipyrine clearance and 6-ethylhydroxycortisol excretion.

This study would seem to confirm the lack of reports of an interaction between oral contraceptives and vigabatrin, but the authors of the report introduce a small note of caution because it is not clear whether the reduced ethinylestradiol AUCs seen in two of the women resulted from an interaction or were simply normal individual variations.1 The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that vigabatrin does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens.2 No special precautions are recommended.

Hormonal contraceptives + Antimarialarials

No clinically significant interaction appears to occur between combined oral contraceptives and chloroquine or primaquine, or between oral contraceptives and mefloquine or quinine. There is some evidence to suggest that a combined oral contraceptive reduced the conversion of proguaill to its active metabolite, cycloguanil.

Clinical evidence and mechanism

(a) Chloroquine

A pharmacokinetic study in 12 healthy women taking a combined oral contraceptive (ethinylestradiol/norethisterone 30 micrograms/1 mg) found that the prophylactic use of chloroquine phosphate 500 mg once a week for 4 weeks caused a small 15% increase in the AUC of ethinylestradiol, and no change in the levels of norethisterone. Chloroquine use did not alter ovulation inhibition, as assessed by mid-luteal progesterone levels and the lack of breakthrough spotting and bleeding. In a further group of 7 women, the same combined oral contraceptive did not alter the pharmacokinetics of a single 500-mg dose of chloroquine phosphate.1 Another study in 6 healthy women given a single dose of a combined oral contraceptive (ethinylestradiol/levonorgestrel 30 micrograms/150 micrograms) confirmed that a single 300-mg dose of chloroquine had no significant effect on the pharmacokinetics of either the oestrogen or the progestogen.2 Furthermore studies in rhesus monkeys infected with malaria, suggest that the curative efficacy of chloroquine is not altered by the use of combined oral contraceptives (ethinylestradiol/norethisterone or ethinylestradiol/levonorgestrel).

Hormonal contraceptives + Antihistamines

The pharmacokinetics of single doses of doxylamine and diphenhydramine do not appear to be altered by combined oral contraceptives.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 25-mg dose of doxylamine in 13 subjects and the pharmacokinetics of a single 50-mg dose of diphenhydramine in 10 subjects were not significantly altered by the use of low-dose combined oral contraceptives.1 Cases of oral contraceptive failure have been attributed to the use of doxylamine, chlorpheniramine, and an unnamed antihistamine,2 but these antihistamines were all used in conjunction with penicillins, which would seem to be a more likely cause of contraceptive failure (see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981). The effect of the antihistamines on the pharmacokinetics and pharmacodynamics of contraceptive steroids appear not to have been studied. No particular precautions would seem necessary during concurrent use.

Hormonal contraceptives + Antiepileptics; Zonisamide

A study in healthy women taking a combined oral contraceptive found that steady-state zonisamide 100 to 400 mg daily did not affect the levels of ethinylestradiol or norethisterone. Contraceptive efficacy was not reduced.1

Similarly, the pharmacokinetics of mefloquine were not affected by oral contraceptives in patients with malaria.4

(c) Primaquine
A study in 6 healthy women given a single dose of a combined oral contraceptive (ethinylestradiol/levonorgestrel 30 micrograms/150 micrograms) confirmed that a single 45-mg dose of primaquine had no significant effect on the pharmacokinetics of either the oestrogen or the progesterone.2

(d) Proguanil
In women who were CYP2C19 extensive metabolisers the use of a combined oral contraceptive (ethinylestradiol/levonorgestrel) reduced the levels of cycloguanil (the active metabolite of proguanil) by 34% after 3 weeks, when compared with the cycloguanil levels before starting the contraceptive.5 It was suggested that the oestrogen might have inhibited the metabolism of proguanil by the cytochrome P450 isoenzyme CYP2C19. However, inhibition of CYP2C19 makes extensive metabolisers into poor metabolisers, and there is some evidence that CYP2C19 poor metaboliser status does not reduce the efficacy of proguanil for prophylaxis6 or treatment7 of malaria (see also ‘Proguanil + Fluvoxamine’, p.238).

(e) Quinine
A controlled study in Thai women showed that the pharmacokinetics of a single 600-mg dose of quinine sulfate in 7 women taking oral contraceptives were not significantly different from those in 7 other women not taking contraceptives. The contraceptives being used were combined oral contraceptives (ethinylestradiol/levonorgestrel or ethinylestradiol/norgestrel) and a progesterone-only oral contraceptive (norethisterone).8 There seem to be no reports that quinine affects the reliability of the oral contraceptives.

Importance and management
No clinically significant interaction appears to occur between the combined oral contraceptives and chloroquine, primaquine or quinine, between oral contraceptives and mefloquine, or between a progesterone-only contraceptive and quinine. There would seem to be no reason for avoiding concurrent use.

The decrease in the active metabolite of proguanil caused by a combined oral contraceptive has not been fully assessed, although the authors recommended that the dose of proguanil should be increased by 50% in women taking oral contraceptives.9 However, there is limited evidence that this pharmacokinetic interaction may not be clinically relevant. More study is needed.

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance (adapted from the World Health Organization Medical Eligibility Criteria (WHOMEC) guidance on contraceptive use) stating that malaria as a condition does not restrict the choice of various contraceptive methods including combined and progesterone-only oral contraceptives.9

Note that tetracycline is increasingly used in the treatment of malaria. See ‘Hormonal contraceptives + Antibacterials; Tetracyclines’, p.983, for further information on possible combined hormonal contraceptive failure with tetracyclines.

Hormonal contraceptives + Aprepitant
Aprepitant reduced the levels of ethinylestradiol and norethisterone given as an oral contraceptive.

Clinical evidence
The manufacturers1,2 note that aprepitant 100 mg daily for 14 days given with a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) decreased the AUC of ethinylestradiol and norethisterone by 43% and 8%, respectively. Reduced contraceptive steroid levels were reported in another study using a recommended antiepileptic regimen including aprepitant (125 mg on the first day, then 80 mg daily for 2 days with dexamethasone 12 mg on the first day, then 8 mg daily for 3 days and ondansetron 32 mg on the first day), which was started on day 8 of the menstrual cycle of a combined oral contraceptive (ethinylestradiol/norethisterone).1,2 Within 2 days of starting the antiepileptic (day 10) the ethinylestradiol AUC was reduced by 19% and the norethisterone level was unchanged.2 However, the trough level of ethinylestradiol was reduced by as much as 64% and that of norethisterone by 60% during days 9 to 21.1,2

Mechanism
During the first few days of use aprepitant is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and therefore it would be expected to increase the levels of the contraceptive steroids. However, aprepitant then becomes an inducer of CYP3A4 (which is usually after the end of a standard 3-day course), reaching a maximal induction effect within 3 to 5 days of stopping aprepitant. This effect lasts only a few days and then reduces to become clinically insignificant within 2 weeks of stopping aprepitant,1 and hence reduces the levels of the contraceptive steroids.

Importance and management
Although the effects of these reduced contraceptive steroids levels on ovulation were not assessed, it is likely that they could result in reduced efficacy. The manufacturer therefore recommends that alternative or additional contraceptive methods should be used during, and for 2 months (UK advice)1 or one month (US advice)2 after, aprepitant use. This seems a sensible precaution. No studies have been done on the effect of a single 40-mg dose of aprepitant 40 mg, as licensed in the US for postoperative nausea and vomiting. However, the US manufacturer states that the timing of the dose may cause contraceptive failure and the same guidance, as stated above, should be used.2

Hormonal contraceptives or HRT + Ascorbic acid (Vitamin C)
Ascorbic acid does not appear to cause a clinically important alteration in the levels of ethinylestradiol or levonorgestrel, but there are a few unconfirmed anecdotal reports of contraceptive failure associated with ascorbic acid. There is some evidence that ascorbic acid may modestly increase estradiol levels in women receiving HRT.

Clinical evidence
(1) Combined oral contraceptives
One study found that ascorbic acid 1 g raised serum ethinylestradiol levels by 16% at 6 hours post-dose and 48% at 24 hours post-dose in 5 women taking combined oral contraceptives.1 However, a later well-controlled study found that ascorbic acid 1 g daily caused no significant changes in ethinylestradiol serum levels in 37 women taking a combined oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms).2 A similar study by the same workers found that ascorbic acid 1 g did not affect the pharmacokinetics of levonorgestrel.3

A single case report describes a woman taking a combined oral contraceptive (ethinylestradiol/levonorgestrel) who experienced heavy break-
through bleeding in 3 cycles within 2 to 3 days of stopping ascorbic acid 1 g daily. This did not occur in 3 other cycles when no ascorbic acid was taken. This was postulated to be due to a fall in ethinylestradiol levels when the vitamin C was stopped, which could increase the risk of contraceptive failure. One report attributed contraceptive failure in one case to ascorbic acid and multivitamins. Another two studies of pregnancies in oral contraceptive users found that vitamin C had been taken in 44 of 209 cases and 15 of 137 cases, although other drugs and/or factors may possibly have been involved in some of these cases.

(b) Hormone replacement therapy

Ascorbic acid 500 mg twice daily for one month caused a non-significant 21% increase in plasma estradiol levels in 25 postmenopausal women receiving transdermal estradiol HRT. However, in the 9 women with initially low estradiol levels, ascorbic acid doubled the levels, and this reached significance.

Mechanism

Both ascorbic acid and ethinylestradiol undergo sulfate conjugation. It was suggested that large doses of ascorbic acid might compete for the metabolism of ethinylestradiol, and therefore increase its levels. This would be expected to increase the efficacy of the oral contraceptive. However, some have postulated that enhanced levels could be followed by rebound ovulation, but there is no evidence to support this. Ascorbic acid may reverse the oxidation of oestrogens.

Importance and management

Documentation about an interaction with contraceptives is limited. From the point of view of reliability, there seems to be little reason for avoiding the use of oral contraceptives and ascorbic acid. No special precautions are required.

The authors of the report on ascorbic acid and HRT say that their findings do not support the general use of ascorbic acid as an adjuvant to HRT, but that further study is needed. No special precautions are required.

Hormonal contraceptives or HRT + Azoles

There are isolated reports of breakthrough bleeding and failure of combined oral contraceptives with fluconazole (including single 150 mg doses), itraconazole and ketoconazole. Conversely, fluconazole, itraconazole and voriconazole have been shown to modestly increase the serum levels of the contraceptive steroids. Ketoconazole slightly increases the levels of estrone following oestrogen administration. Miconazole slightly increases the serum levels of ethinylestradiol and etonogestrel released from an intravaginal contraceptive ring.

Clinical evidence

(a) Fluconazole

Up to 1990 the UK manufacturer of fluconazole had received 11 reports of menstrual disorders possibly associated with single-dose fluconazole 150 mg. Eight of these were in women taking an oral contraceptive who developed breakthrough bleeding (5 cases), no withdrawal bleeding (1 case), unintended pregnancies (2 cases). Three other cases of unintended pregnancy have been very briefly mentioned elsewhere.
Mechanism

The azole antifungals are, to varying degrees, inhibitors of the cytochrome P450 isozyme CYP3A4. They would therefore be expected to increase the levels of the contraceptive steroids, as has been shown for fluconazole, itraconazole and voriconazole. Similarly, ketoconazole and miconazole have been seen to raise the levels of some oestrogens. Therefore the azoles would not be expected to increase the incidence of breakthrough bleeding or contraceptive failure when used with combined oral contraceptives. It should be noted that the manufacturers list menstrual irregularities as adverse effects of itraconazole, ketoconazole and posaconazole irrespective of the use of combined oral contraceptives, and menstrual disorders have also been reported with fluconazole alone.1

Importance and management

The picture presented by these reports is somewhat confusing and contradictory. The anecdotal reports of contraceptive failure and the cases of breakthrough bleeding would suggest that these antifungals can, rarely, make oral contraception less reliable in some individuals. However, the problem with this interpretation is that the pharmacokinetic data suggest that, if anything, an enhanced effect of the combined oral contraceptives is likely. Note that, of all the drugs proven to decrease the efficacy of combined oral contraceptives, all have also been shown to decrease the steroid levels. Menstrual disorders have occurred with the azole antifungals alone, and may not be indicative of reduced contraceptive efficacy. Since there are so few reports of pregnancy, it could just be that they fell within the accepted failure rate of combined oral contraceptives, and it was just coincidental they occurred when the antifungal was being taken. Note that the manufacturers do not advise any special precautions when taking oral contraceptives and these azole antifungals.5,15,16 However, some consider that the data warrant consideration being given to the use of additional contraceptive measures.10 The theoretical teratogenic risk5,15-18 from these azole antifungals may have a bearing on this, and the UK manufacturers of a number of the azoles recommend using effective contraception during azole treatment to reduce this risk.5,15,16,18 More study is clearly needed.

The main concern regarding the increased levels of ethinylestradiol or progestogens is whether this would increase the risk of adverse effects of the steroid. There are no data on the effect of these modest 25 to 40% increases in steroid levels on adverse effects. It could be argued that a 40% increase would turn a standard-strength contraceptive (35 micrograms) into a high-dose contraceptive (50 micrograms). However, early studies showed that the interindividual variation in ethinylestradiol pharmacokinetics was greater than this anyway.10 Further study is needed.

Hormonal contraceptives + Bosantan

Bosantan reduces the levels of ethinylestradiol and norethisterone given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

In randomised, crossover study in 19 healthy subjects a single dose of a combined oral contraceptive containing norethisterone 1 mg and ethinylestradiol 35 micrograms (Ortho-Novum) was given with bosantan 125 mg twice daily for one week. Bosantan reduced the mean AUC of norethisterone by 14% (maximum reduction 56%) and the mean AUC of ethinylestradiol by 31% (maximum reduction 66%). Note that there was marked inter-individual variability. The maximum concentration and half-life of both contraceptive steroids were not significantly affected. The contraceptive steroids are metabolised by the cytochrome P450 isozyme CYP3A4, and it was thought that the changes in their pharmacokinetics may have been caused by induction of CYP3A4 by bosantan. However other mechanisms could not be excluded. The link between these results and actual contraceptive failure is unclear.1

The Pulmonary Hypertension Association has suggested that there is the potential for bosantan to reduce the effectiveness of hormonal contraceptives by any route. They also state that bosantan may have teratogenic effects and therefore it should not be used as the only method of contraception in patients taking bosantan.1 Similarly, the manufacturer contraindicates the use of bosantan in women who are not using reliable methods of contraception and recommends that additional or alternative methods to hormonal contraceptives are used. This must be continued for at least 3 months after treatment is stopped.3

Hormonal contraceptives + Candesartan

Candesartan, 8 mg daily, had no effect on the pharmacokinetics of ethinylestradiol and levonorgestrel in a combined oral contraceptive, and no ovulation occurred during concurrent treatment.1 No special precautions were therefore needed. Consider also ‘Drospirenone + Potassium-sparking drugs’, p.977, for a possible interaction between angiotensin II receptor antagonists and drospirenone, and ‘Antihypertensives + Hormonal contraceptives’, p.880.

Hormonal contraceptives or HRT + Coxibs

Rofecoxib increases contraceptive steroid levels to a small extent, and would not therefore be expected to reduce contraceptive efficacy. Etoricoxib raises ethinylestradiol levels by 50 to 60%, and also appears to raise the levels of conjugated oestrogens in HRT. Celecoxib appears to have no effect on combined oral contraceptive levels. One case of pulmonary embolism has been reported in a patient taking valdecoxib with a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

(a) Celecoxib

Celecoxib had no clinically significant effects on the pharmacokinetics of a combined oral contraceptive containing norethisterone 1 mg and ethinylestradiol 35 micrograms.1 No precautions seem necessary.

(b) Etoricoxib

A study in women taking a combined oral contraceptive (ethinylestradiol-norethisterone 35 micrograms/0.5 to 1 mg) for 21 days found that the
addition of etoricoxib 120 mg with or 12 hours after the oral contraceptive increased the 24-hour steady-state levels of ethinylestradiol by 50 to 60%. It is thought that etoricoxib increases ethinylestradiol levels because it inhibits human sulfotransferase activity. The manufacturer suggests that this increase in ethinylestradiol levels should be considered when choosing the oral contraceptive because of the possible increased risk of adverse events. It may therefore be appropriate to use a contraceptive with a lower dose of ethinylestradiol.

Etoricoxib 120 mg taken with HRT containing 0.625 mg of conjugated oestrogens (Premarin) increased the AUC0-24 of unconjugated estrone, equilin and 17-β estradiol by 41%, 76%, and 22%, respectively; however, the AUCs of these metabolites were less than those seen with 1.25 mg of conjugated oestrogens. The effects of lower doses of etoricoxib have not been studied. The manufacturers say that these increases should be taken into account when selecting HRT in patients taking etoricoxib.

(c) Rofecoxib
In a placebo-controlled, crossover study in 18 healthy women taking a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg), rofecoxib 175 mg daily for 2 weeks raised the AUCs of ethinylestradiol and norethisterone by 13% and 18%, respectively. These small changes, although statistically significant, are within the accepted criteria for bioequivalence, and are unlikely to be clinically important. No abnormal menstrual bleeding was reported. No special precautions are required during concurrent use.

(d) Valdecoxib
A single case of pulmonary embolism has been reported with the concurrent use of a combined oral contraceptive containing norgestimate/ethinylestradiol (Ortho Tri-Cyclen) and valdecoxib. The patient had been taking the same combined oral contraceptive (containing ethinylestradiol doses of 35 and 25 micrograms) for 3 years prior to taking valdecoxib with no adverse effects. The authors note that multiple factors may have contributed to this case, as prolonged stasis (a 6-hour car journey) and oral contraceptives themselves can cause venous thromboembolism. There appear to be no further similar published reports and the clinical significance of this case is unclear. Note that valdecoxib has been withdrawn.

Clinical evidence, mechanism, importance and management
In a randomised, crossover study, 18 healthy women who had been taking a triphasic oral contraceptive (containing ethinylestradiol/norgestrel) were also given etizemib 10 mg daily or placebo on days 8 to 14 of two consecutive contraceptive cycles. Etizemib did not significantly affect the pharmacokinetics of ethinylestradiol or norgestrel. The manufacturers note that etizemib had no effect on the pharmacokinetics of etinylestradiol/norgestrel-containing contraceptives, therefore no additional precautions seem necessary if etizemib is given to women taking these contraceptives.

The effects of the oral contraceptives may possibly be disturbed (either intermenstrual bleeding or amenorrhoea) if griseofulvin is taken concurrently. Reports describe women taking oral contraceptives who became pregnant while taking griseofulvin.

Clinical evidence
In 1984, regulatory authorities in the UK and the Netherlands noted that they had received a total of 22 reports of possible interactions between oral contraceptives and griseofulvin. These included 15 reports of transient intermenstrual bleeding and 5 of amenorrhoea, occurring during the first or second cycle, after griseofulvin 500 mg to 1 g daily was started. Four of these patients were rechallenged with griseofulvin (2 with intermenstrual bleeding and 2 with amenorrhoea) and all developed their original reactions. The other two women were reported to have become pregnant while taking griseofulvin and a sulphonamide (‘co-trimoxazole’, (p.982) in one instance and an unknown sulphonamide in the other). One other case of contraceptive failure has been reported from an analysis of the database of the CSM in the UK from 1968 to 1984, but note this case may be included in the two already reported. One other case report describes a woman taking a triphasic combined oral contraceptive who became pregnant about 2 months after she started to take griseofulvin 330 mg twice daily, and another report describes a woman taking an oral contraceptive who became pregnant 6 weeks after starting to take griseofulvin 500 mg daily for 3 months and a 7-day course of ‘erythromycin’, (p.979). Irregular menses and reduced menstrual flow have been described in another woman taking a combined oral contraceptive (ethinylestradiol 35 micrograms/norethisterone 0.5 to 1 mg) with griseofulvin 250 to 500 mg daily. When the oral contraceptive was substituted with another with more oestrogen (ethinylestradiol/norgestrel 50/500 micrograms), the menstrual cycle became normal again. Breakthrough bleeding has also been seen in one other woman taking an oral contraceptive with griseofulvin.

Mechanism
Not understood. Griseofulvin may possibly stimulate the activity of the liver enzymes concerned with the metabolism of the contraceptive ster-

Hormonal contraceptives + Danazol or Gestrinone

There is a theoretical risk that the effects of danazol or gestrinone and hormonal contraceptives might be altered or reduced by concurrent use.

Clinical evidence, mechanism, importance and management

(a) Danazol
Danazol inhibits ovulation, but it is not considered reliable enough to be used as a hormonal contraceptive. Danazol should not be used during pregnancy, because it can cause virilisation of a female foetus. The manufacturer advises the use of reliable non-hormonal contraceptive methods while taking danazol, and by inference the avoidance of hormonal contraceptives. They say that there is a theoretical risk that danazol and exogenously administered oestrogens and/or progestogens, including oral contraceptives, might possibly compete for the same oestrogen, progestogen, and androgen receptors, thereby altering the effects of both drugs. This would also apply to other hormonal contraceptives such as etonogestrel implants and depot preparations of medroxyprogesterone and norethisterone. However, as yet there appears to be no direct evidence that any interaction actually occurs.

(b) Gestrinone
Although gestrinone, at the dose used for endometriosis, can inhibit ovulation, it is not sufficiently reliable to be used as a contraceptive. The manufacturer strongly emphasises the importance of using a barrier method of contraception while taking gestrinone because they say that not only are the effects of gestrinone possibly modified by oral contraceptives, but its use in pregnancy is totally contraindicated (high doses have been shown to be embryotoxic in some animal species).

Hormonal contraceptives + Ezetimibe
No significant pharmacokinetic interaction appears to occur between ezetimibe and an ethinylestradiol/norgestrel-containing oral contraceptive.

Hormonal contraceptives + Griseofulvin

The effects of the oral contraceptives may possibly be disturbed (either intermenstrual bleeding or amenorrhoea) if griseofulvin is taken concurrently. Reports describe women taking oral contraceptives who became pregnant while taking griseofulvin.

Clinical evidence
In 1984, regulatory authorities in the UK and the Netherlands noted that they had received a total of 22 reports of possible interactions between oral contraceptives and griseofulvin. These included 15 reports of transient intermenstrual bleeding and 5 of amenorrhoea, occurring during the first or second cycle, after griseofulvin 500 mg to 1 g daily was started. Four of these patients were rechallenged with griseofulvin (2 with intermenstrual bleeding and 2 with amenorrhoea) and all developed their original reactions. The other two women were reported to have become pregnant while taking griseofulvin and a sulphonamide (‘co-trimoxazole’, (p.982) in one instance and an unknown sulphonamide in the other). One other case of contraceptive failure has been reported from an analysis of the database of the CSM in the UK from 1968 to 1984, but note this case may be included in the two already reported. One other case report describes a woman taking a triphasic combined oral contraceptive who became pregnant about 2 months after she started to take griseofulvin 330 mg twice daily, and another report describes a woman taking an oral contraceptive who became pregnant 6 weeks after starting to take griseofulvin 500 mg daily for 3 months and a 7-day course of ‘erythromycin’, (p.979). Irregular menses and reduced menstrual flow have been described in another woman taking a combined oral contraceptive (ethinylestradiol 35 micrograms/norethisterone 0.5 to 1 mg) with griseofulvin 250 to 500 mg daily. When the oral contraceptive was substituted with another with more oestrogen (ethinylestradiol/norgestrel 50/500 micrograms), the menstrual cycle became normal again. Breakthrough bleeding has also been seen in one other woman taking an oral contraceptive with griseofulvin.

Mechanism
Not understood. Griseofulvin may possibly stimulate the activity of the liver enzymes concerned with the metabolism of the contraceptive ster-

2. Ezetrol (Ezetimibe). MSD-SP Ltd. UK Summary of product characteristics, December 2006.
oids, thereby reducing their effects (see ‘Hormonal contraceptives and sex hormones’, (p.975)).

Importance and management

Information about this interaction is very limited. The risk of contraceptive failure is uncertain but probably very small. However, it would be prudent for prescribers to warn women taking a combined oral contraceptive who are given griseofulvin that menstrual disturbances may possibly be signs of contraceptive unreliability, and that additional contraceptive precautions should be taken. The CSM in the UK has pointed out the importance of ensuring adequate contraception during and for one month after taking griseofulvin because it can induce aneuropyli (abnormal segregation of chromosomes during cell division), which carries the potential risk of teratogenicity.7 For maximal contraceptive protection additional contraceptive measures (such as a barrier method) should be used routinely while taking griseofulvin and for one month afterwards.

The situation with progestogen-only contraceptives is not clear, but it has been suggested that they are not the contraceptive of choice in those taking griseofulvin, not because of reduced efficacy but because of increased menstrual irregularities.8 The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit states that griseofulvin may reduce the efficacy of hormonal contraceptives as it is a liver enzyme inducer and additional contraceptive protection is advised with concurrent use.9 They have issued guidance on the use of contraceptives with liver enzyme inducers, see ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985.

Hormonal contraceptives + Immunosuppressants

No clinically relevant interactions have been seen between leflunomide, mycophenolate or sirolimus and combined oral contraceptives, but the manufacturer of sirolimus suggests some caution. Mycophenolate has been shown to be teratogenic in animals and so the manufacturer suggests contraceptive precautions in addition to the use of hormonal contraceptives. Tacrolimus may increase the plasma levels of hormonal contraceptives.

Clinical evidence, mechanism, importance and management

(a) Ciclosporin

For the interactions of ciclosporin with hormonal contraceptives see, ‘Ciclosporin + Hormonal contraceptives and Progestogens’, p.1038.

(b) Leflunomide

Leflunomide was given to healthy women taking a triphasic oral contraceptive containing 30 micrograms of ethinylestradiol. During the study it was found that the leflunomide had no effect on the activity of the oral contraceptive and the pharmacokinetics of the active metabolite of leflunomide (A771726) were not changed to a clinically relevant extent.1 No special precautions would therefore appear to be needed on concurrent use.

(c) Mycophenolate

The manufacturer says that no pharmacokinetic interaction was seen in a single-dose study in 15 healthy women taking mycophenolate and Orthonovum (norgestrel/ethinylestradiol 1 mg/35 micrograms).2 A study of mycophenolate 1 g twice daily given with a combined oral contraceptive (containing ethinylestradiol 20 to 40 micrograms and levonorgestrel 50 to 150 micrograms, desogestrel 150 micrograms or gestodene 50 to 100 micrograms) over 3 consecutive menstrual cycles in 18 women not previously taking immunosuppressants found no clinically relevant influence of mycophenolate on the suppression of ovulation by the oral contraceptives.3,4 Large interpatient variability was seen especially for ethinylestradiol. However, the mean levonorgestrel AUC was decreased by about 15%.5 In addition, mycophenolate has been shown to be teratogenic in animal studies at doses lower than those causing maternal toxicity. The manufacturers say that effective contraception must be used before mycophenolate, during, and for 6 weeks after mycophenolate has been stopped.5,6 The US manufacturer also advises that oral contraceptives should be used with caution, and additional birth control methods used.5

(d) Sirolimus

A single-dose study found that the pharmacokinetics of an oral contraceptive (ethinylestradiol/norgestrel 30/300 micrograms) were unaffected by sirolimus. This suggests that the efficacy of the contraceptive is likely to be unchanged, but the UK manufacturer cautiously points out that the effects of long-term sirolimus on oral contraception are unknown.7 They advise that contraception should be continued for 12 weeks after sirolimus is stopped.

(e) Tacrolimus

The UK manufacturer of tacrolimus says that during clinical use ethinylestradiol has been shown to be a weak inhibitor of tacrolimus metabolism and may increase tacrolimus levels, presumably because it inhibits the cytochrome P450 isoenzyme CYP3A4. In vitro data suggest that gestodene and norethisterone may do the same. In addition, tacrolimus may reduce the clearance of steroid-based contraceptives, leading to increased hormone exposure, and therefore the manufacturers suggest that care should be taken when deciding upon contraceptive measures.6

Hormonal contraceptives + Leukotriene antagonists

Montelukast and zafirlukast do not alter the contraceptive efficacy of oral contraceptives.

Clinical evidence, mechanism, importance and management

(a) Montelukast

The manufacturers of montelukast say that it does not affect the pharmacokinetics of an oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg).1,2 No special precautions are therefore needed if both drugs are given together.

(b) Zafirlukast

A single-blind, parallel-group study in 39 healthy women taking unnamed oral contraceptives found that zafirlukast 40 mg twice daily had no effect on the serum levels of ethinylestradiol nor on its contraceptive efficacy.3 This study suggests that concurrent use need not be avoided.

Hormonal contraceptives + Moclobemide

Moclobemide did not alter the efficacy of combined oral contraceptives, as assessed by measures of ovulation suppression.
Clinical evidence, mechanism, importance and management

A study in 7 women taking combined oral contraceptives found no evidence of any significant alterations in estradiol, progesterone, FSH, or LH levels when they took moclobemide 200 mg three times daily for one cycle. This suggests that ovulation did not occur. No serious adverse reactions occurred. It was considered that the efficacy of the oral contraceptives is likely to be maintained during concurrent use.1

Hormonal contraceptives + Modafinil

Modafinil slightly reduces the levels of ethinylestradiol given as part of a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

In 16 healthy women taking a combined oral contraceptive (ethinylestradiol norgestrel), modafinil 200 mg daily for 7 days followed by 400 mg daily for 21 days decreased the AUC and the maximum plasma levels of ethinylestradiol by 18% and 11%, respectively. Increases in plasma FSH and LH were not significant.1 Modafinil is an inducer of the cytochrome P450 isoenzyme CYP3A4, which is partially responsible for the metabolism of ethinylestradiol. These small changes are lower than those seen with other enzyme inducers known to reduce the reliability of combined oral contraceptives (e.g. see ‘phenytoin’, (p.985)). However, it cannot be ruled out that they would be sufficient to cause failure of combined oral contraceptives in very rare cases. The UK manufacturer recommends that additional or alternative methods of contraception should be used during and for up to 2 cycles after stopping modafinil.3 The US manufacturer issues a similar guidance and advises that additional or alternative contraceptive methods need only be continued for one month after stopping modafinil.3 Note that this advice applies to other forms of hormonal contraception including implants and patches.3,4 The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of liver enzyme inducers with hormonal contraceptives,5 see ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985, for further information.

Hormonal contraceptives + Nefazodone

A woman experienced increased combined oral contraceptive adverse effects while taking nefazodone.

Clinical evidence, mechanism, importance and management

Within a week of starting to take nefazodone 50 mg twice daily, a woman taking a low-dose combined oral contraceptive (ethinylestradiol 20 micrograms / norgestrel) reported breast tenderness, bloating, weight gain, and increased menstrual irritability. She had previously experienced identical symptoms while taking a combined oral contraceptive with a higher dose of oestrogen. Nefazodone was discontinued after 6 weeks, and within 24 hours the adverse effects resolved.1 Nefazodone is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which ethinylestradiol is metabolised, and might therefore be expected to increase ethinylestradiol levels. However, the general importance of this isolated case is unknown.

Hormonal contraceptives + NNRTIs

Nevirapine modestly reduces ethinylestradiol and norethisterone levels. Efavirenz and delavirdine increased the levels of ethinylestradiol, while ethinylestradiol had no effect on efavirenz levels. Potential contraceptive failures have been reported in two women taking efavirenz.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

The manufacturer of delavirdine notes that it may increase the levels of ethinylestradiol, but the clinical relevance of this is unknown.1

(b) Efavirenz

The manufacturer notes that efavirenz increased the AUC of a single dose of ethinylestradiol by 37% while the maximum plasma levels remained unchanged. Ethinylestradiol had no effect on the AUC of maximum plasma levels of efavirenz.2,3 These findings suggest that efavirenz does not adversely alter the efficacy of combined oral contraceptives. Nevertheless, the manufacturer notes that because the interaction has not been fully characterised, a reliable method of barrier contraception must be used in addition to other methods of contraception such as hormonal contraceptives.2,3 Furthermore, a retrospective review identified 22 women who were prescribed oral contraceptives and also received an NNRTI. Two of the 16 women taking efavirenz experienced contraceptive failure. However, medication adherence could not be confirmed.4 The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit states that efavirenz can induce liver enzymes and may reduce the levels of ethinylestradiol and progestogens. They therefore recommend that their guidance on hormonal contraceptives and liver enzyme inducers is followed, 5 see ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985 for further detail. Note that, a barrier method of contraception would usually be considered advisable to reduce the risk of HIV transmission.

(c) Nevirapine

A study in 10 HIV-positive women found that nevirapine 200 mg once daily for 2 weeks then twice daily for a further 2 weeks decreased the median AUC of ethinylestradiol by 37% and 31%, respectively, and decreased the median AUC of norethisterone by 19%. The women received two single doses of a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg), 2 days before the nevirapine and on the last day of the nevirapine. Nevirapine was added to established antiretroviral therapy (commonly 3 drugs), which had been unchanged for at least 4 weeks.6 A retrospective study identified 22 women who were prescribed oral contraceptives and also received an NNRTI. None of the 6 women taking nevirapine experienced contraceptive failure. However, medication adherence could not be confirmed.4 It is likely that nevirapine induces the metabolism of the components of the oral contraceptive by cytochrome P450 isoenzymes.6 Although it is not known whether these modest reductions in levels would reduce the anti-ovulatory efficacy of the combined oral contraceptive, it would be prudent to assume they could. The manufacturers recommend that combined oral contraceptives and other hormonal methods of birth control should not be used as the sole method of contraception in women taking nevirapine. Nevirapine should not be used for reasons other than contraception (e.g. endometriosis), that the therapeutic effect should be monitored and the dose increased if necessary.6,7 These precautions seem prudent.

Hormonal contraceptives + NRTIs

There do not appear to have been any reports of hormonal contraceptive or NRTI failure during concurrent use. Tenofivir does not appear to affect the pharmacokinetics of ethinylestradiol or norgestimate. In vitro evidence suggests that ethinylestradiol might possibly reduce the metabolism of zidovudine but the significance of this is unclear.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence and mechanism

(a) Tenofivir

In a study in 20 women taking a combined oral contraceptive containing ethinylestradiol and norgestimate (Ortho Tri-Cyclen), tenofovir 300 mg daily for 7 days had no effect on the pharmacokinetics of ethinylestradiol or norgestimate. The pharmacokinetics of tenofovir were also not affected when compared with historical data.1

(b) Zidovudine

An in vitro study using human liver microsomes found that ethinylestradiol inhibited the glucuronidation of zidovudine by 50% or more, suggesting that ethinylestradiol may increase the effects and toxicity of zidovudine.2 However, note that other drugs that had a similar effect in vitro did not alter zidovudine pharmacokinetics in subsequent clinical studies, see ‘NRTIs; Zidovudine + Drugs that inhibit glucuronidation’, p.808. Further study is needed.

Importance and management

There appears to be no published evidence at present of a clinically significant interaction between the NRTIs (abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zalcitabine and zidovudine) and hormonal contraceptives. The Faculty of Family Planning and Reproductive Health Care (FPRHC) Clinical Effectiveness Unit guidance on drug interactions with hormonal contraception also notes this.3 A study4 found no evidence to suggest that hormonal contraceptives affect the efficacy of HAART. The specific HAART drugs were not named, however most patients were noted to be on a regimen containing an NRTI and a protease inhibitor, but no NNRTI.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

References

Hormonal contraceptives or HRT + Protease inhibitors

Clinical evidence, mechanism, importance and management

Two groups of 10 healthy women taking a combined oral contraceptive were given orlistat 120 mg three times daily or a placebo on days 1 to 23 of two menstrual cycles.1 Orlistat had no effect on ovulation (measured by luteinising hormone and progesterone levels). The contraceptives used all contained ethinylestradiol, but the progestogens differed: 10 contained desogestrel, 4 levonorgestrel, 3 gestodene, 2 cyproterone acetate and 1 lynestrenol. However, the manufacturer has received reports of unexpected pregnancies in patients taking orlistat and hormonal contraceptives. They state that orlistat may indirectly reduce the bioavailability of oral contraceptives as it can cause severe diarrhoea. Therefore, as is standard practice, they recommend using additional contraceptives in patients who develop severe diarrhoea.2 Note that the contraceptive effect of the combined hormonal patch is said not to be affected by diarrhoea.

Hormonal contraceptives or HRT + Protease inhibitors

Ampranavir and atazanavir, given alone increase the levels of ethinylestradiol and norethisterone. Ritonavir and nelfinavir, in contrast to the effect that would normally be expected decrease the levels of ethinylestradiol. Reduced ethinylestradiol and norethisterone levels occur with fosamprenavir, lopinavir and tipranavir given with ritonavir. Indinavir does not appear to interact.

A combined oral contraceptive modestly reduced ampranavir levels, but did not affect the levels of ampranavir derived from fosamprenavir, nor saquinavir levels.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

References

Hormonal contraceptives + Orlisat

Studies suggest that orlistat does not interact with combined oral contraceptives. However, the manufacturers say that pregnancies have occurred.

Clinical evidence

(a) Amprenavir

The UK manufacturer briefly notes that ampranavir increased the minimum plasma concentrations of ethinylestradiol and norethisterone, given as a combined oral contraceptive, by 32% and 45%, respectively. Conversely, the ampranavir minimum concentration and AUC were decreased by 20% and 22%, respectively.1

(b) Atazanavir

Atazanavir 400 mg once daily alone increased the concentration of ethinylestradiol 35 micrograms (when given as a combined oral contraceptive with norethisterone) to a level between the mean concentrations produced by a 35-microgram and a 50-microgram ethinylestradiol dose. The AUC of norethisterone was increased about twofold.2

(c) Fosamprenavir

When fosamprenavir 700 mg twice daily with ritonavir 100 mg twice daily was given with an oral contraceptive containing ethinylestradiol/norethisterone 35/500 micrograms the AUC and maximum plasma concentration of ethinylestradiol were decreased by 37% and 28%, respectively, and the AUC and maximum concentration of norethisterone were decreased by 34% and 38%, respectively. The pharmacokinetics of ampranavir (derived from fosamprenavir) were not significantly affected.3 However, the AUC and maximum concentration of ritonavir were 45% and 63% higher, respectively, compared with historical data in female subjects taking fosamprenavir and ritonavir alone.3 Coadministration of fosamprenavir with ritonavir and a combined oral contraceptive containing ethinylestradiol and norethisterone also resulted in clinically significant increases in liver transaminases in some healthy subjects.5 The clinical relevance of this is not known.

(d) Indinavir

The manufacturer briefly notes that no clinically significant interaction was seen between indinavir and a combined oral contraceptive containing ethinylestradiol and norethisterone.4 In a retrospective study there were no reports of contraceptive failure in 9 patients taking indinavir (overall
there were 8 contraceptive failures out of 33 women taking protease inhibitors. However, medication adherence could not be confirmed.\(^5\)

(e) **Ritonavir**

A study in 12 healthy subjects found that lopinavir/ritonavir 400/100 mg twice daily for 14 days decreased the AUC of ethinylestradiol and norethisterone (given as a combined oral contraceptive for 21 days) by 42% and 17%, respectively.\(^6\)

(f) **Nelfinavir**

The manufacturer briefly notes that in women taking a combined oral contraceptive (ethinylestradiol/norethisterone 35/400 micrograms) nelfinavir 750 mg three times daily for one week decreased the AUCs of ethinylestradiol and norethisterone by 47% and 18%, respectively.\(^7\) In a retrospective study 7 of 21 women taking nelfinavir experienced contraceptive failure (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.\(^5\)

(g) **Ritonavir**

In a study in 23 healthy women ritonavir 500 mg every 12 hours for 16 days decreased the AUC of ethinylestradiol by 41% and decreased its elimination half-life from 17 to 13 hours. The women received a single dose of a combined oral contraceptive (ethinylestradiol/ethinodiol 50 micrograms/1 mg), 14 days before the ritonavir and on day 15 of ritonavir.\(^8\) In a retrospective study there were no reports of contraceptive failure in 6 women taking ritonavir (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.\(^5\)

(h) **Saquinavir**

A study in 8 healthy women found that the pharmacokinetics of a single 600-mg dose of saquinavir were not affected by a combined oral contraceptive containing ethinylestradiol/gestodene 30/75 micrograms (Minulet) taken for 21 days.\(^9\) In a retrospective study there was one report of contraceptive failure out of 5 women taking saquinavir (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.\(^5\)

(i) **Tipranavir**

Tipranavir given with low-dose ritonavir decreased the AUC and maximum concentration of ethinylestradiol by 50%, but did not significantly alter the pharmacokinetics of norethisterone.\(^10,11\)

**Mechanism**

Ritonavir more commonly inhibits the cytochrome P450 isozyme CYP3A4 and the results for ritonavir are the opposite of those originally predicted based on *in vitro* data showing inhibition of ethinylestradiol metabolism (cytochrome P450 isozyme CYP3A mediated 2-hydroxylation).\(^12\) It is possible that ritonavir induces the metabolism of hormonal contraceptives rather than inhibits CYP3A after chronic use. It is also likely that ritonavir induces ethinylestradiol glucuronosyl transferase activity.\(^8\) Nelfinavir probably interacts similarly. Amprenavir, atazanavir, fosamprenavir, indinavir and tipranavir (when combined with ritonavir) may inhibit CYP3A4. However, note that, although indinavir is a relatively potent inhibitor of CYP3A4, it does not appear to interact.

**Importance and management**

Although information is limited, the pharmacokinetic interaction between the ethinylestradiol component of combined hormonal contraceptives and nelfinavir or ritonavir appears to be established and is likely to be clinically important. Similar decreases in plasma levels of ethinylestradiol caused by other drugs have resulted in reduced efficacy and reliability of combined oral contraceptives, and one retrospective report suggests that this has occurred with nelfinavir.\(^5\) It seems likely that the reduced contraceptive levels seen with fosamprenavir, lopinavir and tipranavir were due to the concurrent use of ritonavir (as would be common in practice). Similarly, although no interaction was reported with saquinavir, and *raised* contraceptive steroid levels were reported with amprenavir and atazanavir, in practice these drugs would be given with ritonavir (as a pharmacokinetic enhancer), so that the levels of combined hormonal contraceptives can reasonably be expected to be reduced. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has given general guidance on how to manage the interaction of combined hormonal contraceptives with liver enzyme inducers. See ‘Hormonal contraceptives + Anti-epileptics; Barbiturates or Phenytoin’, p.985. Note that there appears to be no clinically significant interaction between indinavir and combined oral contraceptives.

There is no direct information about *progestogen-only contraceptives* but since lopinavir/ritonavir and nelfinavir cause small reductions in the levels of norethisterone (when given as part of a combined oral contraceptive) it is possible that these protease inhibitors could reduce the contraceptive efficacy of progestogen-only contraceptives containing norethisterone. The progestogen-only oral contraceptives have a higher failure rate than the combined oral contraceptives, so it would seem prudent to use additional or alternative contraceptive measures in this situation as well. Whether this applies to other progestogens used in progestogen-only contraceptives does not appear to have been specifically studied. See ‘Hormonal contraceptives + Anti-epileptics; Barbiturates or Phenytoin’, p.985, for the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit general guidance on how to manage the interaction between liver enzyme inducers and hormonal contraceptives in women using the progestogen-only pill or implant. The progestogen-only depot injection and progestogen-releasing intrauterine system are not affected by liver enzyme inducers.\(^13\)

However, note that whatever other methods of contraception are being used, barrier methods are always advisable to reduce the risk of HIV transmission.

The effects of the protease inhibitors on HRT does not appear to have been studied, although it would be prudent to anticipate some reduction in their effects. The manufacturers of tipranavir specifically note that patients using oestrogens as HRT together with tipranavir and ritonavir should be monitored for signs of oestrogen deficiency. They also note that women using oestrogens with tipranavir may also have an increased risk of non-serious rash.\(^10,11\)

Amprenavir levels are decreased by combined hormonal contraceptives, but the effects are modest. There appears to be no evidence to suggest that combined hormonal contraceptives decrease the antiretroviral efficacy of HAART.\(^14\) but evidence is preliminary and more study is needed.

### Hormonal contraceptives or HRT + Proton pump inhibitors

 Lansoprazole and pantoprazole appear not to interact with combined oral contraceptives. Ethinylestradiol may inhibit the me-
Hormonal contraceptives + Retinoids

There seems to be no evidence that the reliability of the combined oral contraceptives is affected by acitretin, etretinate or isotretinoin, and they are the contraceptive method of choice with these teratogenic drugs. It is unclear whether the effects of the progestogen-only oral contraceptives are altered by acitretin, but, in any case, progestogen-only oral contraceptives are not generally considered reliable enough for use with these teratogenic drugs. The adverse effects of isotretinoin on lipids may be additive with those of oral contraceptives.

Clinical evidence

(a) Combined oral contraceptives

1. Acitretin. Eight women taking a combined oral contraceptive (ethinylestradiol/levonorgestrel) were given acitretin 25 to 40 mg daily for at least two cycles. Suppression of ovulation was not affected by acitretin, as assessed by plasma progesterone levels.

2. Eretinate. In a study in 12 women taking a combined oral contraceptive (ethinylestradiol plus levonorgestrel, norethisterone, norgestrel, or cyproterone) the use of etretinate 0.7 to 1 mg/kg did not affect the suppression of ovulation.

3. Isotretinoin. A pharmacokinetic study in 9 women taking a combined oral contraceptive found that the plasma levels of ethinylestradiol and levonorgestrel were not significantly changed by the use of isotretinoin 500 micrograms/kg. Suppression of ovulation was maintained. Another study in 26 women taking a combined oral contraceptive containing ethinylestradiol 35 micrograms and norethisterone 0.5/0.75/1 mg (Ortho Novum 7/7/7) found a small reduction in the levels of ethinylestradiol and norethisterone when isotretinoin 1 mg/kg daily was also given. These changes were not associated with significant changes in the levels of FSH, LH or progesterone. However large inter-patient variability in the results was noted and two patients showed increases in progesterone levels, possibly indicating that ovulation had occurred. One of these patients was noted to be non-compliant. The adverse effects of isotretinoin and combined oral contraceptives on plasma lipids may be additive. A case-control study found that women who had hypertriglyceridaemia and/or hypercholesterolaemia while taking isotretinoin were 2 to 12 times as likely to be also taking an oral contraceptive.

(b) Progestogen-only oral contraceptives

One woman taking a progestogen-only contraceptive (levonorgestrel 30 micrograms) had a significant increase in her progesterone levels after 3 cycles while taking acitretin 400 micrograms/kg daily. Plasma progesterone levels rose from 2.15 nanograms/mL before taking the acitretin to 3.87 to 13.46 nanograms/mL with acitretin. This rise in progesterone levels was taken as evidence that ovulation had occurred.

Mechanism, importance and management

Information is limited, but it appears that these retinoids do not usually alter the efficacy of combined oral contraceptives. The one available case suggests that acitretin reduces the efficacy of progestogen-only oral contraceptives. However, note that progestogen-only oral contraceptives do not reliably suppress ovulation in all cycles, and that this is not considered their primary mechanism of action (see ‘Hormonal contraceptives and Sex hormones’, (p.975)). The single report cannot therefore be taken as evidence that acitretin reduces the efficacy of progestogen-only contraceptives.

Also note that because the retinoids are established human teratogens, it is very important that women taking them do not become pregnant. For this reason, progestogen-only oral contraceptives are generally not considered suitable for use with retinoids. Unless contraindicated, combined oral contraceptives are the method of choice.8,9 The combined oral contraceptive should be started one month before the retinoids and continued for one month after stopping isotretinoin,3,15 and for 2 years after stopping etretinate or acitretin.6,8 In the US, it is standard practice to recommend that a second form of contraception, such as a barrier method, should also be used.9 This is also recommended by the UK manufacturer of isotretinoin.10 This is because, even though hormonal methods of contraception are highly effective, they do, on rare occasions, fail.7 The general significance of the reduction in steroid levels seen in one study with isotretinoin is unclear and the results were subject to wide inter-patient variability, however the authors state that their results reinforce the advice of using two forms of contraception,4 one of which should usually be a barrier method, such as condoms.7 Note that an oral contraceptive containing a non-androgenic (third generation) progestogen (e.g. desogestrel, gestodene, norgestimate) is preferred, since these have less detrimental effects on lipids,3 and some favour the use of the anti-androgen cyproterone.

Hormonal contraceptives are less reliable during treatment with rifampicin. Breakthrough bleeding and spotting commonly occur, and pregnancy may not be prevented. Rifabutin also reduces the reliability of hormonal contraceptives, although it interacts to a lesser extent, and no contraceptive failures appear to have been reported.

Clinical evidence

(a) Rifabutin

In two studies rifabutin 300 mg daily for 10 or 14 days reduced the plasma levels of ethinylestradiol and norethisterone in women taking a combined oral contraceptive, but to a lesser extent than rifampicin. The AUC for ethinylestradiol decreased by about 35% in both studies, and the AUC of norethisterone decreased by 17%. In one study, spotting occurred in 21.7% of women when they took rifabutin (compared with 3.7% in the control cycle and 36% with rifampicin). Ovulation did not occur with rifabutin or rifampicin in either study. There appear to be no reports of contraceptive failure attributed to rifabutin.

(b) Rifampicin (Rifampin)

A report in 1971 noted a marked increase in the frequency of intermenstrual breakthrough bleeding (regarded as loss of reliability of the contraceptive) in women taking a combined oral contraceptive and rifampicin. In a later report by the same researchers, 62 out of 88 women taking a combined oral contraceptive had menstrual cycle disorders of various kinds (spotty, bleeding, failure to menstruate) while taking a rifampicin-based regimen for tuberculosis, compared with only 1 of 26 treated with a streptomycin-based regimen. In addition, 5 pregnancies occurred in women taking the rifampicin-based regimen. Other case reports have confirmed this interaction, and there have been a total of at least 11 other pregnancies reported. Combined oral contraceptives commonly mentioned in these reports include ethinylestradiol with norgestrel or norethisterone. There has also been a report of a pregnancy occurring in a woman who was using a progestogen-only implant: a 29-year-old woman who had been fitted with an etonogestrel implant (Implanon) for approximately 2 years was prescribed rifampicin 300 mg twice daily for hiradenitis suppurativa and was found to be 5 weeks pregnant about 6 months later.

One pharmacodynamic study found that 11 out of 21 women taking a triphasic oral contraceptive (ethinylestradiol/levonorgestrel 30 to 40 micrograms/50 to 125 micrograms) ovulated (assessed by increased progesterone levels) while taking rifampicin 300 mg daily. In another study, 2 out of 7 women taking a combined oral contraceptive (ethinylestradiol/norethisterone 30 micrograms/1 mg) ovulated while taking rifampicin. In addition, rifampicin reduced the AUC of norethisterone by 30%. Conversely, two other studies did not detect ovulation in 34 women taking a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) and rifampicin. However, an increased incidence of spotting was noted in one of these studies (36% versus 3.7% in the control cycle). Furthermore, both of these studies found that rifampicin 300 mg daily for 10 days or 600 mg daily for 14 days reduced the AUC of ethinylestradiol by about 63% and norethisterone by about 55%. These pharmacokinetic results confirm the findings of earlier studies. Rifampicin plasma levels and efficacy are reported to be unchanged by oral contraceptives.

Mechanism

Rifampicin is a potent non-specific enzyme inducer, which has been shown to increase the hydroxylation of ethinylestradiol fourfold in an in vitro study, and twofold in an in vivo study. Another study showed that the metabolism of ethinylestradiol derived from mestranol was similarly affected. As a result, the reduced steroid levels may be insufficient to prevent the re-establishment of a normal menstrual cycle with ovulation, which would explain the breakthrough bleeding and pregnancies that have occurred. Rifabutin similarly acts as an enzyme inducer, but it is less potent than rifampicin (said to be half as potent in reducing contraceptive steroid levels).

Importance and management

The interaction between the combined oral contraceptives and rifampicin is well documented, well established and clinically important. Menstrual cycle disturbances of 36 to 70%, and an ovulation rate of up to 52% show very clearly that women receiving combined oral contraceptives should use an alternative or additional form of contraception while taking rifampicin, and for 4 to 8 weeks after its withdrawal. Direct information about the interaction between combined oral contraceptives and rifabutin seems to be limited to the pharmacodynamic studies cited, but it is supported by the well-recognised enzyme-inducing properties of rifampicin. It would clearly be prudent for women receiving rifabutin to take the same precautions as with rifampicin, although the risks are lower because rifabutin is a less potent enzyme inducer. No cases of contraceptive failure appear to have been attributed to the use of rifabutin. Nevertheless, to be on the safe side, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) recommends that alternative methods of contraception to the progestogen-only oral pill should be used when receiving liver enzyme-inducing antibacterials.

There has been a report of a pregnancy in a woman who was using a progestogen-only implant about 6 months after starting rifampicin. The FFPRHC recommends that patients with a progestogen-only implant should use additional methods of contraception during and for 4 weeks after stopping a short course of a liver enzyme-inducing antibiotic. Alternative forms of contraception should be considered in pregnant women requiring long-term treatment with these antibacterials.

The progestogen-only injection and levonorgestrel-releasing IUD do not appear to be affected, so no additional protection is required. The effectiveness of the emergency progestogen-containing oral contraceptive will also be reduced in women taking liver enzyme inducers. In the UK it is possible to purchase this type of emergency hormonal contraceptive without a prescription; however, it is recommended that patients taking liver enzyme inducing antibacterials should not be supplied with the emergency contraceptive but should be referred to a doctor or family planning service.

The FFPRHC has issued guidance on the use of liver enzyme inducers, such as rifampicin and rifabutin, with all forms of hormonal contraceptives, including the emergency hormonal contraceptive, and these are given in detail elsewhere, see ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985.

St John’s wort may affect the pharmacokinetics of desogestrel, ethinylestradiol, and norethisterone. Both breakthrough bleeding and, more rarely, combined oral contraceptive failure have been reported in women taking St John’s wort. Two cases describe the failure of emergency hormonal contraception, which was attributed to the use of St John’s wort.

Clinical evidence

(a) Combined hormonal contraceptives

A study in 17 healthy women taking ethinylestradiol/desogestrel 20/150 micrograms daily found that St John’s wort (300 mg twice or three times daily) did not affect the AUC or maximum levels of ethinylestradiol. However, the AUC and maximum levels of the active metabolite of desogestrel were significantly decreased by about 40% and 20%, respectively. There was no evidence that ovulation occurred. However, the frequency of breakthrough bleeding increased significantly from 35% to around 80%, which may affect compliance.1 Another study in 12 healthy women taking ethinylestradiol/norethisterone 35 micrograms/1 mg (Ortho-Novum) found that St John’s wort 300 mg three times daily for 8 weeks increased the oral clearance of norethisterone and reduced the half-life of ethinylestradiol, but the serum levels of LH, FSH and progesterone were unaffected. However, of more importance, was the increase in breakthrough bleeding, which the authors state as a major cause of patients stopping hormonal contraceptives.2 A further study in 16 subjects also found reductions in the levels of low-dose ethinylestradiol/norethisterone 20 micrograms/1 mg. Furthermore, they found increased progesterone levels of more than 3 nanograms/mL (an indication that ovulation occurred) in 3 patients who also took St John’s wort with compared to one subject who took placebo. Breakthrough bleeding occurred in was also increased.2

The Adverse Drug Reactions Database of the Swedish Medical Products Agency has recorded cases of pregnancy due to the failure of a combined oral contraceptive, which was attributed to the use of products containing St John’s wort (Exbericum and Kira). One woman was taking ethinylestradiol and norethisterone and the other was taking ethinylestradiol and levonorgestrel.3 This follows an earlier report from the Swedish Medical Products Agency of 8 cases of breakthrough bleeding in women aged 23 to 31 taking long-term oral contraceptives and St John’s wort. Breakthrough bleeding occurred within about a week of starting St John’s wort in 5 of the cases, and was known to have resolved in 3 cases when the St John’s wort was stopped.4 The CSM in the UK has on record a further 7 cases of pregnancy in women taking St John’s wort and oral contraceptives in the two-year period from February 2000 to February 2002. Another earlier brief report describes 3 women taking a combined oral contraceptive (ethinylestradiol/desogestrel 30/150 micrograms) who developed breakthrough bleeding one week (2 cases) and 3 months (1 case) after starting to take St John’s wort.5 A single case of pregnancy has also been reported in a patient taking St John’s wort with ethinylestradiol/dienogest (Valette).6 The German Federal Institute for Drugs and Medical Devices has received a total of 8 case reports of ineffective contraception with St John’s wort.7

(b) Emergency hormonal contraceptives

The CSM in the UK has received reports of 2 women taking St John’s wort who became pregnant despite taking emergency hormonal contraception. One of them was also taking an oral contraceptive.8

Mechanism

It is believed that St John’s wort can induce the cytochrome P450-mediated metabolism of the contraceptive steroids, thereby reducing their serum levels and their effects.9,10 This can lead to breakthrough bleeding and, in some cases, contraceptive failure. This is consistent with the way St John’s wort appears to lower the serum levels of some other drugs. Note that St John’s wort is a herbal preparation, and the specific constituents responsible for enzyme induction are currently unknown. Also, the levels of individual constituents can vary between different preparations of the herb.

Importance and management

Information appears to be limited to these reports but the interaction between hormonal contraceptives and St John’s wort appears to be established. Its incidence is not known but the evidence so far suggests that breakthrough bleeding may be a problem, although pregnancy resulting from this interaction appears to be uncommon. However, since it is not known who is particularly likely to be at risk, women taking oral contraceptives should be advised to avoid St John’s wort (the recommendation of the CSM/MCA and the FFPHC in the UK10,11) or they should use an additional form of contraception. Only two cases of emergency hormonal contraceptive failure attributed to an interaction with St John’s wort have so far been reported, but the effects of any interaction here would be very difficult to assess. The Faculty of Family Planning and Reproductive Health Care (FPFPRHC) Clinical Effectiveness Unit is in agreement with the CSM advice but recommends that, if St John’s wort must be continued, the guidelines for the use of liver enzyme inducers with hormonal contraceptives should be followed, see ‘Hormonal contraceptives + Antiepileptics; Barbbiturates or Phenytoin’, p.985, for details of this guidance. Note that combined hormonal contraceptive patch, progesterone-only pills and implants may also be affected.

See also ‘Emergency hormonal contraceptives + Enzyme inducers’, p.977 for information on how to manage the interaction with emergency hormonal contraception.

Although the considerable worldwide popularity of St John’s wort is fairly recent, it is currently the most widely used antidepressant in Germany and has been used for very many years in both Germany and Austria. Yet, there seems to be no published evidence that oral contraceptive failure in those countries is more frequent than anywhere else. This would seem to confirm that contraceptive failure leading to pregnancy occurring as a result of this interaction is very uncommon, or perhaps that it has failed to be identified as a possible cause.9

Hormonal contraceptives + St John’s wort

(Hypericum perforatum)

St John’s wort may affect the pharmacokinetics of desogestrel, ethinylestradiol, and norethisterone. Both breakthrough bleeding and, more rarely, combined oral contraceptive failure have been reported in women taking St John’s wort. Two cases describe the failure of emergency hormonal contraception, which was attributed to the use of St John’s wort.

Hormonal contraceptives or HRT + Statins

Atorvastatin and rosuvastatin may modestly increase the plasma levels of combined oral contraceptives. Rosuvastatin pharmacokinetics and lipid-lowering effects were unaffected by an oral contraceptive containing ethinylestradiol and norgestomet. The pharmacokinetics of a single dose of pravastatin were also unaffected by combined oral contraceptives. However, noretisterone abolished the beneficial effects of atorvastatin and/or estradiol on the lipid profile.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

A study in 12 healthy women taking a combined oral contraceptive (ethinylestradiol/noretisterone 35 micrograms/1 mg) found that atorvastatin 40 mg daily increased the AUC of noretisterone and ethinylestradiol by about 28% and 19%, respectively, and increased their maximum plasma levels by 24% and 30%, respectively. These increases are only moderate and unlikely to be clinically important, but the manufacturers say that they should be considered when selecting an appropriate oral contraceptive dosage for women given atorvastatin. A double-blind, randomised, placebo-controlled study in postmenopausal women with hypercholesterolaemia and arterial hypertension found that whilst atorvastatin alone, estradiol alone, or the combination of both had beneficial effects on the lipid profile and endothelium-dependent vasodilation, these effects were abolished by the addition of noretisterone. It was suggested that progestogen derivatives with high androgenic activity, such as noretisterone, have a negative effect on lipid profile.

(b) Pravastatin

The pharmacokinetics of a single 20-mg dose of pravastatin were found to be unaffected in 15 young women taking combined oral contraceptives (ethinylestradiol with noretisterone, norgestrel or levonorgestrel), when compared with similar women not taking contraceptives. No adverse effects attributable to concurrent use were seen.

(c) Rosuvastatin

A non-randomised study in 18 healthy women taking a combined oral contraceptive (Ortho Tri-Cyclen; ethinylestradiol 35 micrograms for 21 days with norgestomet 180/250 micrograms, 7 days of each) found that the addition of rosuvastatin 40 mg daily increased the AUC and maximum concentration of ethinylestradiol by 26% and 25%, respectively, and increased the AUC and maximum concentration of norgestomet, an active metabolite of norgestomet, by 34% and 23%, respectively. The contraceptive efficacy was unchanged as measured by FSH, LH and progesterone levels. These increases in hormonal steroid levels are unlikely to be clinically significant in patients taking low-dose oral contraceptives, although the manufacturer notes that these changes should be considered when choosing a hormonal contraceptive preparation. The pharmacokinetics and lipid-lowering effects of rosuvastatin were unaffected.

Hormonal contraceptives + Sucrose polyesters

Sucrose polyesters do not interact with oral contraceptives.

Clinical evidence, mechanism, importance and management

When 28 healthy women took 18 g of sucrose polyester (Olestra) daily for 28 days, the pharmacokinetics of the components of a combined oral contraceptive (ethinylestradiol/norgestrel 30/300 micrograms) were unchanged. Serum progesterone levels also remained unaltered, suggesting no ovulation occurred. This agrees with the findings of earlier single-dose studies, which found that sucrose polyesters had no effect on the bioavailability of single doses of ethinylestradiol or noretisterone. No special contraceptive precautions appear to be necessary.

Hormonal contraceptives + Terbinafine

Terbinafine does not have a clinically significant interaction with oral contraceptives.

Clinical evidence, mechanism, importance and management

An in vitro study in human livers found that terbinafine did not alter the pharmacokinetics of ethinylestradiol. However, the manufacturer of terbinafine notes that menstrual disturbances have occurred in patients taking both oral contraceptives and terbinafine. In a post-marketing survey, which included 314 patients taking both oral contraceptives and terbinafine, the rate of menstrual disorders was within the rate reported for patients taking oral contraceptives alone.

Hormonal contraceptives + Tobacco

There is some evidence that smoking increases the risk of breakthrough bleeding with combined oral contraceptives, although smoking appears not to alter contraceptive steroid levels. The risk of cardiovascular disease in women taking combined oral contraceptives is greatly increased if they smoke, particularly in the older age group. Progestogen-only oral contraceptives are an alternative.

Clinical evidence

(a) Cardiovascular effects

Early after the introduction of combined oral contraceptives it was realised that they increase the risk of cardiovascular effects such as thromboembolism, myocardial infarction, and stroke, and that the risks were markedly increased if they smoke. Smoking appears not to alter contraceptive steroid levels. The risk of death from ischaemic heart disease was slightly, but not statistically significantly, raised in all oral contraceptive users. However, smoking had a substantial effect on mortality from ischaemic heart disease; in heavy smokers (more than 15 cigarettes per day), there was a twofold increased risk of myocardial infarction and a twofold increased risk of death from ischaemic heart disease.
daily) the mortality rate ratios for oral contraceptive use for 48 months or less, for 49 to 96 months, and for 97 months or more compared with non-use were 2.4, 4.8, and 2.8, respectively.7

(b) Contraceptive efficacy

An analysis of data from three large clinical studies in a total of 2956 women found that smoking was associated with an increased incidence of spotting and bleeding in users of combined oral contraceptives. The relative risk was 1.3 during the first cycle of use and increased to 1.9 by the sixth cycle.8 Similarly, in a study of women who became pregnant while taking oral contraceptives, smokers were more likely to have menstrual disturbances, and smokers taking the combined oral contraceptive had a 20% greater pill failure rate than expected.9 This association was not noted for progestogen-only oral contraceptive failure.9 Conversely, in a large cohort study in the UK, the failure rate of oral contraceptives was not increased in smokers.10 In one study in 311 women taking oral contraceptives, plasma levels of ethinylestradiol and norgestrel were similar in smokers and non-smokers,11 and another study found only a small increase in ethinylestradiol clearance in smokers.12

Mechanism

The cardiovascular effects reported do not appear to be attributable to any effect of smoking on the metabolism of contraceptives steroids (see below). Rather, the adverse effects of combined oral contraceptives on cardiovascular risk factors, such as plasma lipids and coagulation parameters, appear to be accentuated by smoking.

Smoking increased the metabolism (2-hydroxylation) of endogenous estradiol in one study in premenopausal women.13 Smoking does not appear to alter the levels of contraceptive steroids to a clinically relevant extent.

Importance and management

The cardiovascular interaction between smoking and combined hormonal contraceptives is well established. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit and Royal College of Obstetricians and Gynaecologists guidelines on criteria for the use of contraceptives recommend that the combined hormonal contraceptive should not be used in women aged over 35 who are current smokers or who stopped smoking less than one year ago as the risks, particularly of cardiovascular disease, outweigh the benefits.6,14 Women over the age of 35 years with no additional risk factors (such as diabetes, hypertension etc) and who stopped smoking more than one year ago may consider using a combined hormonal contraceptive. This is because the risk of cardiovascular disease reduces by as much as 50% one year after stopping smoking, although it may not become comparable to that of a non-smoker for up to 4 to 10 years.14 Women aged under 35 years who smoke and have no other associated risk factors may use a combined hormonal contraceptive, but should be informed about the increased risk of cardiovascular disease. Any woman with multiple risk factors for cardiovascular disease (older age, smoking, diabetes, hypertension, obesity, family history of arterial disease, migraine) should not take the combined hormonal contraceptive.14,15 The BNF recommends that women who smoke 40 or more cigarettes a day should not receive combined oral contraceptives.15 In women who smoke, for whom a combined oral contraceptive is not contraindicated, ones with the lowest doses of ethinylestradiol may be safer.16

All smokers should be encouraged to stop.17 In the UK, progestogen-only oral contraceptives are considered suitable for women who are heavy smokers,14 although it should be remembered that they have a higher failure rate than the combined oral contraceptives.

Smoking may increase the incidence of breakthrough bleeding. This may decrease the acceptability of the oral contraceptive, and lead to the use of less effective contraceptive methods.8 However, it also raises the question of whether smoking increases the failure rate of oral contraceptives. The only evidence that this may occur is anecdotal. Further study is needed.

Hormonal contraceptives + Tolterodine

Tolterodine does not appear to interact with combined oral contraceptives.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 24 women found that tolterodine 2 mg twice daily on days 1 to 14 of two 28-day contraceptive cycles had no effect on the pharmacokinetics of the steroids in a combined oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms). The pharmacokinetics of the tolterodine were also not significantly altered, and the serum levels of estradiol and progesterone indicated that suppression of ovulation continued during both periods of treatment.1 No special precautions would therefore seem to be needed if these drugs are used concomitantly.

Hormonal contraceptives or HRT + Triptans

Oral contraceptives appear to modestly raise the levels of frovatriptan, naratriptan and zolmitriptan, and slightly increase those of sumatriptan. These changes are not considered clinically significant. HRT did not appear to affect the pharmacokinetics of naratriptan.

Almotriptan, rizatriptan and sumatriptan appear not to alter the levels of oral contraceptives.

Clinical evidence

(a) Almotriptan

A study in 21 women found that a single 12.5-mg dose of almotriptan had no clinically significant effect on the pharmacokinetics of a combined oral contraceptive containing ethinylestradiol 30 micrograms and desogestrel 150 micrograms, taken for two cycles.1

(b) Frovatriptan

In a retrospective analysis of pharmacokinetic data from phase I studies, the mean maximum concentration and AUC of frovatriptan were 25% and 30% higher, respectively, in women taking oral contraceptives than in women not taking oral contraceptives.2

(c) Naratriptan

The clearance of naratriptan was reduced by 32% by oral contraceptives leading to a slightly higher level of naratriptan. HRT had no effect on the pharmacokinetics of naratriptan.3 A case of ischaemic colitis has been reported in a patient taking an oral contraceptive containing ethinylestradiol 30 micrograms and drospirenone 3 mg long-term with naratriptan 2.5 mg, taken to relieve migraine attacks.4
A placebo-controlled study in 20 healthy young women taking a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) found that the concurrent use of rizatRIPTAN (6 days of 10 mg daily followed by 2 days of 10 mg every 4 hours to a total of 3 doses daily) did not affect the pharmacokinetics of either contraceptive steroid. Blood pressure, heart rate and temperature were unaffected and adverse effects were similar to those seen with placebo.5

A study to investigate the effects of a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) on the pharmacokinetics of sumatriptan was done in 26 women who had been taking this contraceptive for at least 3 months. A single 50-mg oral dose of sumatriptan was given once after 21 days of active treatment with the oral contraceptive, and again after 7 days of placebo (day 28). A 16% higher AUC and a 7% higher maximum concentration of sumatriptan was noted on day 21, compared with day 29. There was an 18% reduction in the maximum concentration of norethisterone when it was given with sumatriptan, but no change in its AUC. Similarly, there was no change in the AUC or maximum concentration of ethinylestradiol when it was given with sumatriptan.6

In a retrospective analysis of pharmacokinetic data from several studies, the mean maximum concentration and AUC of zolmitriptan were 30 to 50% higher, respectively, in women taking oral contraceptives than in women not taking oral contraceptives.7 The effects of zolmitriptan on oral contraceptive steroids have not been studied.3

**Mechanism**

Not known.

**Importance and management**

Although data are limited, the minor to modest possible increases in frovatriptan, naratriptan, sumatriptan and zolmitriptan pharmacokinetics described are not likely to produce clinically relevant adverse effects. Almotriptan, rizatRIPTAN and sumatriptan do not appear to have any clinically important effect on levels of contraceptive steroids. The significance of the single case report of ischaemic colitis associated with concurrent use of naratriptan and a combined oral contraceptive is unclear. Note that ischaemic colitis has, rarely, been reported with naratriptan itself.8 The manufacturers have found no cases of ischaemic colitis in approximately 450 women on oral contraceptives and taking naratriptan for prophylaxis for 5 to 6 days.9 However, caution may be needed with concurrent use in those patients with risk factors for ischaemic colitis, such as those with a history of abdominal surgery, low blood pressure, diabetes, cardiovascular disease or stroke.

More importantly, women who suffer from migraine and take a combined oral contraceptive are at increased risk of a stroke compared with those using combined oral contraceptives who do not suffer from migraine.8 11 The Faculty of Family Planning and Reproductive Health Care (FPPRHC) guidance states that women of all ages who currently have migraines with aura should not use a combined hormonal contraceptive. Women over the age of 35 who have migraine attacks with aura should also not use combined hormonal contraceptives.10 Women taking any hormonal contraceptive and a combined oral contraceptive are at increased risk of a stroke compared with day 29. There was an 18% reduction in the maximum concentration of norethisterone when it was given with sumatriptan, but no change in its AUC. Similarly, there was no change in the AUC or maximum concentration of ethinylestradiol when it was given with sumatriptan.6

**Ziprasidone**

Ziprasidone appears not to interact to a clinically relevant extent with combined oral contraceptives.

**Clinical evidence, mechanism, importance and management**

In a placebo-controlled, crossover study, 18 women taking an oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms) for at least 3 months were also given ziprasidone 20 mg twice daily for 8 days. The only change in the pharmacokinetics of the two steroids was an approximately 30-minute increase in the time to maximum plasma concentration of the levonorgestrel, but this was not considered to be clinically significant. No adverse effects occurred. It was concluded that combined use is safe and that ziprasidone does not affect the efficacy of this oral contraceptive and is also unlikely to affect the metabolism and therefore efficacy of other similar contraceptives.

**HRT + Enzyme inducers**

Enzyme inducers that increase the metabolism of contraceptive steroids might also be expected to reduce the efficacy of menopausal HRT. An isolated case describes reduced efficacy of oral conjugated oestrogens in a patient taking phenytoin.

**Clinical evidence, mechanism, importance and management**

A report describes a 28-year-old woman taking oral conjugated oestrogens (Premarin) 1.25 mg daily after oviductomy, who had a dramatic increase in the incidence of hot flushes when she began to take phenytoin 300 mg daily. Her estrone and estradiol levels were found to be very low, and they subsequently increased by four to sixfold after the phenytoin was stopped, at which point the incidence of hot flushes decreased.1 This was considered to be the only report of this interaction.

However, it is not unreasonable to assume that enzyme inducers that increase the metabolism of contraceptive steroids (see ‘Table 28.1’, p.975)) would also increase the metabolism of oestrogens used for HRT. Some manufacturers state that these drugs may reduce the efficacy of HRT preparations. This would be most likely to be noticed where HRT is prescribed for menopausal vasomotor symptoms, but might be difficult to detect where the indication is osteoporosis. The interaction is not relevant to HRT applied locally for menopausal vaginitis. It has also been suggested that any interaction is less likely with transdermal HRT, which bypasses hepatic first-pass metabolism. Further study is needed to confirm the importance of this possible interaction.

**HRT + Moexipril**

Moexipril is reported not to interact adversely with HRT.

**Clinical evidence, mechanism, importance and management**

A placebo-controlled study involving 95 hypertensive postmenopausal women taking HRT found that moexipril, given for 12 weeks, did not affect metabolic parameters associated with cardiovascular disease and concurrent use was considered to be safe and effective.1 HRT had no effect on...
the blood pressure-lowering ability of moexipril. Consider also ‘Drospirenone + Potassium-sparing drugs’, p.977, for a possible interaction between ACE inhibitors and drospirenone.

IUDs; Copper + Anti-inflammatory drugs

There are a few early reports suggesting that the very occasional contraceptive failure of a copper IUD may have been due to an interaction with a corticosteroid, aspirin or NSAID.

Clinical evidence, mechanism, importance and management

The cases of 4 women who, despite being fitted with copper IUDs, each had two successive pregnancies have been reported. Two were taking corticosteroids regularly and the other two often took aspirin or migraine.1,2 Unwanted pregnancies have also been reported in 3 women with copper IUDs who were taking corticosteroids.3,4 and in 2 women taking NSAIDs (indometacin and naproxen).5 A later case-control study found that aspirin and NSAIDs were used more frequently in 717 women who became pregnant while using IUDs than in 717 non-pregnant IUD users (the majority of IUDs were copper). The difference was significant only for aspirin (102 IUD failures, 59 control failures). It is possible that this finding could have resulted from bias in recall or reporting.2 The postulated mechanism for any interaction was that part of the efficacy of copper IUDs may be based on local inflammatory effects, and that anti-inflammatory drugs might reduce this.

The evidence for this possible interaction is very slim and inconclusive, and there appear to be no further reports of any problems. Modern copper-containing IUDs are one of the most effective methods of contraception. Also, intermittent use of anti-inflammatory drugs such as NSAIDs is widespread. A recent Cochrane Database Systematic Review of studies on the use of NSAIDs to reduce pain and/or bleeding with IUDs recommends the use of NSAIDs as first-line drugs to reduce these adverse effects.6 One manufacturer of copper IUDs states that the evidence does not justify general precautions.7 No special precautions therefore appear to be necessary.

Clinical evidence, mechanism, importance and management

The most likely reason for this interaction is that aminoglutethimide acts as an enzyme inducer, increasing the metabolism of the progestogens, thereby decreasing their levels. When the aminoglutethimide is withdrawn, the enzyme induction ceases, and the progestogen level rises.

Importance and management

Both interactions appear to be established and are possibly clinically important. A 50% reduction in the plasma levels of medroxyprogesterone and megestrol should be expected during concurrent use, and this may reduce the adrenal suppressive effect.1 The authors of one report1 say that to achieve adequate plasma medroxyprogesterone acetate levels in breast cancer (above 100 nanograms/mL) a daily dose of 800 mg of Provera is probably necessary in the presence of aminoglutethimide 125 or 250 mg twice daily. This is double the usual recommended dose for this condition.

Oestrogens + Diltiazem

Diltiazem may slightly raise estradiol levels but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A study in 5 healthy postmenopausal women given diltiazem 30 mg twice daily for 4 days with a single 2-mg oral dose of estradiol on day 2, found that there was a slight but non-significant increase in the maximum levels of estrone. Diltiazem is a moderate inhibitor of the cytochrome P450 isozyme CYP3A4 and would be expected to decrease the metabolism of estradiol. This single-dose study appears to suggest that the increase in oestrogen levels caused by diltiazem is small and unlikely to cause any clinically significant adverse effects. However, the dose of diltiazem given was much lower than commonly prescribed doses, the number of patients involved in the study was small, and therefore these results may not accurately reflect the effect of concurrent use.1 More study is needed.

Oestrogens + Grapefruit juice

No clinically significant interaction appears to occur between grapefruit juice and a single dose of either estradiol or ethinylestradiol, although their levels are modestly increased by grapefruit juice.

Clinical evidence, mechanism, importance and management

(a) Estradiol

In women given a single 2-mg dose of estradiol, grapefruit juice produced a small 16% increase in the AUC of estrone, a metabolite of estradiol, but did not affect the AUC of estradiol.1

(b) Ethinylestradiol

In 13 healthy young women given a single 50-microgram dose of ethinylestradiol, grapefruit juice increased the mean maximum plasma level and AUC0–12h of ethinylestradiol by 37% and 30%, respectively, when compared with a control drink (herb tea). There was wide intersubject variation in the increase, but the mean 28% rise in the AUC0–12h was not significant. The subjects drank grapefruit juice 100 mL or herb tea.
30 minutes before the ethinylestradiol, a further 100 mL with the ethinyleral, and then 200 mL every 3 hours for 12 hours after taking the ethinylestradiol. It is thought that this increase in bioavailability probably occurs because grapefruit juice inhibits intestinal cytochrome P450 isoencezyme CYP3A4, which metabolises ethinylestradiol.2 Grapefruit juice may be taken at the same time of day as the combined oral contraceptive (which usually contains ethinylestradiol) but it seems unlikely that this interaction is of practical importance because the increased bioavailability is still less than the extent of known variability between individuals. However, this requires confirmation in a longer-term study. The authors suggest that diet may be a factor in the known inter-individual variability of contraceptive steroid levels.2

### Progestogen-only contraceptives + Antibacterials

The reliability of progestogen-only methods of hormonal contraception are not affected by antibiotics that do not induce liver enzymes, such as the penicillins and tetracyclines.

### Clinical evidence, mechanism, importance and management

Four of the 63 contraceptive failures attributed to antibiotics in the records of the CSM in the UK for 1968 to 1984 occurred with a progestogen-only contraceptive (unspecified).1 In another study, 2 of 37 cases of contraceptive failure attributed to antibiotics occurred with a progestogen-only contraceptive (unspecified).2

Note that the mechanism behind the rare cases of failure of combined oral contraceptives seen with various broad-spectrum antibiotics is postulated to be reduced enterohepatic recycling of ethinylestradiol (see ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981). Since progestogens are largely metabolised to inactive substances before they are conjugated, they do not undergo enterohepatic recycling of the active substance.

Pharmacokinetic data show that the progestogen component (levonorgestrel, norethisterone) of combined oral contraceptives is not affected by ampicillin,3,4 clarithromycin,5 doxycycline,6 metronidazole,7 moxifloxacin,8 or tetracycline.9 There is no reason to expect that the contraceptive efficacy of the various progestogen-only methods (tablets, implants, injections, IUDs) would be affected by antibiotics that alter gut flora and do not induce liver enzymes.

It is generally accepted that no interaction occurs,9 and it is likely that the few cases seen with progestogen-only contraceptives are chance associations.1 The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit does not recommend any additional contraceptive precautions when antibiotics that do not induce liver enzymes are taken with any method of progestogen-only hormonal contraception, including the emergency contraceptive pill.10 However, note that rifampicin and rifabutin are likely to reduce the efficacy of most forms of hormonal contraceptives, as they induce the metabolism of both oestrogens and progestogens, see ‘Hormonal contraceptives + Rifamycins’, p.1001.

### Progestogen-only contraceptives + Enzyme inducers

Enzyme inducers appear to reduce the contraceptive reliability of the levonorgestrel implant, and pregnancies have been reported following the use of carbamazepine, phenytoin, and phenobarbital. Pregnancies have also been reported when the etonogestrel implant was used in women taking enzyme-inducing antiepileptics, particularly carbamazepine. The efficacy of medroxyprogesterone depot injection does not appear to be affected by enzyme inducers. Similarly, noristerone depot injection is thought unlikely to be affected. The contraceptive reliability of the progestogen-releasing intrauterine system is also not thought to be affected.

### Clinical evidence, mechanism, importance and management

#### (a) Implants

A woman taking phenytoin 300 mg daily became pregnant 9 months after the insertion of a levonorgestrel-releasing subdermal contraceptive implant (Norplant). Levonorgestrel levels decreased by 50% after discontinuation of the phenytoin, and progesterone levels fell, suggesting greater suppression of ovulation.1 Another report plasma levonorgestrel levels (from an implant) were 38% lower in 6 women taking phenytoin alone or in combination with carbamazepine or valproate than in 10 subjects taking no medication. Two of the 6 women became pregnant (one taking phenytoin and one taking phenytoin with carbamazepine).2 Similarly, one woman taking phenobarbital 210 mg daily became pregnant about 17 months after the insertion of a levonorgestrel implant.3 Another report4 briefly mentions that one woman taking enzyme-inducing antiepileptics became pregnant while using a levonorgestrel implant, and mentions that the manufacturer had 30 other similar cases on file as of 1995. Pregnancy has been reported in a patient taking carbamazepine 600 mg daily and using the etonogestrel implant (Implanon).5 A report describes 8 other cases of contraceptive failure with this implant in Australian patients who were taking liver enzyme-inducing antiepileptics (7 of the 8 were taking carbamazepine).6 The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that the progestogen-only implant may be continued with short courses of enzyme inducers but only if combined with additional contraceptive methods, see ‘Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin’, p.985, for more detailed guidance. The progestogen-only implant should be reviewed to an alternative form of contraceptive with long-term use of liver enzyme inducers.7 A list of enzyme inducers can be found in ‘Table 28.1’, (p.975).

#### (b) Injectable preparations

The manufacturer states that the clearance of medroxyprogesterone acetate is approximately equal to hepatic blood flow, and as such, would not be expected to be affected by drugs that alter hepatic enzyme activity. Therefore, they say that no dosage adjustment is needed.8 This is in line with the FFPRHC guidance.7

There are data showing that rifampicins can reduce the plasma levels of norethisterone when it is used as a component of combined oral contraceptives (see ‘Hormonal contraceptives + Rifamycins’, p.1001). The manufacturer of Noristerat notes that enzyme inducers may reduce the efficacy of the norethisterone enantiomer injection.9 However, guidance from the FFPRHC Clinical Effectiveness Unit is to continue with the normal injection schedule for norethisterone.10

#### (c) Progestogen-releasing intrauterine system (IUS)

Some enzyme inducers increase the metabolism and reduce the efficacy of combined oral contraceptives (see ‘Table 28.1’, (p.975), for a list). The manufacturer has not studied the influence of these drugs on the efficacy of the levonorgestrel-releasing IUS (Mirena),11 and has said that they cannot be sure that the foreign body effect (i.e. the effect whereby the presence of the IUS prevents menstruation) and/or locally acting hormone will provide reliable contraception when systemic hormone levels and sup-
pression of ovaries are reduced by drug interactions. However, this appears to be overly cautious. The systemic absorption of levonorgestrel from the IUS leads to lower blood levels than are seen with standard progesterogen-only oral contraceptives, and women using a levonorgestrel IUS usually continue to ovulate. Thus, the contraceptive effects of the levonorgestrel IUS are mainly local. Also, a pilot study in 56 women (49 epileptics) using a levonorgestrel IUS, most of them also taking enzyme inducers, who accumulated 1075 months of use, found only one apparent contraceptive failure.

The FFPRHC Clinical Effectiveness Unit considers that the levonorgestrel-releasing IUS is unlikely to be affected by enzyme inducers and recommends that no additional contraceptive protection is required. It is therefore a suitable contraceptive for women taking these drugs.

### Tibolone + Enzyme inducers

On theoretical grounds the manufacturer of tibolone says that the effects of tibolone may be reduced by enzyme-inducing antiepileptics and rifampicin.

**Clinical evidence, mechanism, importance and management**

The manufacturer says that on a theoretical basis enzyme inducers such as the barbiturates, carbamazepine, phenytoin and rifampicin may accelerate the metabolism of tibolone and thus decrease its efficacy. However, they note that no examples of these interactions have been reported in clinical practice, and pharmacokinetic studies are required to demonstrate this interaction. Nevertheless it would be prudent to monitor concurrent use.

Immunosuppressants

The immunosuppressants dealt with in this section are the corticosteroids, basiliximab, daclizumab, etanercept, infliximab, ciclosporin, everolimus, leflunomide, muromonab-CD3, mycophenolate, sirolimus, and tacrolimus. A classification is given in ‘Table 29.1’, (see below). When any of these drugs acts as the interacting agent the relevant monograph is categorised in the section dealing with the drug whose effects are changed. Other drugs that are also used for immunosuppression (e.g. azathioprine and methotrexate) are found in the section on antineoplastic drugs.

**Basiliximab + Miscellaneous**

The concurrent use of basiliximab with azathioprine, muromonab-CD3 or mycophenolate is not associated with an increase in adverse effects or infections. The dose requirements of ciclosporin or tacrolimus may be altered by basiliximab. Basiliximab is reported not to interact with analgesics, anti-infective drugs, diuretics, beta blockers or calcium-channel blockers.

**Clinical evidence, mechanism, importance and management**

(a) **Azathioprine**

Azathioprine, added to regimens including basiliximab, ciclosporin micromulsion and corticosteroids reduced the clearance of basiliximab by 22%. However, the use of basiliximab in triple regimens with azathioprine did not increase adverse effects or infections.1

(b) **Ciclosporin**

A study in 39 paediatric renal transplant patients taking ciclosporin found that in 24 patients, who were also given basiliximab 10 or 20 mg on days 0 and 4 after transplantation, lower doses of ciclosporin resulted in significantly higher trough levels and some evidence of early ciclosporin toxicity within the first 10 days. At days 28 to 50 ciclosporin levels declined and 20% higher doses were required to maintain adequate trough levels in the basiliximab group.2 Another study in 54 paediatric liver transplant patients found that the addition of basiliximab to ciclosporin and corticosteroids did not significantly alter the overall ciclosporin dose requirements.

However, 9 basiliximab-treated patients experienced acute rejection at 21 to 28 days after transplantation, and this was associated with low ciclosporin trough levels, requiring an increased ciclosporin dosage in 6 of the 9 patients.3 It was considered that the effect on ciclosporin was due to an interleukin-2 receptor mediated alteration of the cytochrome P450 enzyme system.2 This was considered to only play a minor role in the liver-transplant patients because of significantly lower target trough levels in these patients.4 However, a further study found no increase in rejection episodes between days 28 to 50 in kidney-transplant patients treated with basiliximab and ciclosporin.4

The authors of the first study recommend that the initial dose of ciclosporin should be limited to 400 mg/m² in children receiving renal transplants who are also given with basiliximab. Dose reductions were not considered necessary by other authors, but close monitoring was recommended.5,4

A retrospective analysis of renal transplant patients compared the rates of acute rejection within 6 months in patients given ciclosporin, mycophenolate mofetil and prednisone, with or without basiliximab. Overall, the rates of acute rejection were 11% and 23% in the basiliximab and no-basiliximab groups, respectively. In 74 patients not given basiliximab, low therapeutic ciclosporin exposure on day 3 was associated with increased acute rejection within the first 6 months post-transplantation (45% with ciclosporin AUC less than 4400 nanogram.h/mL compared with 15% with a ciclosporin AUC of greater than 4400 nanogram.h/mL). In 93 patients given basiliximab, rates of acute rejection were similar (about 10%) in patients with low or therapeutic ciclosporin exposure at day 3. It was suggested that achieving early ciclosporin therapeutic targets may not be required if basiliximab is also used.5

(c) **Muromonab-CD3**

The manufacturers of basiliximab say that patients in phase 3 studies received basiliximab with muromonab-CD3 for episodes of rejection, with no increase in adverse events or infections. Human antimurine antibody responses were reported in 2 of 138 patients receiving basiliximab and 4 of 34 patients receiving both basiliximab and muromonab-CD3. Therefore, the manufacturers say that if basiliximab has been given, muromonab-CD3 or other murine antilymphocytic antibody preparations can still subsequently be given.1

(d) **Mycophenolate**

Azathioprine, added to regimens including basiliximab, ciclosporin micromulsion and corticosteroids, reduced the clearance of basiliximab by 51%. However, the use of basiliximab in triple regimens with mycophenolate did not increase adverse effects or infections.1

(e) **Tacrolimus**

A study in 12 adult renal-transplant patients found that trough tacrolimus levels on day 3 were increased by 63% in patients also given basiliximab and in 50% of these patients this was associated with the development of acute tubular necrosis. By day 30, tacrolimus trough levels showed a downward trend in the basiliximab treated group, despite similar dose requirements to those on day 10. Tacrolimus dose requirements were lower in the basiliximab group compared to the control group throughout the 60-day study period.6 Dose reductions were not considered necessary by the authors, but close monitoring was recommended.6

(f) **Other drugs**

The manufacturers report that basiliximab has been used with antibiotics, antifungals, antivirals, diuretics, beta blockers and calcium-channel blockers without any increase in adverse reactions. None of the drugs was individually named.1

**Ciclosporin + ACE inhibitors and Angiotensin II receptor antagonists**

Acute renal failure developed in four kidney transplant patients taking ciclosporin when they were given enalapril. Oliguria was seen in another patient taking ciclosporin with captopril. Other studies have found no significant changes in renal function with candesartan and losartan or with enalapril. Hyperkalaemia may develop in patients taking ACE inhibitors or angiotensin II receptor antagonists with ciclosporin.

**Clinical evidence**

(c) **ACE Inhibitors**

Two kidney transplant patients on ciclosporin developed acute renal failure 10 to 42 days after starting to take enalapril 5 to 10 mg twice daily. Recovery was complete when the enalapril was stopped in one of the patients, and when both enalapril and ciclosporin were stopped in the other. The latter patient had no problems when the ciclosporin was restarted. Both recovered renal function after 10 to 30 days. Neither had any previous evidence of renal artery stenosis or chronic rejection, which are conditions known to predispose to renal failure during ACE inhibitor treatment. Two other patients appeared to tolerate concurrent use well.1 Two further kidney transplant patients developed acute renal failure when given enalapril. Neither had renal arterial stenosis or acute rejection.2 The manufacturer briefly mentions that transient oliguria was seen in a kidney transplant patient given ciclosporin and captopril.3

A study in 13 kidney transplant patients taking ciclosporin found that concurrent treatment with enalapril 5 or 10 mg daily for 3 weeks caused a larger increase in potassium levels (mean increase of 0.5 mmol/L) than in those patients given losartan 50 mg daily (mean increase of 0.2 mmol/L). Potassium levels were not increased above 5.5 mmol/L in any of the patients studied. Uric acid levels were also increased by enalapril but decreased by losartan, although this was not statistically significant. No changes in ciclosporin trough levels were seen during the study and the serum creatinine remained stable.4 Another study in kidney transplant patients taking ciclosporin with either enalapril (33 patients) or enalapril plus amlopidine (32 patients) found that the potassium and serum creatinine levels did not increase in the enalapril/amlopidine group whereas they increased by 0.2 mmol/L and 9 micromol/L, respectively, in the group who received enalapril alone. Ciclosporin levels remained stable in all patients.5
A study in kidney transplant patients taking ciclosporin with losartan found that the serum creatinine was only slightly and non-significantly increased in 5 patients. Losartan was stopped in 3 patients because of a rise in creatinine levels. Transient hyperkalaemia (potassium above 5.5 mmol/L) developed in 4 patients but the potassium had fallen to below 5.5 mmol/L by week 12 in all patients. Ciclosporin levels were remained stable during the study and no significant dose changes were made, although one patient was withdrawn from the study due to ciclosporin toxicity which the authors state was not related to the use of losartan. Another study in 14 kidney transplant patients taking ciclosporin with losartan 50 to 100 mg daily for 8 weeks found serum creatinine, potassium and ciclosporin levels were unaffected. Another study in 41 kidney transplant patients with proteinuria taking ciclosporin found that the addition of candesartan 4 to 12 mg daily had no significant effects on the creatinine clearance or ciclosporin levels.

Mechanism
Not understood. One suggestion is that ciclosporin reduces renal blood flow and reduces perfusion through the glomerulus, which is worsened when angiotensin II is inhibited by the ACE inhibitor. One study suggested that the larger increase in potassium levels may be related to changes in aldosterone levels seen with enalapril.

Importance and management
There have been few specific case reports of renal failure and hyperkalaemia with ciclosporin and ACE inhibitors or angiotensin II receptor antagonists. Data from the efficacy studies above suggest that the incidence of renal failure and hyperkalaemia is low, nevertheless care and good monitoring are needed if ACE inhibitors or angiotensin II receptor antagonists and ciclosporin are used concurrently. Also note that the manufacturers of ciclosporin warn about the possible risk of hyperkalaemia with ACE inhibitors and angiotensin II receptor antagonists with ciclosporin as these drugs may raise potassium levels. Monitor potassium levels more closely in the initial weeks of concurrent use, bearing in mind that an increase in potassium levels may be due to worsening renal function as well as these drugs.

Clinical evidence
A retrospective study in kidney transplant patients taking ciclosporin (serum levels in the range 100 to 250 nanograms/mL) found that in 12 patients oral aciclovir 800 mg four times daily for 3 months had no significant effect on their ciclosporin serum levels or on nephrotoxicity when compared with 9 control subjects. No significant changes in renal function were seen in 11 patients taking ciclosporin when they were given intravenous aciclovir 750 to 1500 mg/m² daily for at least 7 days to treat herpes infections. No significant changes in serum creatinine or ciclosporin levels were seen during the 14 days following kidney transplant in 17 patients given aciclovir 800 mg daily. Fifty-three kidney transplant patients were given ciclosporin and aciclovir 800 mg to 3.2 g daily for 12 weeks. The aciclovir was withdrawn from 2 patients because of unexplained and temporary increases in serum creatinine levels. The serum ciclosporin levels were not reported. Five patients (2 adults and 3 children) taking ciclosporin, prednisone and azathioprine were given aciclovir 200 mg five times daily for 6 days for herpes zoster or chicken pox. Ciclosporin serum levels remained unchanged and renal function improved.

In contrast to the cases cited above, 3 of 7 bone marrow transplant patients given ciclosporin and intravenous aciclovir 500 mg/m² every 8 or 12 hours (depending on renal function) developed nephrotoxicity, which was fatal in one case. Histological evidence suggested ciclosporin nephrotoxicity. The manufacturer briefly notes that an increase in serum creatinine was seen in ciclosporin recipients in one report, and increased aciclovir levels accompanied by reversible acute tubular necrosis in another. Yet another report describes a threefold increase in ciclosporin serum levels, which occurred when a child with a heart transplant was given intravenous aciclovir.

Mechanism
Not understood; although both drugs are known to be nephrotoxic, all be it rarely in the case of aciclovir.

Ciclosporin + Acetazolamide
There is some limited evidence to suggest that acetazolamide can cause a marked and rapid rise in ciclosporin serum levels, possibly accompanied by renal toxicity.

Clinical evidence, mechanism, importance and management
A study in 3 men found that 72 hours after they started taking acetazolamide (dose not stated) their trough serum ciclosporin levels rose by more than sixfold, from a range of 54 to 270 nanograms/mL up to 517 to 1827 nanograms/mL. Another man with a heart transplant had a fivefold increase in his serum ciclosporin levels, marked renal impairment, and neurotoxicity when he was given oral acetazolamide for raised intra-op-
Ciclosporin + Alcohol

An isolated report describes a marked increase in serum ciclosporin levels in a patient after an episode of binge drinking, but a subsequent study found that moderate, single doses of alcohol in other patients had no such effect. Red wine decreases ciclosporin bioavailability.

Clinical evidence

The serum ciclosporin levels of a kidney transplant patient doubled, from 101 to 205 nanograms/mL, and remained high for about 4 days after he went on a 2-day alcohol binge. A subsequent study in 8 other patients with kidney transplants found no changes in serum ciclosporin or creatinine levels when they drank 50 mL of 100% alcohol in orange juice (about equivalent to 4 oz of whisky).1

A crossover study in 12 healthy subjects given a single 8 mg/kg dose of ciclosporin with water or 350 mL (12 oz) of Californian red wine found that red wine caused a 50% increase in the oral clearance of ciclosporin. The ciclosporin AUC was reduced by 30% and the maximum blood levels were reduced by 38%, from 1258 to 779 micrograms/L. There was a high correlation with increased clearance of ciclosporin when they drank 50 mL of 100% alcohol in orange juice (about equivalent to 4 oz of whisky).1

Ciclosporin + Amiodarone

Ciclosporin serum levels can be increased or decreased by amiodarone, and nephrotoxicity has occurred as a result of increased levels. Increased amiodarone levels and pulmonary toxicity have been reported in patients also given ciclosporin.

Clinical evidence

(a) Ciclosporin affected

Eight patients with heart transplants and 3 patients with heart-lung transplants taking ciclosporin were also given amiodarone for atrial flutter or fibrillation. Their serum ciclosporin levels rose by 9% despite a 13 to 14% reduction in the ciclosporin dosage, serum creatinine levels rose by 38% (from 157 to 216 micromol/L), and blood urea nitrogen rose by 30%.1 In another report by some of the same authors, one patient is said to have shown a 50% decrease in the clearance of ciclosporin when given amiodarone.2 Eight other patients with heart or heart-lung transplants were effectively treated with amiodarone for atrial flutter and/or atrial fibrillation, but they had a 31% rise in serum ciclosporin levels, from 248 to 325 nanograms/mL despite a 44% reduction in the ciclosporin dosage (from 6.2 to 3.5 mg/kg daily). Serum creatinine levels rose by 39%.3 In the same study, the serum ciclosporin levels of a kidney transplant patient doubled when amiodarone was given.

In contrast, in 5 heart transplant patients amiodarone was discontinued and ciclosporin initiated, but the metabolism of ciclosporin was increased for 4 to 5 weeks (total plasma metabolites increased from 720 to 1437 nanograms/mL). The mean maintenance ciclosporin level was reduced by 15 nanograms/mL.5

(b) Amiodarone affected

In two heart transplant patients who had stopped amiodarone and started ciclosporin an increase in the plasma levels of amiodarone and its main metabolite, desethylamiodarone, was seen for 4 to 5 weeks. During this period increased adverse effects, including pulmonary toxicity, were seen.5
Mechanism

Uncertain. A reduction in or an increase in the metabolism of the ciclosporin by the amiodarone has been suggested. An interaction between amiodarone and phospholipids in the plasma membrane may inhibit transport processes. Blocking of P-glycoprotein in the intestinal mucosa and liver by both amiodarone and ciclosporin may result in decreased excretion and increased toxicity of amiodarone as well as accumulation of ciclosporin metabolites.

Importance and management

An established and clinically important interaction. Concurrent use need not be avoided but close monitoring and ciclosporin dosage reductions are needed to minimise the potential nephrotoxicity. Remember to re-adjust the ciclosporin dosage if the amiodarone is stopped, bearing in mind that it may take weeks before the amiodarone is totally cleared from the body.

The significance of the increase in amiodarone levels in two patients and the occurrence of pulmonary toxicity in another, all of whom had stopped amiodarone and started ciclosporin, is unclear but bear these reports in mind.

Ciclosporin + Amphotericin B

There is some good evidence to suggest that the risk of nephrotoxicity is increased if ciclosporin and amphotericin B are used concurrently. However, other evidence suggests that a liposomal form of amphotericin B (AmBisome) does not increase nephrotoxicity or hepatotoxicity when given to infants taking ciclosporin. Ciclosporin blood levels may be increased or decreased by amphotericin B.

Clinical evidence

(a) Toxic effects

1. Nephrotoxicity. The concurrent use of ciclosporin and amphotericin B increased the incidence of nephrotoxicity in 47 patients with bone marrow transplants. Out of 10 patients who had received both drugs, 5 doubled and 3 tripled their serum creatinine levels within 5 days. In contrast only 8 out of 21 (38%) taking ciclosporin alone and 3 out of 16 (19%) taking methylprednisolone and ciclosporin doubled their serum creatinine within 14 to 30 days and 5 days, respectively. Two studies of the risk factors associated with amphotericin B identified the concurrent use of ciclosporin as posing a particularly significant risk for the development of the moderate to severe nephrotoxicity in 8 to 12% of patients given amphotericin B. Two other studies in bone marrow transplant patients taking ciclosporin found that amphotericin B contributed significantly to nephrotoxicity and renal failure. It can apparently develop even after amphotericin B has been withdrawn. Methylprednisolone is described in one patient in another report. However, a retrospective study of patients taking ciclosporin also found an increase in creatinine levels during the concurrent use of a continuous infusion of amphotericin B (sodium deoxycholate complex; Fun-gizone) in 22 patients (compared with 62 patients taking ciclosporin alone), but severe reductions in renal function (creatinine clearance less than 30 mL/minute) were not found. In contrast, a study including 8 severely ill infants undergoing bone marrow transplantation for severe immunodeficiency, found no evidence of significant nephrotoxicity or hepatotoxicity when liposomal amphotericin B (AmBisome) was given with ciclosporin. The average course of treatment lasted for 29 days.

2. Neurotoxicity. An isolated case report described severe tremors, later becoming myoclonic, attributed to the concurrent use of liposomal amphotericin B (AmBisome) and ciclosporin. Serum ciclosporin levels were unaltered and creatinine levels only rose slightly. This alleged neurotoxicity was challenged in a letter citing 187 transplant patients who had received ciclosporin and AmBisome, none of whom developed neurotoxicity attributable to an interaction.

3. Other adverse effects. Renal tubular acidosis and hypomagnesaemia were noted to be the most common adverse effects of concurrent low-dose amphotericin B 5 to 10 mg daily with ciclosporin in a retrospective analysis in bone marrow transplant patients.

(b) Ciclosporin levels

A retrospective analysis in allogeneic bone marrow transplant patients found that those patients taking high-dose prednisone with continuous infusion ciclosporin and also given prophylactic amphotericin B 5 to 10 mg daily had 13 to 23% lower plasma levels of ciclosporin in the first four weeks post-transplant when compared with those on the same GVHD (graft-versus-host-disease) prophylaxis regimen who did not receive amphotericin B. No obvious dose reductions or changes in renal function were noted in these patients. It was also noted in this study that patients with ciclosporin plasma levels of 500 nanograms/mL had a 2.2-fold increased risk of developing GVHD when compared with patients with levels of 1000 nanograms/mL.

In contrast, a study in 187 transplant patients given an average dose of ciclosporin 10 mg/kg daily found that ciclosporin blood levels increased significantly from 275 nanograms/mL to 328 nanograms/mL during treatment with liposomal amphotericin B (AmBisome) and decreased to 242 nanograms/mL one week after amphotericin B was stopped. A retrospective study found a non-significant increase in mean ciclosporin blood levels (from 259 to 296 nanograms/mL) with the concurrent use of amphotericin B (0.6 to 2 mg/kg daily for 3 to 112 days) in 22 patients who had undergone allogeneic stem cell transplants. However, a lower maximum mean ciclosporin blood level of 775 nanograms/mL was seen in those patients who received amphotericin B compared with 1240 nanograms/mL in 62 patients receiving ciclosporin without amphotericin B, although this was not significant.

Mechanism

The precise mechanism of the effects of amphotericin B on ciclosporin blood levels and the nephrotoxicity is not understood, although simple additive nephrotoxicity is a likely explanation for the latter.

Importance and management

The increased nephrotoxicity associated with ciclosporin and amphotericin B appears to be established and clinically important. The authors of one report say that “if amphotericin must be given, withholding ciclosporin until the serum level is less than about 150 nanograms/mL may be a means of decreasing renal toxicity without losing the immunosuppressive effect.”

The reports supporting a lack of significant nephrotoxicity all used liposomal amphotericin B, a formulation that is recommended when amphotericin toxicity (particularly nephrotoxicity) is considered to be a significant risk. This would seem to suggest that in patients taking ciclosporin, the less nephrotoxic forms of amphotericin B are advisable. Renal function should be closely monitored during concurrent use.

The changes in ciclosporin blood levels reported with amphotericin B are inconsistent. However, these studies should be borne in mind when using both drugs, and ciclosporin levels as well as renal function should be closely monitored.

References

Ciclosporin + Anabolic steroids and Androgens

Raised ciclosporin levels occurred in two patients given methyltestosterone. Hepatotoxicity has been seen in three patients given ciclosporin and norethandrolone.

Clinical evidence

(a) Methyltestosterone

A man with a kidney transplant who had been stable taking ciclosporin, prednisolone and azathioprine for 23 months was given methyltestosterone 5 mg three times daily for impotence. After 4 weeks he developed anorexia and pruritus. He was found to have a raised bilirubin level and his ciclosporin level had risen from 70 to 252 nanograms/mL, with an accompanying decrease in his renal function. The methyltestosterone was withdrawn and he was later restabilised. Another case describes abnormally high ciclosporin levels (in excess of 2000 nanograms/mL) when a patient was given ciclosporin 15 mg/kg daily. If no alternative is available it may be prudent to increase the frequency of liver function monitoring.

(b) Norethandrolone

Three out of four patients with bone marrow aplasia taking ciclosporin and prednisone developed liver toxicity. The adverse effects developed in 2 of them when norethandrolone was added. No toxicity occurred when they were given either of the drugs alone. Jaundice associated with hepatic hepatitis that occurred in a 14-year-old girl during the post-transplant period was attributed to the concurrent use of ciclosporin and norethandrolone.

Mechanism

Uncertain. In the first case, the increase in ciclosporin levels were attributed to cholestatic jaundice brought on by the methyltestosterone. Both norethandrolone and ciclosporin are known to be hepatotoxic, so additive hepatotoxicity may occur.

Importance and management

Information is limited. However, it would seem prudent to avoid the use of androgens or anabolic steroids in patients taking ciclosporin wherever possible. If no alternative is available it may be prudent to increase the frequency of liver function monitoring.

Ciclosporin + Antibacterials; Aztreonam

Aztreonam does not appear to alter ciclosporin levels.

Clinical evidence, mechanism, importance and management

A study in 20 kidney transplant patients taking ciclosporin found that when aztreonam was added for the treatment of various infections the ciclosporin serum levels were not significantly changed. The ciclosporin blood levels before, during, and after aztreonam treatment were 517, 534, and 592 nanograms/mL, respectively. On the basis of this study there would seem to be no need to take special precautions if ciclosporin and aztreonam are used concurrently.

Ciclosporin + Antibacterials; Aminoglycosides

Both animal and human studies indicate that nephrotoxicity may be increased by the concurrent use of ciclosporin and gentamicin. This has also been shown for tobramycin. Cases of renal impairment have been reported for amikacin and gentamicin.

Clinical evidence

A comparative study in patients given gentamicin 30 mg with lincomycin just before renal transplantation found that the concurrent use of ciclosporin increased the incidence of nephrotoxicity from 5% to 67%. When gentamicin and lincomycin were replaced with ampicillin, cefazidime and lincomycin the incidence of nephrotoxicity was 10%. Another study describes increased nephrotoxicity associated with the concurrent use of ciclosporin and tobramycin in bone marrow transplant recipients. The interaction between ciclosporin and gentamicin has also been well demonstrated in animals. One case report describes reversible acute worsening of renal function in a renal transplant patient receiving ciclosporin with gentamicin, and another case report describes impaired renal function in a heart transplant patient taking ciclosporin and given amikacin.

In contrast, a retrospective analysis of the medical records of bone marrow transplant patients suggested that aminoglycosides can be safely given with a continuous infusion of ciclosporin without excessive nephrotoxicity, if the patient is carefully monitored.

Mechanism

Uncertain. Since both ciclosporin and the aminoglycosides can individually be nephrotoxic, it seems that their toxicities can be additive.

Importance and management

Established and clinically important interactions. The concurrent use of ciclosporin and aminoglycosides should be avoided where possible, and only undertaken with care and very close monitoring of renal function.

been implicated in an increase in ciclosporin plasma levels. However, the manufacturers of ceftazidime state that there is no evidence to suggest that ceftazidime itself is nephrotoxic when used in the recommended doses, although dose adjustment is required in renal failure. A study in 28 bone marrow transplant patients taking ciclosporin found no evidence that ceftazidime 2 g three times daily worsened renal function. Information about these cephalosporins is very limited indeed. The general relevance of these reports is uncertain, but bear them in mind in the event of unexpected response to treatment.

Ciclosporin + Antibacterials; Chloramphenicol

Four patients had a marked rise in serum ciclosporin levels when they were given chloramphenicol. A small study supports these findings.

Clinical evidence

A retrospective study identified 3 transplant patients taking ciclosporin who had received a total of 6 courses of intravenous chloramphenicol, each lasting for at least 12 days. By day 4 of concurrent use ciclosporin blood levels had increased on average by 41.3%. Ciclosporin doses tended to be slightly reduced over the course of treatment, and by day 10, ciclosporin levels were about 31% below baseline.

A woman with a heart-lung transplant and on ciclosporin and oral chloramphenicol (dosage not stated) to treat an infection with Xanthomonas maltophilia. On the next day the ciclosporin levels had risen to 240 micrograms/L. The chloramphenicol was continued but the chloramphenicol dosage was reduced from 300 to 225 mg daily. By day 8 the ciclosporin levels were back within the therapeutic range.

Two kidney transplant patients had marked increases in ciclosporin blood levels (almost doubled in one case) when they were given chloramphenicol for urinary tract infections.

There is another report of this interaction, but the case is greatly complicated by the presence of clindamycin, vancomycin, ceftazidime, and a recent course of rifampicin taken by the patient.

Mechanism

Uncertain. Chloramphenicol is a recognised enzyme inhibitor and it seems possible that it may reduce the metabolism of the ciclosporin by the liver.

Importance and management

Information seems to be limited to these reports, so although the interaction appears to be established, its incidence is obviously uncertain. It would now be prudent to monitor ciclosporin levels if systemic chloramphenicol is added, being alert for the need to reduce the ciclosporin dosage. The study highlights the need to monitor levels closely throughout the whole chloramphenicol course. It seems doubtful if there will be enough chloramphenicol absorbed from eye drops to interact with ciclosporin, but this needs confirmation.

Ciclosporin + Antibacterials; Clindamycin

Two patients had a marked reduction in their serum ciclosporin levels when they took clindamycin.

Clinical evidence, mechanism, importance and management

A lung transplant patient receiving ciclosporin in a dose to maintain levels of 100 to 150 nanogram/mL required dose increases to achieve this level when clindamycin 600 mg three times daily was given. Initially the levels were almost halved by the addition of clindamycin. Ciclosporin was reduced to the original dose when the clindamycin was stopped.

In a second lung transplant patient, the use of clindamycin 600 mg three times daily necessitated ciclosporin dose increases from 325 mg daily to 1.1 g daily over 4 weeks to maintain serum levels of about 200 nanogram/mL. The reasons for the interaction are not understood, but the authors suggest close monitoring of ciclosporin levels to prevent underdosing if clindamycin is given; however, this seems exceptionally cautious as these two cases appear to be all that have been reported.

Ciclosporin + Antibacterials; Imipenem/Cilastatin

Several transplant patients with impaired renal function have experienced adverse CNS effects (including convulsions and tremors) while taking imipenem/cilastatin and ciclosporin. Imipenem/cilastatin may affect ciclosporin levels.

Clinical evidence, mechanism, importance and management

A woman taking ciclosporin following a kidney transplant developed a urinary-tract infection for which she was given imipenem/cilastatin 500 mg intravenously every 12 hours (dose adjusted for renal function). About 20 minutes after the second dose she became confused, disorientated, agitated, and developed motor aphasia and intense tremor. This was interpreted as being a combination of the adverse CNS effects of both drugs. The imipenem/cilastatin was not given again and the effects subsided over the next few days. However, it was noted that the ciclosporin blood levels rose over the next 4 days from about 400 to 1000 nanogram/mL.

Four transplant patients who were taking ciclosporin developed seizures when they were given imipenem/cilastatin 1 g daily, and a fifth patient developed myoclonia. These patients all had chronic renal impairment.

In contrast, imipenem/cilastatin 2 g daily for 4 weeks, given with ciprofloxacin, was effectively and successfully used in another patient taking ciclosporin after a heart transplant. This patient was switched to imipenem/cilastatin and ciprofloxacin after developing acute renal failure while receiving amikacin.

Reduced serum ciclosporin levels following the use of imipenem/cilastatin have been seen in rats.

It should be noted that focal tremors, myoclonus and convulsions are a known adverse effect of imipenem/cilastatin and are most likely to occur in patients with reduced renal function. However, the patients cited above received imipenem/cilastatin in doses adjusted for their renal function. The manufacturers of imipenem/cilastatin recommend that patients who develop focal tremors, myoclonus and convulsions while receiving the antibacterial should be started on an antiepileptic drug. If symptoms persist the dose should be reduced, or the drug withdrawn.

Ciclosporin + Antibacterials; Macrolides

Ciclosporin levels can be markedly raised by clarithromycin, erythromycin, josamycin, pristinamycin and possibly midecamycin. Rokitamycin and troleandomycin are predicted to interact similarly. Roxithromycin appears to interact minimally, while no interaction is normally seen with azithromycin, dirithromycin or spiramycin, although there are isolated reports of an interaction with azithromycin.

Clinical evidence

(a) Azithromycin

Eight healthy subjects were given ciclosporin 3.75 to 7.5 mg/kg alone and then after taking azithromycin 500 mg initially then 250 mg daily for 4 days. Azithromycin did not alter ciclosporin levels.1 Other studies have also found no evidence of a clinically significant interaction between ciclosporin and azithromycin in a total of 62 kidney transplant patients,2,4 but there are case reports describing a marked increase in ciclosporin levels in 2 patients attributed to azithromycin.5,6

(b) Clarithromycin

In a study in 8 healthy subjects, ciclosporin 3.75 to 7.5 mg/kg was given alone and after they took clarithromycin 250 mg every 12 hours for 7 days. The maximum ciclosporin levels were raised by 50% by the clarithromycin. In another study a mean 30% reduction in the dosage of ciclosporin was needed in 6 transplant patients also given clarithromycin.7 Clarithromycin 500 mg twice daily as part of a Helicobacter pylori eradication regimen caused a two- to threefold increase in ciclosporin levels in 27 kidney transplant patients.8,9 The ciclosporin levels in 4 renal transplant patients with stable renal function increased by approximately 72% when clarithromycin 250 mg twice daily for 6 days was added to treat gingival hyperplasia. Ciclosporin levels returned to baseline levels within 7 days of stopping clarithromycin. Only two patients required a ciclosporin dose reduction.10

Numerous case reports also describe this interaction: ciclosporin levels or AUC have been increased by two- to threefold,11-14 with changes being seen within 3 to 6 days of clarithromycin 250 or 500 mg twice daily being started.11,14 Another patient had a seven- to twelffold rise in serum ciclosporin levels and acute renal failure within 3 weeks of starting to take clarithromycin 1 g daily.15 Another case report in a heart transplant patient taking ciclosporin found that the addition of rifampicin to clarithromycin negated the increase in ciclosporin levels seen with clarithromycin alone, and the ciclosporin dose requirement with concurrent clarithromycin plus rifampicin was similar to that before clarithromycin or rifampicin were started.16

(c) Dirithromycin

Dirithromycin 500 mg daily for 14 days did not significantly affect the pharmacokinetics of a single 15-1 mg/kg oral dose of ciclosporin in 8 healthy subjects.17

(d) Erythromycin

A study in 9 transplant patients taking ciclosporin found that erythromycin increased the mean trough serum levels of 3 kidney transplant patients sevenfold, from 147 to 1125 nanograms/mL, and of 6 heart transplant patients four- to fivefold, from 185 to 815 nanograms/mL. Acute nephrotoxicity occurred in all 9 patients, and 7 showed mild to severe hepatotoxicity caused by the increased ciclosporin levels.18

Markedly raised ciclosporin blood levels and/or toxicity have been described in a number of other studies and case reports with erythromycin given orally or intravenously to about 50 other patients.19-34 The interaction has also been demonstrated in healthy subjects.33 Oral erythromycin may possibly have a greater effect than intravenous erythromycin.35,36 Erythromycin-related ototoxicity, possibly associated with the use of ciclosporin, has been reported in liver transplant patients.37

(e) Josamycin

A man with a renal transplant who was taking azathioprine, prednisone and ciclosporin 330 mg daily had a marked rise in his plasma ciclosporin levels from about 90 to 600 nanograms/mL when he took josamycin 2 g daily for 5 days. He responded in the same way when later rechallenged with josamycin. Another patient also reacted in the same way.38 Two- to fourfold rises in ciclosporin levels have been seen in 9 other patients given josamycin 2 to 3 g (50 mg/kg) daily.39,41 Another patient had a 40% rise in ciclosporin levels when given josamycin 500 mg twice daily.42

(f) Midecamycin

The steady-state ciclosporin blood levels of 10 kidney transplant patients were roughly doubled when they took midecamycin 800 mg twice daily.43 A 43-year-old kidney transplant patient taking ciclosporin, azathioprine and prednisone, began further treatment on day 27 after the transplant with midecamycin diacetate 600 mg twice daily and co-trimoxazole three times daily for pneumonia. By day 33 the concentration/dose ratio of the ciclosporin had doubled, and ciclosporin levels had reached 700 nanograms/mL, accompanied by a rise in serum creatinine levels. When the midecamycin was replaced by cefuroxime, the concentrations of both ciclosporin and creatinine fell to their former levels within 3 days.44 Ciclosporin levels in another kidney transplant patient taking ciclosporin 120 mg twice daily increased from 95 to 380 nanograms/mL 3 days after starting midecamycin 800 mg twice daily.45 Blood levels of ciclosporin in a kidney transplant patient also increased from 97 to 203 nanograms/mL 4 days after starting midecamycin diacetate 600 mg twice daily.46

(g) Pristinamycin

A kidney transplant patient had a tenfold increase in plasma ciclosporin levels from 30 to 290 nanograms/mL after taking pristinamycin 2 g daily for 8 days. Blood creatinine levels rose from 75 to 120 micromol/L. Another patient given pristinamycin 1.25 g had a rise in ciclosporin levels from 78 to 855 nanograms/mL after 6 days. Ciclosporin and creatinine levels fell to normal levels within 2 days of stopping both drugs.47 Pristinamycin 50 mg/kg daily raised the ciclosporin blood levels of 10 patients by 65% from 560 to 925 nanograms/mL. Ciclosporin levels fell when the pristinamycin was stopped.48 Within 5 days of starting to take pristinamycin 4 g daily the ciclosporin levels of another patient more than doubled. His serum creatinine levels also rose. Both fell back to baseline levels within 3 days of stopping the antibacterial.49

(h) Roxithromycin

Eight patients with heart transplants taking ciclosporin 8 mg/kg daily, prednisolone and azathioprine for at least one month, were given roxithromycin 150 mg twice daily for 11 days. A 37.5% rise in plasma ciclosporin levels occurred at the time the roxithromycin was given, and a 60% rise occurred 4 hours later. Ciclosporin levels fell again when the roxithromycin was stopped. A small (10%) increase in serum creatinine levels occurred. There was no evidence of a deterioration in renal function.50 The half-life of roxithromycin was found in one study to be doubled, from 17 to 34.4 hours, in patients with kidney transplants who were taking ciclosporin.51

(i) Spiramycin

The ciclosporin plasma levels of 6 heart transplant patients taking corticosteroids, azathioprine and ciclosporin remained unchanged when they were given spiramycin 3 MIU twice daily for 10 days.52 Similarly, no interaction was found between ciclosporin and spiramycin in other studies in patients with renal transplants.53-56

(j) Telithromycin

There appears to be no clinical reports of an interaction between ciclosporin and telithromycin. However, the manufacturers of telithromycin note that it is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and it may therefore increase ciclosporin levels, requiring dose adjustment.57

(k) Other macrolides

In vitro studies (see ‘Mechanism’ below) suggest that rokitamycin and troleandomycin interact with ciclosporin in the same way as erythromycin,58 but as yet there seems to be no direct clinical evidence of an interaction.

Mechanism

In vitro studies with human liver microsomes have found that clarithromycin, erythromycin, josamycin, rokitamycin, roxithromycin and trolean-
domycin (but not spiramycin) inhibit ciclosporin metabolism in the liver, which is catalysed by the cytochrome P450 isoenzyme CYP3A. This would be expected to result in raised ciclosporin levels. Telithromycin is also an inhibitor of CYP3A4 and may increase ciclosporin levels. Erythromycin and clarithromycin also possibly increase the absorption of ciclosporin from the gut by inhibiting intestinal wall metabolism.

Azithromycin is believed to be metabolised by routes independent of the cytochrome P450 enzyme system. Intravenous azithromycin was thought to change the ciclosporin dosage. The interaction between ciclosporin and erythromycin is well documented, well established and potentially serious. If concurrent use is thought appropriate, monitor the ciclosporin blood levels closely and reduce the dosage appropriately. A reduction of about 35% has been calculated to be necessary. The dosage should be increased again when the erythromycin is stopped. The effect of intravenous erythromycin is less than oral erythromycin so if the route of administration is changed, be alert for the need to change the ciclosporin dosage.

Information about the interactions with clarithromycin, josamycin, midecamycin and pristinamycin is much more limited, but they appear to behave like erythromycin. The same precautions should be taken. There seems to be no direct clinical information about telithromycin, trovafloxacin and roxithromycin but they would be expected to interact like erythromycin. Note that telomycin is usually a more potent inhibitor of CYP3A4 than erythromycin, so it may be expected to have a larger effect on ciclosporin levels.

Drithromycin and spiramycin normally appear not to interact and rosithromycin appears only to interact very minimally. Also bear in mind that roxithromycin serum levels may be increased.

Although most reports suggest that azithromycin does not interact, increased monitoring is recommended by some, because of the isolated reports of increased ciclosporin levels.

Importance and management

The interaction between ciclosporin and erythromycin is well documented, well established and potentially serious. If concurrent use is thought appropriate, monitor the ciclosporin blood levels closely and reduce the dosage appropriately. A reduction of about 35% has been calculated to be necessary. The dosage should be increased again when the erythromycin is stopped. The effect of intravenous erythromycin is less than oral erythromycin so if the route of administration is changed, be alert for the need to change the ciclosporin dosage.

Note that telomycin is usually a more potent inhibitor of CYP3A4 than erythromycin, so it may be expected to have a larger effect on ciclosporin levels.

Drithromycin and spiramycin normally appear not to interact and rosithromycin appears only to interact very minimally. Also bear in mind that roxithromycin serum levels may be increased.

Although most reports suggest that azithromycin does not interact, increased monitoring is recommended by some, because of the isolated reports of increased ciclosporin levels.

Three reports have described an increase in ciclosporin levels in patients given metronidazole.

Clinical evidence, mechanism, importance and management

The ciclosporin blood levels of a kidney transplant patient rose from 850 to 1930 nanograms/ml when metronidazole 2.25 g daily and cimetidine 800 mg thrice daily were added. When the metronidazole dosage was halved and the cimetidine stopped, because the levels of ciclosporin were still so high, the dose of ciclosporin was reduced to 1500 mg thrice daily.
Ciclosporin serum levels are normally unaffected by the use of ciprofloxacin, but increased serum levels and nephrotoxicity may occur in a small number of patients. There is also some evidence that the immunosuppressant effect of ciclosporin are reduced by ciprofloxacin. One study, and two case reports describe rises in ciclosporin levels in patients given norfloxacin, but another study found no change. Similar results have been found with levofloxacin. No significant interaction appears to occur between ciclosporin and enoxacin, ofloxacin, pefloxacin and trovafloxacin.

**Clinical evidence**

(a) Ciprofloxacin

A single-dose study in 10 healthy subjects found that after taking ciprofloxacin 500 mg twice daily for 7 days the pharmacokinetics of oral ciclosporin 5 mg/kg were unchanged.³ Five other studies confirm the lack of a pharmacokinetic interaction:

- kidney transplant patients taking ciprofloxacin 750 mg twice daily for 13 days;²
- kidney transplant patients taking ciprofloxacin 500 mg twice daily for 7 days;³
- bone marrow transplant patients given ciprofloxacin 500 mg twice daily for 4 days;⁴
- heart transplant patients given ciprofloxacin 250 to 500 mg for 7 to 140 days;⁵
- heart transplant patients given ciprofloxacin 800 mg to 1.5 g daily.⁶

There were no changes in serum ciclosporin levels or evidence of nephrotoxicity.

In contrast, a handful of cases of nephrotoxicity have been reported, with three cases of increased ciclosporin levels.² ³ A heart transplant patient developed acute renal failure within 4 days of being given ciprofloxacin 750 mg every 8 hours.⁷ Another patient who had undergone a kidney transplant developed reversible nephrotoxicity.⁸ Decreased renal function in a heart-lung transplant patient has been described in another report.² This patient and another also had increased ciclosporin blood levels when given ciprofloxacin 500 mg three times daily.⁹ Acute interstitial nephritis in a cardiac transplant patient has also been reported.¹⁰ ¹¹ A patient taking ciclosporin for red cell aplasia had an increase in ciclosporin levels from 120 nanograms/mL to 297 nanograms/mL, requiring a dose reduction from 250 mg to 200 mg daily, when intravenous ciprofloxacin 200 mg two or three times daily (exact dose unclear) was started. A ciclosporin dose increase back to 250 mg daily was required when the ciprofloxacin course was finished.¹²

A case-control study in 42 kidney transplant patients suggested that the proportion of cases experiencing at least one episode of biopsy-proven rejection within 1 to 3 months of receiving a transplant were significantly greater in those who had taken ciprofloxacin (45%) than in those who had not (19%). There was also a marked increase in the incidence of rejection associated with ciprofloxacin use (29%) compared with the controls (2%).¹³

(b) Enoxacin

Enoxacin 400 mg twice daily for 5 days had little effect on either blood or plasma levels of single doses of ciclosporin in 10 healthy subjects.¹⁴

(c) Levofloxacin

A single-dose study in 12 healthy subjects found that levofloxacin 500 mg had no effect on the pharmacokinetics of ciclosporin oral solution (Sandimmune).¹⁵ A case report in a patient taking oral ciclosporin 250 mg daily (as the emulsion formulation) found no change in ciclosporin levels.
Ciclosporin + Antibacterials; Quinupristin/Dalfopristin

A study found that quinupristin/dalfopristin increased the AUC and maximum blood levels of ciclosporin. In an isolated case quinupristin/dalfopristin was found to increase ciclosporin levels by about threefold.

Clinical evidence, mechanism, importance and management

In a study in 24 subjects given a single 300-mg dose of ciclosporin, taken 1.5 hours before the fourth of 9 infusions of quinupristin/dalfopristin (7.5 mg/kg given at intervals of 8 hours) the AUC and maximum blood levels of ciclosporin were increased by 63% and 30%, respectively, and ciclosporin clearance was decreased by 34%.13

A kidney transplant patient taking ciclosporin with trough blood levels of between 80 and 105 nanograms/mL developed a vancomycin-resistant enterococcal infection. After a series of antibacterials had failed to clear the infection she was given intravenous quinupristin/dalfopristin 300 mg every 8 hours. After 3 days of treatment her ciclosporin trough level rose to almost 300 nanograms/mL. A ciclosporin dose reduction from 75 to 50 mg twice daily returned her levels to baseline. However, 2 days after the antibacterials were discontinued she was found to have a trough ciclosporin level of only 34 nanograms/mL. She was subsequently stabilised on her original dose of ciclosporin.2

Information is limited. However, the manufacturers state that quinupristin/dalfopristin has been shown in vitro to inhibit the cytochrome P450 isozyme CYP3A4 and advise that ciclosporin levels are closely monitored during concurrent use.4,5 Ciclosporin dose reductions may be necessary.

Clinical evidence is, however, lacking.4

Ciclosporin + Antibiotics; Sulfonamides and/or Trimethoprim

In isolated cases, sulfadiazine given orally or sulfadimidine given intravenously with trimethoprim have caused a reduction in se-
rum ciclosporin levels. Sulfamethoxadiazine possibly caused a minor reduction in ciclosporin levels in one case. Although co-trimoxazole increases serum creatinine levels in kidney transplant patients taking ciclosporin, it normally appears to be safe and effective.

Clinical evidence

(a) Co-trimoxazole

A large-scale study in 132 kidney transplant patients taking ciclosporin encompassing 33 876 patient days found that co-trimoxazole was effective and well tolerated. Ciclosporin pharmacokinetics remained unchanged. A 15% rise in serum ciclosporin levels occurred, which reversed when the co-trimoxazole was stopped. This rise was not interpreted as a sign of nephrotoxicity but appeared to be due to inhibition of the tubular excretion of creatinine by the co-trimoxazole. Other reports describe a few patients given ciclosporin with co-trimoxazole who developed rises in creatinine levels (interpreted as evidence of nephrotoxicity), interstitial nephritis, granulocytopenia and thrombocytopenia. Apparent nephrotoxicity has also been seen with trimethoprim and ciclosporin.

(b) Sulfadiazine or Sulfamethoxadiazine

Three heart transplant patients treated for toxoplasmosis had a reduction in their ciclosporin levels when they were given sulfadiazine 4 to 6 g daily. Their dosage-to-level ciclosporin ratios rose by 58%, 82%, and 29%, respectively. Two had previously been given sulfamethoxadiazine and this had caused a minor reduction in ciclosporin levels in one of these patients.

(c) Sulfadimidine with trimethoprim

A heart transplant patient taking ciclosporin and prednisolone developed undetectable serum ciclosporin levels 7 days after starting intravenous sulfadimidine 2 g four times daily and trimethoprim 300 to 500 mg twice daily. Doubling the ciclosporin dosage had little effect and evidence of transplant rejection was seen. Within 10 days of starting to take the antibacterials orally instead of intravenously the serum ciclosporin levels returned to roughly their former levels and the rejection problems disappeared.

Another report by some of the same authors describes a similar marked fall in serum ciclosporin levels in 5 heart transplant patients (one of them the same as the report already cited) when given sulfadimidine and trimethoprim intravenously.

Mechanism

Uncertain. Co-trimoxazole and trimethoprim can raise serum creatinine levels, possibly due to inhibition of creatinine secretion by the kidney tubules. The reduction in serum ciclosporin levels apparently caused by the sulfonamides is not understood.

Importance and management

The documentation is only moderate, and these interactions are not firmly established. Be aware that intravenous sulfadimidine with trimethoprim may cause a marked reduction in serum ciclosporin levels with accompanying inadequate immunosuppression. Sulfadiazine may also reduce ciclosporin levels. The evidence suggests that oral sulfadimidine with trimethoprim, sulfamethoxadiazine, and co-trimoxazole do not interact adversely and are normally safe and effective, although toxicity can apparently occur in a small number of patients. Until more information is available it would be prudent to keep a close check on ciclosporin levels if any sulphonamide is added to established treatment with ciclosporin. The manufacturer recommends close monitoring of renal function when ciclosporin is used with co-trimoxazole.

Ciclosporin + Antidiabetics

Some preliminary evidence suggests that glibenclamide (glyburide) can raise serum ciclosporin levels to a moderate extent. Glibizide caused about a twofold increase in ciclosporin levels in 2 patients, but no change was noted in a study in 11 patients. A single-dose study found ciclosporin significantly increased repaglinide bioavailability. However a study in kidney transplant patients found no consistent increase in blood glucose-lowering effects in patients taking both drugs. Pioglitazone and rosiglitazone are predicted to not interact with ciclosporin.

Clinical evidence, mechanism, importance and management

(a) Pioglitazone

In vitro and human studies have shown that pioglitazone does not affect cytochrome P450 isoenzymes, including CYP3A4. Therefore no interaction would be expected with ciclosporin, which is mainly metabolised by CYP3A4.

(b) Repaglinide

A placebo-controlled study in 12 healthy subjects given ciclosporin 100 mg twice daily for two doses, with a single 250-microgram dose of repaglinide on day 2, found that ciclosporin significantly increased the maximum plasma level and AUC of repaglinide by 175% and 244%, respectively. It was suggested that ciclosporin inhibited the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of repaglinide, as well as affecting OAT-mediated liver uptake of repaglinide.

No significant changes were seen in ciclosporin, sirolimus or tacrolimus blood levels and no dosage changes were required in a study in kidney transplant patients taking repaglinide (18 as monotherapy and 5 combined with either metformin or rosiglitazone). The effects of ciclosporin on repaglinide metabolism were not investigated in this study, although concurrent use was found to be effective. Commenting further, the authors noted that they were unable to demonstrate a consistent, increased blood glucose-lowering effect with concurrent use of repaglinide and ciclosporin, although other authors, citing the study above, noted that ciclosporin may markedly increase plasma repaglinide levels and enhance its blood glucose-lowering effects.

Although the clinical study found no serious adverse effects with concurrent ciclosporin and repaglinide, the situation is not clear. The large increases in repaglinide levels seen were significant, although they were found in a single-dose study in healthy subjects taking no other potentially interacting medication. The possibility of increased hypoglycaemia should be borne in mind if ciclosporin and repaglinide are used concurrently. Patients should be advised to report any adverse effects, particularly an increase in the number of hypoglycaemic events.

(c) Sulphonylureas

A review of 6 post-transplant diabetic patients taking ciclosporin found that their steady-state plasma ciclosporin levels rose by 57% when they were given glibenclamide (glyburide). Hepatic and renal function were unchanged. The reason for this reaction is not known, but it is suggested that glibenclamide possibly inhibits the cytochrome P450 isoenzyme CYP3A4, the major isoenzyme involved in the metabolism of ciclosporin.
resulting in a reduction in its clearance.6

Ciclosporin blood levels in 2 patients were more than doubled, and they needed reductions of 20 to 30% in their ciclosporin dosage when they were also given glipizide 10 mg daily.7 In contrast, a study in 11 post-transplant diabetic patients found no significant alterations in ciclosporin pharmacokinetics when glipizide was given.8 This interaction is unconfirmed and of uncertain clinical significance. However, note that one of the rare adverse effects of ciclosporin is hyperglycaemia. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment. Information about other sulphonylureas appears not to be available.

Ciclosporin + Antiepileptics

Serum ciclosporin levels are markedly reduced by carbamazepine, phenobarbital, or phenytoin. The dosage of ciclosporin may need to be increased two- to fourfold to maintain adequate immunosuppression. Oxcarbazepine may cause a small decrease in ciclosporin levels. Valproate appears not to affect ciclosporin levels but two case reports suggest that it may damage renal grafts and cause hepatotoxicity in patients taking ciclosporin.

Clinical evidence

(a) Carbamazepine

The ciclosporin serum levels of a kidney transplant patient fell from 346 to 64 nanograms/mL within 3 days of starting to take carbamazepine 200 mg three times daily. A week later serum levels were down to 37 nanograms/mL. They rose again when the carbamazepine was stopped but fell once more when it was restarted. The ciclosporin dosage was increased to keep the levels within the therapeutic range.

The mean average steady-state blood levels of ciclosporin (adjusted for dose) in a group of 3 children with kidney transplants taking carbamazepine were 50% lower than in 3 other matched patients not taking carbamazepine.2 Four other individual patients have also shown this interaction.3,4 One needed her ciclosporin dosage to be doubled in order to maintain adequate blood levels while taking carbamazepine 800 mg daily.5 When the carbamazepine was replaced by sodium valproate in 3 patients, the ciclosporin dosages could be reduced to their previous level.6

(b) Oxcarbazepine

A kidney transplant patient taking ciclosporin 270 mg daily and valproate, gabapentin, prednisone, doxepin, allopurinol, levotheroxine and pravastatin was also given oxcarbazepine. Fourteen days later, with the dose of oxcarbazepine at 750 mg daily, the ciclosporin trough level fell below 100 nanograms/mL and after a further 2 days was 87 nanograms/mL. The ciclosporin dose was increased to 290 mg daily and the oxcarbazepine dose reduced to 600 mg daily. Ciclosporin levels then remained stable above 100 nanograms/mL and seizure frequency was reduced by 95%.6

(c) Phenobarbital

A 4-year-old child with a bone marrow transplant who was receiving phenobarbital 50 mg twice daily had serum ciclosporin levels of less than 60 nanograms/mL even after raising the ciclosporin dosage to 18 mg/kg daily. When the phenobarbital dosage was reduced to 25% of the original dose the trough serum ciclosporin levels rose to 205 nanograms/mL.7 Another report describes an increase in ciclosporin levels from 512 to 810 nanograms/mL after phenytoin and phenobarbital were replaced by sodium valproate.8

The report of severe gingival overgrowth in a kidney transplant patient was attributed to the additive adverse effects of ciclosporin and phenytoin. Ciclosporin was replaced by tacrolimus, which may have fewer oral adverse effects, and almost complete reversal of gingival overgrowth was achieved within 6 months.20

Mechanism

It is thought that phenytoin,14,15 carbamazepine1,2 and phenobarbital7,11 increase the metabolism of the ciclosporin by the liver (hepatic cytochrome P450 oxygenase system) thereby decreasing the serum levels. Oxcarbazepine produced only small reductions in ciclosporin levels, and the effect is probably due to weak induction of the cytochrome P450 isoenzyme CYP3A.8 Pheynytoin also possibly reduces the absorption of the ciclosporin.23

Importance and management

None of these interactions is extensively documented but all appear to be established and of clinical importance. Serum ciclosporin levels should be well monitored if carbamazepine, phenobarbital or phenytoin are added and the ciclosporin dosage increased appropriately. Primidone is metabolised to phenobarbital by the liver, and therefore would be expected to reduce ciclosporin levels. Information about oxcarbazepine is very limited but small reductions in its dose, together with an increase in ciclosporin dose, may be adequate to control any interaction. However, more study is required before oxcarbazepine can be recommended as a suitable alternative.6 The effects of the interaction may persist for a week or more after the anticonvulsant is withdrawn. Sodium valproate seems not to alter ciclosporin levels, but the case reports of nephritis and hepatotoxicity suggest some caution is warranted.
Ciclosporin + Antimycobacterials

Ciclosporin serum levels are markedly reduced by rifampicin and transplant rejection can rapidly develop. Rifampicyn seems to interact similarly, but limited evidence suggests that rifabutin interacts to a lesser extent. Ethambutol and isoniazid do not generally appear to interact with ciclosporin although case reports have described alterations in ciclosporin levels.

Clinical evidence

(a) Rifabutin

The clearance of ciclosporin in a patient with a kidney transplant doubled when isoniazid, ethambutol, pyridoxine and rifampicin 600 mg daily were given. When these drugs were replaced by rifabutin 150 mg and clofazimine 100 mg daily, the ciclosporin clearance fell to about its former levels, but after about 3 weeks the clearance was about 20% greater than before the antimycobacterial drugs were given.1

(b) Rifampicin (Rifampin)

A study in 39 kidney transplant patients taking ciclosporin at a mean dose of 158 mg daily found that the ciclosporin dose needed to be increased by between 150 to 525 mg daily (an average dose of 469 mg daily) when rifampicin 450 to 600 mg daily was taken as part of a regimen for tuberculous therapy. In ciclosporin and rifampicin and 16 patients had kidney graft failure and needed to go back on haemodialysis because of this interaction.2

A heart transplant patient taking ciclosporin started taking rifampicin 600 mg daily with amphotericin B for the treatment of an Aspergillus fumigatus infection. Within 11 days her serum ciclosporin levels had fallen from 473 to less than 31 nanograms/mL and severe acute graft rejection occurred. The dosage of ciclosporin was increased stepwise and the levels climbed to a plateau before suddenly falling again. The dosage had to be increased to more than 30 mg/kg daily to achieve serum levels in the range 100 to 300 nanograms/mL.3

A considerable number of other reports about individual patients, both adult and paediatric, confirm that a very marked fall in serum ciclosporin levels occurs, often to undetectable levels, accompanied by transplantation rejection in many instances, if rifampicin is given either intravenously or orally without raising the ciclosporin dosage.4-28 Ciclosporin levels become toxic within 2 weeks of stopping the rifampicin unless the previously adjusted ciclosporin dosage is reduced.4-6

Three patients needed increases in the dosage of ciclosporin when given rifampicin and erythromycin, although the latter normally reduces ciclosporin requirements.5,29,30 Another patient whose ciclosporin levels had been raised by ‘clarithromycin’, (p.1016), had a fall in their levels when rifampicin was added.31

Mechanism

Rifampicyn stimulates the metabolism of the ciclosporin by the cytochrome P450 isoenzyme CYP3A36 resulting in a marked increase in ciclosporin clearance. In addition, rifampicin decreases ciclosporin absorption by inducing its metabolism by the gut wall,27 thus producing a significant fall in ciclosporin levels. If rifampicin is given with erythromycin or clarithromycin, the enzyme inhibitory effects of the macrolides are superimposed on the more potent enzyme-inducing effects of rifampicin. Rifabutin has some enzyme-inducing properties but the extent is quite small compared with rifampicin, and the onset may be delayed.38

Importance and management

The interaction between ciclosporin and rifampicyn is very well documented, well established and clinically important, as transplant rejection may occur unless the ciclosporin dosage is markedly increased. In one study 27% of patients taking rifampicin lost grafts due to rejection, and this was directly attributed to the interaction.22 The interaction develops within a few days (within a single day in one case)20. The monitor the effects of concurrent use and increase the ciclosporin dosage appropriately. Three- to fivefold dosage increases sometimes frequency-increases from two to three times daily) have proved to be effective, with daily monitoring. Remember also to reduce the ciclosporin dosage when rifampicin is stopped to reduce the risk of ciclosporin toxicity. The authors of one large study concluded that it is better to avoid rifampicyn in patients taking ciclosporin and to use other antimycobacterials instead.22 They found that the use of three antitubercular drugs (not including rifampicyn) for at least 9 months reduced mortality. Other reports similarly found that regimens without rifampicyn were suitable for the treatment of tuberculosis in transplant patients.23,34,35

Another suggested alternative is to replace the ciclosporin with another non-interacting immunosuppressant, such as azathioprine and low-dose prednisolone for immunosuppression, if rifampicyn is needed.39,40 Other rifamycins may also be an option; limited evidence suggests that rifabutin interacts minimally. However, the manufacturer and the CSM do not normally interact with ciclosporin or clarithromycin, the enzyme inhibitory effects of the macrolides are superimposed on the more potent enzyme-inducing effects of rifampicyn. Rifabutin has some enzyme-inducing properties but the extent is quite small compared with rifampicyn, and the onset may be delayed.38

Rifampicyn is frequently used to irrigate a wound to reduce the risk of infection. Other anti-tuberculars

Isoniazid2,22,23 and ethambutol22,23 do not normally interact with ciclosporin. However, there is one case report describing a patient who had a gradual rise in serum ciclosporin levels when isoniazid and ethambutol were stopped.4,6 another which attributed a marked rise in ciclosporin levels to the use of isoniazid.4,14 There have been several other case reports of successful treatment of tuberculosis in heart and kidney transplant patients using isoniazid, ethambutol, pyrazinamide with ofloxacin, or streptomycin.34,35 Consider also ‘pyrazinamid’, (p.1044), and ‘quinolones’, (p.1018).
Ciclosporin + Azoles

The evidence suggests that all the azole antifungals can raise ciclosporin levels to a greater or lesser degree. Ketoconazole may cause five- to tenfold rises, while itraconazole, fluconazole and voriconazole may cause two- to threefold rises. A case report suggests that intravenous miconazole interacts similarly and in theory, miconazole oral gel may also interact. Posaconazole may also modestly raise ciclosporin levels. Rhabdomyolysis has been reported with the combination of ciclosporin and itraconazole, but four of these cases were complicated by the presence of statins.

Clinical evidence

(a) Fluconazole

Fluconazole 200 mg daily for 14 days roughly doubled the ciclosporin trough blood levels of 8 kidney transplant patients, from 27 to 58 nanograms/mL. The AUC increased 1.8-fold but serum creatinine levels were unchanged.1,2 Other reports describe two- to threefold rises in ciclosporin blood levels in kidney transplant recipients within 6 to 11 days of starting treatment with fluconazole 100 to 200 mg daily.3–8 One patient developed nephrotoxicity, which resolved when the dosages of both drugs were reduced.9

In contrast, some patients have had little or no changes in serum ciclosporin or creatinine levels when fluconazole was given.10–13 This may have been because the interaction is dose-dependent.14,15 One study found a lack of interaction in females and African-American patients, suggesting that gender and ethnicity may also be factors.17 Another study found that there was only a 20% increase in ciclosporin levels when intravenous ciclosporin was given with high-dose intravenous fluconazole, which was not considered clinically relevant.18

An in vitro study suggests that the activity of fluconazole against C. albicans may be enhanced by ciclosporin.19

(b) Itraconazole

In 4 heart-lung, 2 heart and 1 lung transplant patient an average 56% reduction (range 33 to 84%) in the ciclosporin dosages were needed when itraconazole (dosage not stated) was given. Serum creatinine levels rose temporarily until the ciclosporin dosage had been readjusted.20 Two- to threefold rises in ciclosporin levels were seen in another 2 patients given itraconazole 200 mg daily,21,22 and in one case the raised levels persisted for more than 4 weeks after the itraconazole was stopped.22 Intravenous itraconazole 200 mg twice daily for 2 days then 200 mg daily caused a twofold increase in the levels of intravenous ciclosporin in 2 patients.23 Other case reports and studies suggest that dosage reductions of about 50 to 80% (where stated) were needed when patients taking ciclosporin were given itraconazole.24,25 Enhanced itraconazole absorption in the presence of a carbonated drink that increased stomach acidity was found to allow decreases in ciclosporin dose and increases in its dose interval21,22,24,26

These reports contrast with another describing 14 bone marrow transplant patients taking ciclosporin. Those given itraconazole 100 mg twice daily had significantly more changes in ciclosporin or creatinine serum levels.27 Another patient required only a 10% reduction in ciclosporin dose when given itraconazole 400 mg daily for 40 days.8

Rhabdomyolysis has been reported in 3 lung transplant patients24,29 and 2 heart transplant patients30–31 when itraconazole was used in combination with ciclosporin. However, in three of these cases the concurrent use of simvastatin and in one case concurrent simvastatin and gemfibrozil would have also been factors,28,29,31 as both ciclosporin and itraconazole can increase simvastatin levels (see ‘Statins + Ciclosporin’, p.1097, and ‘Statins + Azoles’, p.1093).

(c) Ketoconazole

Ketoconazole 200 mg daily caused a marked and rapid rise in the ciclosporin blood levels of 36 renal transplant patients. On the basis of experience with previous patients, the ciclosporin dosage was reduced by 70% when ketoconazole was started, and after a year the dosage reduction was only 50% (from 420 mg to 66 mg daily). Minimal nephrotoxicity was seen.22–24 A case report in children with nephrotic syndrome found the addition of ketoconazole allowed a ciclosporin dose reduction of approximately 37%. They also found that those in the ketoconazole treated group (153 patients) had a lower frequency of renal impairment, were more likely to be able to stop taking steroids and had a better chance of staying in remission than those not given ketoconazole (54 patients).35

Other reports28–30,32,33 describe essentially similar rises in ciclosporin levels during the use of ketoconazole. The effects of ketoconazole on ciclosporin were found to be slightly increased (from 80 to 85%) when diltiazem was also given.31 Ketoconazole 2% cream has been found not to interact with ciclosporin 1 mg/kg daily in the treatment of contact allergic dermatitis and the ciclosporin dosage does not need to be reduced.52 Impaired glucose tolerance has been attributed to the use of ketoconazole and ciclosporin in one patient.31

(d) Miconazole

A single case report describes a rise of about 65% in ciclosporin serum levels within 3 days of intravenous miconazole 1 g every 8 hours being started. Ciclosporin levels rose again during subsequent treatment with miconazole.34

(e) Posaconazole

Posaconazole 200 mg daily was given to 4 heart transplant patients receiving stable doses of ciclosporin. Three of the 4 required dose reductions of between about 15 and 27% to maintain ciclosporin levels.55 Although these dosage adjustments were considered low, they do indicate that posaconazole interacts in a similar manner to the other azoles. The manufacturer also reports cases of ciclosporin toxicity which resulted in significant adverse effects, including nephrotoxicity and one fatal case of leukoencephalopathy.56
In a placebo-controlled, crossover study, 14 kidney transplant patients receiving stable doses of ciclosporin were given voriconazole 200 mg every 12 hours for 15 doses. Of the 14 patients, 7 discontinued treatment due to the voriconazole phase dose to adverse effects, 4 due to raised ciclosporin levels, one due to raised liver function, one due to asthe- nia, dyspnoea and oedema, and one due to an underlying condition unrelated to the voriconazole. In the remaining 7 patients voriconazole caused 1.7-fold increases in the ciclosporin AUC.57 Ciclosporin levels were significantly reduced in a bone marrow transplant patient, from a range of 150 to 184 nanograms/mL to 56 to 111 nanograms/mL, when prophylactic voriconazole was stopped due to abnormal liver function tests. The levels returned to range when the voriconazole was restarted.58

Mechanism

In vitro studies show that these azole antifungals inhibit the metabolism of ciclosporin by human liver microsomal enzymes, ketoconazole being the most potent.59,60 As a result ciclosporin blood levels rise. Fluconazole and ketoconazole also appear to inhibit the metabolism of ciclosporin by the gut wall.18,46

Importance and management

The interaction between ciclosporin and ketoconazole is very well established and clinically important. Ciclosporin blood levels rise rapidly and sharply, but they can be controlled by reducing the ciclosporin dosage by about 70% to 80%.25,32,38,50 thereby preventing kidney damage. A ciclosporin dosage reduction of 68 to 89% was required over a 13-month period in one study, with no adverse changes in immunosuppressive activity, resulting in a total cost saving of about 65%, partially offset because of the need for more frequent patient follow-up and the cost of the ketoconazole.14,23 Other studies have suggested that this interaction can be exploited to make cost savings.47,48,50 Reviews of the pros and cons of concurrent use have been published.18,61 Ketoconazole may possibly have a kidney-protective effect.23,25 A study in renal transplant patients suggested that variability in absorption and in the response to metabolic inhibition by ketoconazole made the ciclosporin blood level response difficult to predict and monitor.62 There are also other confounding factors. For example, an patient who was given ketoconazole to increase ciclosporin levels was subsequently given famotidine. The famotidine raised gastric pH, which resulted in a reduction in the ketoconazole absorption, and the ciclosporin levels consequently fell.63

Information about ciclosporin with fluconazole or itraconazole is less extensive, but concurrent use should be closely monitored, being alert for the need to reduce the ciclosporin dosage, in some cases by up to 50% or more, although some patients may demonstrate no significant changes at all. There is also some evidence that in the case of fluconazole, the interaction may possibly depend on its dosage,14 gender and ethnicity,17 and the route of ciclosporin administration.18

The interaction between intravenous miconazole and ciclosporin may be potentially serious and of clinical importance. There is no evidence of an interaction with other forms of miconazole. However, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur for interactions with other medications. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of ciclosporin if given concurrently.64 An interaction with intravaginal miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.65

The manufacturers of voriconazole suggest that the dose of ciclosporin should be halved when initiating voriconazole, and that ciclosporin levels should be carefully monitored during voriconazole treatment. It is important that the ciclosporin dose is increased again as necessary if voriconazole is withdrawn.38,66,67

The dose of ciclosporin should be reduced by about 25% when posaconz- azole is started, with careful monitoring of ciclosporin levels and dose adjustment as needed.55,56

Additional caution is required where ciclosporin and azoles are used in patients taking statins, and either ciclosporin dose reduction,24 replace-
Clinical evidence, mechanism, importance and management

A study in 21 kidney transplant patients found that when atenolol was gradually replaced by carvedilol in a stepwise manner, starting with carvedilol 6.25 mg daily, gradually increasing to 50 mg daily, the ciclosporin dosage had to be gradually reduced. At 90 days the daily ciclosporin dosage had been reduced by 20% (from 3.7 to 3 mg/kg) to maintain levels within the therapeutic range but considerable inter-individual variations were seen. A retrospective study in 12 heart transplant patients found that carvedilol increased the ciclosporin level in 10 patients from a mean of 257 nanograms/mL to 380 nanograms/mL. This required a mean dose reduction of 31 mg daily (10%). In the same study, 20 patients taking metoprolol did require any significant ciclosporin dosage alterations. A study in 30 renal transplant patients found no change in the ciclosporin levels of those taking atenolol 25 to 100 mg daily.

The reason for the interaction with carvedilol is not understood. The manufacturers of carvedilol recommend close monitoring of ciclosporin levels with appropriate dose adjustment when carvedilol is added. Information about other beta blockers seems to be lacking, although metoprolol and atenolol do not appear to interact.

**Ciclosporin + Beta blockers**

Two case reports show that bifendate can cause a gradual fall in the serum levels of ciclosporin.

**Clinical evidence, mechanism, importance and management**

Two kidney transplant patients were successfully treated with ciclosporin and prednisolone for 30 and 36 months, respectively. When they were given bifendate 75 mg daily for the treatment of chronic hepatitis, both of them had a gradual fall in their trough serum ciclosporin levels. The ciclosporin levels of the first patient fell from 97.7 to 78 nanograms/mL at 4 weeks and to 49 nanograms/mL at 6 weeks. The other patient had a fall from 127.5 to 70.5 nanograms/mL at 8 weeks and to 45 nanograms/mL at 16 weeks. The reasons are not understood. The ciclosporin dosages remained unchanged throughout, and despite the low serum levels that occurred, no graft rejection was seen. When the bifendate was stopped, the ciclosporin levels gradually climbed again, at about the same rate as their decline, to about their former levels. There would seem to be no clear reason for avoiding concurrent use but it would be prudent to monitor the outcome, being alert for the need to increase the ciclosporin dosage.

**Ciclosporin + Bifendate**

Two case reports show that bifendate can cause a gradual fall in the serum levels of ciclosporin.

**Clinical evidence, mechanism, importance and management**

Two kidney transplant patients were successfully treated with ciclosporin and prednisolone for 30 and 36 months, respectively. When they were given bifendate 75 mg daily for the treatment of chronic hepatitis, both of them had a gradual fall in their trough serum ciclosporin levels. The ciclosporin levels of the first patient fell from 97.7 to 78 nanograms/mL at 4 weeks and to 49 nanograms/mL at 6 weeks. The other patient had a fall from 127.5 to 70.5 nanograms/mL at 8 weeks and to 45 nanograms/mL at 16 weeks. The reasons are not understood. The ciclosporin dosages remained unchanged throughout, and despite the low serum levels that occurred, no graft rejection was seen. When the bifendate was stopped, the ciclosporin levels gradually climbed again, at about the same rate as their decline, to about their former levels. There would seem to be no clear reason for avoiding concurrent use but it would be prudent to monitor the outcome, being alert for the need to increase the ciclosporin dosage.

**Ciclosporin + Bile acids or Ursodeoxycholic acid (Ursodiol)**

Ursodeoxycholic acid unpredictably increases the absorption and raises the serum levels of ciclosporin in some but not all patients. Bile acids (cholic/dihydrocholic acids) appear not to interact with ciclosporin.

**Benzbromarone does not interact adversely with ciclosporin.**

Clinical evidence, mechanism, importance and management

Twenty-five kidney transplant patients taking ciclosporin were given benzbromarone 100 mg daily to treat hyperuricaemia. The plasma uric acid levels decreased from 579 to 313 micromol/L and the 24-hour urinary uric acid secretion rose from 2082 to 3233 micromol after 4 weeks of treatment. The plasma uric acid levels normalised in 21 of the patients who had creatinine clearances of over 25 mL/minute. No significant adverse effects developed and the ciclosporin serum levels remained unchanged. The authors of the report emphasise the advantages of benzbromarone over allopurinol because of its efficacy, lack of significant adverse effects and because, unlike allopurinol, it does not interact with azathioprine, which often raises ciclosporin treatment.1

Clinical evidence

(a) Bile acids (Cholic/dehydrocholic acids)

Eleven healthy subjects were given a single oral dose of ciclosporin on three occasions: while fasting, with breakfast, and with breakfast plus bile acid tablets (cholic acid 400 mg, dehydrocholic acid 100 mg). The mean ciclosporin AUCs were 7283, 7453 and 9078 nanograms/mL, respectively, indicating that the bile acids increased the absorption of the ciclosporin by 22%. However, a related study in 19 transplant patients found that their 12-hour trough ciclosporin serum levels were unchanged by the concurrent use of this dosage of bile acids over an 8-day period.1

(b) Ursodeoxycholic acid

A patient who had previously had his entire ileum removed and about 1 metre of the residual jejunum Anastomosed to the transverse colon, had a heart transplant. It was possible to reduce his ciclosporin dosage from 1.6 to 1.2 g daily when he started taking ursodeoxycholic acid 1 to 2 g daily. However, when the ursodeoxycholic acid was stopped, his ciclosporin serum levels became subtherapeutic and severe acute rejection developed. The ciclosporin levels rose once again when ursodeoxycholic acid was restarted, and the ciclosporin AUC was increased by more than threefold.2

The trough serum ciclosporin levels of a patient with chronic active hepatitis C increased from 150 to 500 nanograms/mL when he was given ursodeoxycholic acid, and it was necessary to halve his daily ciclosporin dosage to keep the ciclosporin levels at 150 nanograms/mL.3

In contrast, a study in 7 liver transplant patients found no statistically significant changes in mean ciclosporin levels when a single 600-mg dose of ursodeoxycholic acid was given at the same time as the ciclosporin.4 Yet another study in 12 liver transplant patients, 6 of whom were cholestatic, found that ciclosporin was absorbed more rapidly after a single dose of ursodeoxycholic acid in 8 patients, but, although 7 patients had some rise in their AUC, the mean 24-hour AUC was not significantly changed. There was no consistent improvement in ciclosporin pharmacokinetics in the cholestatic patients.5

Mechanism

When an interaction occurs it is thought to do so because the ursodeoxycholic acid improves micellation of the oil-containing oral ciclosporin formulation so that its absorption is increased.2

Importance and management

Information is limited but bile acids do not apparently interact with ciclosporin, while the interaction with ursodeoxycholic acid appears to be uncertain and unpredictable. It would therefore be prudent to monitor the effects of adding or stopping ursodeoxycholic acid in any patient taking ciclosporin, being alert for the need to adjust the ciclosporin dosage. More study is needed.

Ciclosporin + Bupropion

An isolated case describes a large fall in ciclosporin levels in a 10-year-old boy given bupropion.

Clinical evidence, mechanism, importance and management

A 10-year-old boy, who had received a heart transplant 6 years previously started taking bupropion 75 mg twice daily in addition to his usual transplant medication, which included ciclosporin. After taking bupropion for 22 days, his ciclosporin level was found to be only 39 nanograms/mL. The last level taken before bupropion treatment had been 197 nanograms/mL. Despite an increase in his ciclosporin dose from 420 to 500 mg daily, the ciclosporin levels fell further, to 27 nanograms/mL. The ciclosporin dosage was then increased to 550 mg daily and bupropion was stopped.1

The reason for this probable interaction is unclear, although an interaction via the cytochrome P450 isoenzyme CYP3A4 is a possibility. This appears to be the only reported case of an interaction between ciclosporin and bupropion, and its general importance is unknown.

Ciclosporin + Busulfan and Cyclophosphamide

The development of seizures in patients taking ciclosporin after bone marrow transplants has been attributed to previous treatment with busulfan and cyclophosphamide. Cyclophosphamide was found to reduce ciclosporin levels.

Clinical evidence, mechanism, importance and management

A study in stem cell transplant patients found that the ciclosporin levels in 47 patients whose pre-transplant conditioning regimens contained cyclophosphamide were reduced to a mean of 149.7 nanograms/mL, compared with a mean of 217.3 nanograms/mL in 56 patients whose regimens did not contain cyclophosphamide.1 Five of 182 patients receiving allogenic bone marrow transplants developed seizures within 22 to 61 days of starting ciclosporin and methylprednisolone. All of them had received busulfan 16 mg/kg and cyclophosphamide 120 mg/kg as preparative therapy without radiation. Magnetic resonance imaging found brain abnormalities, which resolved a few days after the ciclosporin was withdrawn.2 The reasons for the effects on ciclosporin levels and the increase in adverse effects seen are not understood, nor is the association between the use of the preparative drugs, the ciclosporin, and the development of the seizure clearly

dition, bosentan had no effect on the ciclosporin-induced rise in blood pressure, and headache, nausea, and vomiting were a problem with the combination. Moreover, the steady-state AUC of bosentan was raised 1.7-fold when compared with the AUC of a single dose of bosentan.3 It should be noted that bosentan induces its own metabolism, and after 7 days, plasma levels are about 50 to 65% of those seen after a single dose.4 Therefore, the effect of ciclosporin on the bosentan AUC may be twice those described in this study (i.e. up to a fourfold increase in the AUC of bosentan). The manufacturers of bosentan say that when bosentan is given with ciclosporin its plasma levels were markedly raised (30-fold after a single dose and three- to fourfold at steady state). They also list ciclosporin as an example of a drug, like bosentan, that inhibits the bile salt export pump, and is therefore expected to increase the risk of liver toxicity when used with bosentan. They therefore contraindicate the combination.5 Further study is needed, as some consider the combination to have clinical potential.

The combination of tacrolimus or sirolimus with bosentan has not been studied but based on the information available for ciclosporin, the manufacturers of bosentan advise against concurrent use, but if it is required, close monitoring is recommended.2

Ciclosporin + Bosentan

Bosentan modestly decreases ciclosporin levels, and ciclosporin increases bosentan levels. The manufacturer of bosentan contraindicates the combination, because of the possible increased risk of liver toxicity.

Clinical evidence, mechanism, importance and management

In a study designed to assess the effects of bosentan on ciclosporin renal toxicity, 7 healthy subjects were given bosentan 500 mg and ciclosporin 300 mg, both twice daily, for 7 days. Bosentan did maintain renal plasma flow, which is markedly decreased by ciclosporin. However, bosentan was calculated to have reduced the AUC of ciclosporin by about 50%. In ad-
Ciclosporin + Calcium-channel blockers

Diltiazem, nicardipine and verapamil markedly raise serum ciclosporin levels but also appear to possess kidney protective effects. A single case describes elevated ciclosporin levels caused by nisoldipine. Nifedipine normally appears not to interact, but rises and falls in ciclosporin levels have been seen in a few patients. Felodipine, isradipine, lacidipine and nitrendipine normally appear not to raise serum ciclosporin levels. Amlodipine has modestly increased ciclosporin levels in some studies, but not in others, and it may also have kidney-protective properties.

Clinical evidence

(a) Amlodipine

Ten hypertensive patients with kidney transplants taking ciclosporin (3 of them also taking azathioprine) were also given amlodipine 5 to 10 mg daily for 4 weeks. The hypertension was well controlled, the drug well tolerated, and the pharmacokinetics of the ciclosporin remained unaltered. However, another study in 11 hypertensive kidney transplant patients found that amlodipine, given for 7 weeks, raised the ciclosporin levels by an average of 40%, without affecting creatinine levels. A review identified two other studies that have found increases in ciclosporin levels of 23% and 43% with amlodipine, whereas four studies have found no change. Amlodipine is reported to reduce ciclosporin-associated nephrotoxicity in a study in patients with psoriasis, and in a review of kidney-transplant recipients.

(b) Diltiazem

A pharmacokinetic study in 9 patients taking ciclosporin found that the addition of diltiazem 180 mg daily increased the trough blood level, maximum blood level and half-life of ciclosporin by 112%, 37%, and 43%, respectively. Sixty-five kidney transplant patients taking ciclosporin and diltiazem were found to need less ciclosporin when compared with 63 control patients not given diltiazem (7.3 mg/kg daily compared with 9 mg/kg daily). There were considerable individual differences in dose requirements. Other studies clearly confirm that diltiazem can raise ciclosporin blood levels. In some cases the ciclosporin blood levels were not only controlled by reducing the ciclosporin dosage by 30 to 60%, but it appeared that diltiazem had a kidney protective role (reduced nephrotoxicity, fewer rejection episodes and haemodialysis sessions). A study found that a reduction in ciclosporin dose of about 21% was required for both men and women during chronic administration of diltiazem 90 mg twice daily, despite reports of higher activity of the cytochrome P450 isoenzyme CYP3A4 in women than in men.

(c) Felodipine

Thirteen kidney transplant patients had no significant changes in their serum ciclosporin levels when they took felodipine 2.5 to 10 mg daily and serum creatinine levels were also unchanged. Mean blood pressures fell from 161/100 to 152/90 mmHg. Another study found no significant changes in ciclosporin levels in patients also given felodipine. A single 10-mg dose of felodipine was found to have beneficial effects on blood pressure, renal haemodynamics, renal tubular sodium and water handling in ciclosporin-treated kidney transplant patients. The effects of long-term use were not studied. A single-dose study in 12 healthy subjects found that the maximum serum levels of ciclosporin 5 mg/kg were slightly raised by 16% by felodipine 10 mg, while the AUC and maximum plasma level of the felodipine were raised by 58% and 151%, respectively, but blood pressures were unchanged. The same group of workers also briefly described acute and short-term studies in groups of kidney transplant and dermatological patients, which found that felodipine 5 to 10 mg reduced blood pressure and opposed ciclosporin nephrotoxicity. A study in heart transplant patients taking ciclosporin found that felodipine attenuated the hypertrophic effects of ciclosporin on transplanted hearts.

(d) Isradipine

Twelve kidney transplant patient had no changes in their ciclosporin levels over 4 weeks while taking up to 2.5 mg of isradipine twice daily. Similar findings are noted in another study. Three other studies in 31 kidney transplant patients confirmed that ciclosporin blood levels are unchanged by isradipine and blood pressures are reduced.

(e) Lacidipine

Ten kidney transplant patients taking ciclosporin, prednisone and azathioprine started taking lacidipine 4 mg daily. A very small increase in the trough blood levels (6%) and AUC (14%) of the ciclosporin occurred. The blood pressures fell from 142/93 to 125/79 mmHg, and the 14-hour urinary output rose from 1401 to 2050 mL.

(f) Lercanidipine

The manufacturers of lercanidipine contraindicate the concurrent use of ciclosporin as the plasma levels of lercanidipine were raised threefold by ciclosporin, and the ciclosporin AUC was raised by 21% by lercanidipine.

(g) Nicardipine

Nicardipine 20 mg three times daily raised the ciclosporin blood levels in 9 patients by 110% (from 226 to 430 nanograms/mL, range 24 to 341%). Their serum creatinine concentrations rose from 136 to 147 micromol/L. Other studies have found increases in serum ciclosporin levels, in some cases as much as two to threefold, when nicardipine was given.

(h) Nifedipine

Five of 9 patients who had an interaction with nicardipine (see above) had no interaction when they were given nifedipine. In ciclosporin levels were seen in other studies but raised and reduced levels have been reported in others. Two studies found that nifedipine appeared to protect patients against the nephrotoxicity of ciclosporin. However, there is some evidence that the adverse effects of nifedipine such as flushing, rash and gingival overgrowth may be increased. However, another study in 121 renal transplant patients found the prevalence of gingival overgrowth in patients taking ciclosporin was increased (but not to a statistically significant extent) by the concurrent use of calcium-channel blockers (not specified).

(i) Verapamil

Twenty-two kidney transplant patients given ciclosporin and verapamil had ciclosporin blood levels that were 50 to 70% higher than in 18 other patients not given verapamil, despite similar ciclosporin doses in both groups. Serum creatinine levels were lower in those taking verapamil. Moreover, only 3 of the 22 had rejection episodes within 4 weeks compared with 10 out of 18 not given verapamil. Other studies have found that verapamil 120 to 320 mg daily can increase, double or even triple ciclosporin blood levels in individual patients with kidney or heart transplants. Combined use does not apparently increase the severity or prevalence of gingival overgrowth caused by ciclosporin.

Mechanism

The increased ciclosporin levels are largely due to the calcium-channel blockers inhibiting ciclosporin metabolism by the cytochrome P450 isoenzyme CYP3A4 in the liver. Note that, of the calcium-channel blockers, diltiazem and verapamil are the strongest CYP3A4 inhibitors (see ‘Calcium-channel blockers’). Diltiazem also appears to reduce ischaemia-induced renal tubular necrosis. Other calcium-channel blockers also seem to have a kidney-protective effect. The raised felodipine levels are possibly due to competitive inhibition by ciclosporin of intestinal and liver metabolism, or changes in P-glycoprotein activity.
The interactions of ciclosporin with diltiazem, nicardipine and verapamil are established and relatively well documented. Concurrent use need not be avoided, but ciclosporin levels should be well monitored and dosage reductions made as necessary. Even though ciclosporin blood levels are increased, these calcium-channel blockers appear to have a kidney-protective effect. One study noted, although calcium-channel blockers increase ciclosporin blood levels, this is of no harm to the patient, since no changes in renal function were observed. With diltiazem and verapamil the ciclosporin dosage can apparently be reduced by about 25 to 50% and possibly more with nicardipine. One case suggests that this is also true with nisoldipine. Several studies suggest that substantial cost savings can be made by combining either diltiazem or verapamil with ciclosporin. Take care not to substitute one diltiazem product for another after the patient has been stabilised because there is evidence that their bioequivalence differences may alter the extent of the interaction.17,26 Concurrent use with lercanidipine is contraindicated by the manufacturers.20

The situation with nifedipine is not totally clear (no effect or decreases or increases) but it appears to have a kidney-protective effect as does felodipine. The manufacturers of ciclosporin recommend avoiding nifedipine in patients who develop gingival overgrowth.27

The situation with amloidipine is also uncertain, but isradipine, lacidipine and nitrendipine appear to be non-interacting alternatives. Many of the calcium channel blockers have a kidney-protective effect.

Ciclosporin + Chlorambucil

An isolated report describes a reduction in ciclosporin levels in a patient given chlorambucil.

Clinical evidence, mechanism, importance and management

A woman with B-chronic lymphocytic leukaemia and autoimmune haemolytic anaemia controlled with ciclosporin started taking chlorambucil 5 mg daily because of disease progression. When she reached a total cumulative dose of chlorambucil of 200 mg she suddenly relapsed, and her serum ciclosporin levels were found to have dropped to 60 nanograms/mL from a range of 200 to 400 nanograms/mL. The ciclosporin levels remained low despite a doubling of the ciclosporin dose and withdrawal of the chlorambucil. After only one month did the anaemia respond and the ciclosporin levels rise again.1

This appears to be an isolated report so the general significance of this interaction is unclear.

Ciclosporin + Chloroquine or Hydroxychloroquine

Three patients had rapid rises in serum ciclosporin levels, with evidence of nephrotoxicity in two of them, when they were given chloroquine. Some loss of renal function has even been seen with low doses of ciclosporin used with chloroquine for rheumatoid arthritis. Hydroxychloroquine is expected to interact similarly

Clinical evidence

A kidney transplant patient taking ciclosporin, azathioprine and prednisolone had a threefold rise in ciclosporin blood levels, from 148 to 420 nanograms/mL, accompanied by a rise in serum creatinine levels within 48 hours of starting chlorambucil 900 mg daily for suspected malarial fever. On days 2 and 3 the chloroquine dosage was reduced to 300 mg daily. The ciclosporin and creatinine returned to their former levels 7 days after the chloroquine was stopped.1

When another kidney transplant patient taking ciclosporin, azathioprine and prednisolone was given chloroquine 100 mg daily for 6 days, his ciclosporin serum levels rose from 105 to 470 nanograms/mL and his serum creatinine levels rose from 200 to 234 micromol/L, accompanied by a rise in blood pressure from 130/80 to 160/100 mmHg. These changes reversed when the chloroquine was stopped, and occurred again when chloroquine was restarted.2 The ciclosporin serum levels of another patient were doubled by chloroquine 100 mg daily.3

A randomised, controlled study in 88 patients with recent onset rheumatoid arthritis found that the addition of ciclosporin (1.25 or 2.5 mg/kg daily) to chloroquine 100 mg daily was moderately effective, but changes in serum creatinine levels occurred. In the presence of chloroquine the creatinine was not significantly altered by placebo or ciclosporin 1.25 mg/kg, but was raised by 10 micromol/L by ciclosporin 2.5 mg/kg, indicating that some renal effects can occur.4

Mechanism

Not understood. Both chloroquine and ciclosporin can impair renal function.

Ciclosporin + Clodronate

Clodronate does not appear to alter ciclosporin blood levels.

Clinical evidence, mechanism, importance and management

Ten heart transplant patients taking ciclosporin, azathioprine and diltiazem were also given clodronate 800 mg daily for one week. No statistically significant differences were seen in their ciclosporin blood levels or AUCs while they were taking clodronate. Three of them were also taking simvastatin, two were taking ranitidine and one was taking propafenone, furosemide and cyclophosphamide. There would seem to be no reason for avoiding concurrent use, but the authors of the report suggest that longer-term use of clodronate should be well monitored.1

A number of cases of ciclosporin toxicity, multiple organ failure and serious muscle disorders (myopathy, rhabdomyolysis) have been seen when colchicine and ciclosporin were given concurrently.

Clinical evidence and mechanism

A patient with a kidney transplant had a transient rise (lasting 2 to 3 days) in serum creatinine and ciclosporin blood levels, from 100 to 200 nanograms/mL up to 1519 nanograms/mL one day after receiving a total of 4 mg of colchicine. Another kidney transplant patient taking ciclosporin, azathioprine and prednisone developed colchicine neuromyopathy (possibly rhabdomyolysis), ciclosporin nephrotoxicity and liver function abnormalities when given colchicine. Acute myopathy (muscle weakness, myalgia) or rhabdomyolysis occurred in a further 11 patients who took ciclosporin and colchicine. There is also a report of colchicine-induced myopathy and hepatonephropathy in a heart transplant patient who took both ciclosporin and colchicine. A syndrome of myopathy, gastrointestinal disturbances and mild hepatic and renal impairment has been described in 6 patients and was attributed to the use of colchicine with ciclosporin. This may be due to inhibition of P-glycoprotein by ciclosporin and subsequent impairment of colchicine excretion in to the bile and urine, resulting in elevated, toxic colchicine levels.

Importance and management

The overall picture presented by these reports is unclear. It is not known whether the colchicine toxicity is made worse by ciclosporin, or the ciclosporin toxicity is made worse by colchicine, or the reaction is a result of both effects. If concurrent use is thought to be appropriate, it should be very carefully monitored because the outcome can be serious. Rhabdomyolysis appears to be a rare complication and the manufacturer of ciclosporin advises a change of treatment if any signs and symptoms develop. Patients should be reminded to report any unexplained muscle pain, tenderness or weakness. More study is needed.

Ciclosporin + Colchicine

Ciclosporin + Corticosteroids

The concurrent use of ciclosporin and corticosteroids is very common, but some evidence suggests that ciclosporin serum levels are raised by corticosteroids. Ciclosporin can reduce the clearance of corticosteroids. Conflations have also been described during concurrent use, and the incidence of diabetes mellitus may be increased following the use of ciclosporin with methylprednisolone. One case of osteonecrosis has been reported with topical betamethasone and ciclosporin.

Clinical evidence

(b) Betamethasone

A patient with psoriasis taking ciclosporin and applying an average of betamethasone 30 mg daily (as 15 g to 150 g of topical betamethasone 0.05% cream or ointment) developed avascular osteonecrosis of the femoral heads of both hip joints.

(b) Methylprednisolone

A study found that the pharmacokinetics of methylprednisolone in patients taking ciclosporin and azathioprine varied widely between individual kidney transplant patients, but the mean values were similar to those found in normal subjects.

The plasma ciclosporin levels of 22 out of 33 patients were reported to be more than doubled by intravenous methylprednisolone and the ciclosporin dosage needed to be reduced in 6 patients. Other studies have found that high doses of methylprednisolone increased or more than doubled ciclosporin levels. However, another study found that the clearance of ciclosporin was increased by high-dose methylprednisolone, although ciclosporin levels were unchanged. A report describes 4 young patients (aged 10, 12, 13 and 18 years) who had undergone bone marrow transplants for severe aplastic anaemia and who developed convulsions when given high-dose methylprednisolone (5 to 20 mg/kg daily) and ciclosporin. Convulsions also occurred in a 25-year-old woman given ciclosporin with high-dose methylprednisolone.

A study of 314 kidney transplant patients during the period 1979 to 1987 found that the incidence of diabetes mellitus in those given ciclosporin and methylprednisolone was twice that of other patients given azathioprine and methylprednisolone. The diabetes developed within less than 2 months.

Furosemide and nifedipine postoperatively in an attempt to control his blood pressure. Minoxidil was added, but was considered unacceptable because of adverse cosmetic effects. When it was replaced with clonidine, the ciclosporin levels increased about threefold to 927 nanograms/mL, despite a dose reduction. Ciclosporin levels returned to the patient's normal range of 150 to 300 nanograms/mL when the clonidine was withdrawn, and blood pressure was controlled by the addition of an ACE inhibitor. It is possible that clonidine inhibited the metabolism of ciclosporin by cytochrome P450.1

As this appears to be the only report of an interaction, there is insufficient evidence to recommend routinely increasing the monitoring of ciclosporin levels in every patient taking these drugs. However, the possibility of an interaction should still be considered if both drugs are given.

Ciclosporin + Colchicine

Ciclosporin + Corticosteroids

Ciclosporin + Colchicine

Ciclosporin + Corticosteroids

Ciclosporin + Colchicine
A pharmacokinetic study in 40 patients found that the clearance of prednisolone was reduced by about 30% in those taking ciclosporin when compared with those taking azathioprine.12

Another study in patients with kidney transplants by the same group of workers reported a 25% reduction in the clearance of prednisolone in the presence of ciclosporin.13 Other studies3,14,15 confirm that ciclosporin reduces the clearance of prednisolone by about one-third, and as a result some patients develop signs of steroid toxicity (cushingoid symptoms such as steroid-induced diabetes, osteonecrosis of the hip joints).1 These studies have all been questioned by the authors of another study, which found that the metabolism of prednisolone was not affected by ciclosporin.16

A comparative study over a year, in two groups of kidney transplant patients taking ciclosporin and azathioprine, one group with and the other without prednisolone, found that those taking prednisolone had lower trough ciclosporin levels (about 10 to 20%) despite using the same or higher doses of ciclosporin.17

There is other evidence that low-dose prednisolone does not increase the immunosuppression of ciclosporin, but it can reduce ciclosporin nephrotoxicity.18

### Mechanism

The evidence suggests that ciclosporin reduces the metabolism of the corticosteroids by the liver thereby raising their levels.1,19 Corticosteroids are known to cause osteonecrosis and ciclosporin may depress bone resorption as well as bone remodelling.1

### Importance and management

None of these adverse interactions is well established, and the picture is confusing. Concurrent use is common and advantageous but be alert for any evidence of increased ciclosporin and corticosteroid effects. It is not clear whether high-dose corticosteroids cause a rise in serum ciclosporin levels or not. Ciclosporin levels measured by RIA (radioimmunoassay) should be interpreted with caution in patients taking high-dose corticosteroids as the levels of ciclosporin metabolites, which can interfere with the test, may be altered.20 The authors of one report point out that this interaction could possibly lead to a misinterpretation of clinical data as a rise in serum creatinine levels in patients with kidney transplants is assumed to be due to rejection, unless proven otherwise. If a corticosteroid is given, this could lead to increased ciclosporin levels, which might be interpreted as ciclosporin nephrotoxicity.4 The contribution of ciclosporin and topical corticosteroid to the development of osteonecrosis in the isolated case report is not known. More study is needed.

---

Ciclosporin + Danazol

Marked increases in serum ciclosporin levels have been seen in seven patients taking danazol.

Clinical evidence
A 15-year-old girl, one-year post kidney transplant, taking ciclosporin and prednisone, had a marked rise in serum ciclosporin levels over about 2 weeks (from a range of 250 to 325 nanomol/mL up to 700 to 850 nanomol/mL) when she was given danazol 200 mg twice daily, even though the ciclosporin dosage was reduced from 350 to 250 mg daily.1

Similar rises in ciclosporin levels, from about 400 to 600 nanomols/mL, and from 150 to about 450 nanomols/mL, were seen in another patient on two occasions over about a 6-week period when danazol 400 mg daily and later 600 mg daily was given.2 A 12-year-old boy needed a reduction in his ciclosporin dosage from 10 to 2 mg/kg daily when danazol 400 mg twice daily was added.3 A marked rise in ciclosporin blood levels has been described in 2 other patients when given danazol 200 mg three or four times daily.4,5

A pharmacokinetic study in one kidney transplant patient found that danazol 200 mg three times daily for 16 days reduced the ciclosporin clearance by 50%, prolonged its half-life by 66%, and raised its AUC by 65%.6

A patient with aplastic anaemia taking ciclosporin was given danazol 200 mg daily for pancytopenia and endometriosis. Within 4 days the patient had epigastric pain and elevated serum ciclosporin and creatinine levels.7 The ciclosporin dosage was reduced from 350 to 250 mg daily.8

Isolated cases of nephrotoxicity have been described when patients taking ciclosporin were given either amiloride with hydrochlorothiazide, metolazone, or mannitol. Furosemide can possibly protect the kidney against ciclosporin damage. The concurrent use of ciclosporin with thiazides, but not loop diuretics, may increase serum magnesium levels. The concurrent use of ciclosporin with potassium-sparing diuretics may cause hyperkalaemia.

Clinical evidence, mechanism, importance and management
A 39-year-old man taking ciclosporin, whose second kidney transplant functioned subnormally, and who required treatment for hypertension with atenolol and minoxidil, developed ankle oedema, which was resistant to furosemide, despite doses of up to 750 mg daily. When metolazone 2.5 mg daily was added for 2 weeks his serum creatinine levels more than doubled, from 193 to 449 micromol/L. When metolazone was stopped the creatinine levels fell again. Ciclosporin serum levels were unchanged and neither graft rejection nor hypovolaemia occurred.1

The kidney transplant of another patient taking ciclosporin almost ceased to function when mannitol was given, and a biopsy indicated severe ciclosporin nephrotoxicity. Transplant function recovered when the mannitol was stopped.2 The same reaction was demonstrated in rats.2

A woman taking ciclosporin had a rise in serum creatinine levels from 121 to 171 micromol/L three weeks after she started to take Moduretic (amiloride with hydrochlorothiazide). Trough serum ciclosporin levels were unchanged.1

Although animal studies suggested that furosemide might increase the nephrotoxicity of ciclosporin,4 more recent human studies suggest that it may have a protective effect.5

Although ciclosporin and loop diuretics are both known to cause magnesium wasting, a review of magnesium serum levels, magnesium replacement doses and diuretic use in 50 heart transplant recipients indicated that magnesium requirements were not altered by the use of ciclosporin with loop diuretics. However, the use of thiazides with ciclosporin resulted in increases in serum magnesium and decreases in magnesium replacement.6

Ciclosporin alone can cause hyperkalaemia, especially if renal function is impaired. Because of this, the US manufacturers suggest that ciclosporin should not be used with potassium-sparing diuretics,7 whereas the UK manufacturers suggest that caution is required with combined use, with close control of potassium levels.5

The general importance of all these adverse interactions is not clear, but good monitoring is obviously needed if diuretics are given with ciclosporin.
Ciclosporin + Fibrates

The use of bezafibrate with ciclosporin has resulted in significantly increased serum creatinine and reductions, no change, or increased serum ciclosporin levels. The use of fenofibrate has also been associated with reduced renal function and possibly reduced serum ciclosporin levels. Two studies found no pharmacokinetic interaction between ciclosporin and gemfibrozil while a third found gemfibrozil caused a significant reduction in ciclosporin levels.

Clinical evidence, mechanism, importance and management

(a) Bezafibrate

A kidney transplant patient had a rise in his previously stable ciclosporin blood levels from a range of 150 to 200 nanograms/mL to about 340 nanograms/mL over a 6-week period after bezafibrate 200 mg twice daily was given. The rise was accompanied by increases in blood urea nitrogen and creatinine levels. Renal biopsy found evidence of possible ciclosporin toxicity, and rejection. The patient recovered when the bezafibrate was stopped.1

Two other transplant patients (one kidney and the other heart) had a reversible deterioration in renal function when they were given bezafibrate. This was severe in one, and the other had the effect on two occasions. Neither had any changes in ciclosporin blood levels.2,3 Two other similar cases have been reported, one of whom was subsequently given gemfibrozil without problems.4

Another study over 3 months in 40 heart transplant patients taking ciclosporin found that bezafibrate was associated with a rise in serum creatinine levels, although none of the patients had to be withdrawn from the study because of this. The ciclosporin level tended to be lower (198 nanograms/mL at baseline, compared with 144 nanograms/mL after 3 months).5

Neither the incidence nor the reasons for these reactions are known, but because the outcome is uncertain and potentially serious, keep a close check on the effects of adding bezafibrate to ciclosporin in any patient. The manufacturers of bezafibrate suggest close monitoring of renal function.6

(b) Fenofibrate

Fenofibrate 200 mg once daily effectively reduced the blood cholesterol levels of 10 heart transplant patients from 7.7 to 6.5 mmol/L without significantly altering ciclosporin blood levels over a 2-week period. The only possible adverse effect was an increase in creatinine levels from 145 to 157 mmol/L, suggesting some possible nephrotoxicity. No other clinically adverse effects were seen. However, the authors of this study suggested that longer follow-up studies were needed to confirm the safety of using these drugs together.7 They followed this up with a 1-year study8 in 43 heart transplant patients, only 14 of whom completed the study (67% withdrew for various reasons). Fourteen patients had a rise in blood creatinine levels and a decrease in renal function, which improved when the fenofibrate was stopped. There was also some evidence of a reduction in ciclosporin levels in 5 patients, who developed rejection, and 14 patients, who had to stop fenofibrate because ciclosporin levels could not be maintained without adversely affecting renal function.

The evidence from these reports emphasises the importance of monitoring the long-term concurrent use of these two drugs because there are clearly some potential hazards.

(c) Gemfibrozil

Forty kidney transplant patients taking ciclosporin had a reduction in their hypertriglyceridaemia when gemfibrozil was added, and their ciclosporin blood levels and serum creatinine remained unaltered.9 Another study in 12 patients similarly found that gemfibrozil did not affect ciclosporin blood levels.10

However, in contrast to these findings, another study in 7 kidney transplant patients with hyperlipidaemia found that gemfibrozil 450 mg once or twice daily was associated with a decline in trough ciclosporin levels. Levels declined from 93 to 76 nanograms/mL after 6 weeks of treatment and after dose increases in 3 patients the level at 3 months was 88 nanograms/mL. In 8 similar patients not given gemfibrozil, and with the same ciclosporin dose throughout, trough levels changed from 99 to 98 nanograms/mL at 6 weeks and to 123 nanograms/mL at 3 months. In 2 patients there was a significant increase in serum creatinine, and biopsy revealed chronic rejection in one and ciclosporin toxicity in the other. The study was stopped at 6 months because a drug interaction was suspected. The mechanism is not known, but changes in distribution of lipoproteins during gemfibrozil treatment may cause changes in the free fraction of ciclosporin. Ciclosporin absorption may also be reduced. Close monitoring is recommended during concomitant use.11

Food and milk can increase the bioavailability of ciclosporin. Lipid mixtures for parenteral nutrition appear not to affect ciclosporin pharmacokinetics.

Clinical evidence

(a) Food or Milk

Patients taking ciclosporin with milk had a 39% higher AUC after food and 23% higher AUC when fasting, compared with other patients taking ciclosporin with orange juice (which is not known to interact).2 Food more than doubled the AUC of ciclosporin (bioavailability increased from about 21% to 53%) and almost tripled its maximum serum levels, from 783 to 2062 nanograms/mL.2 When 18 patients with kidney transplants were given ciclosporin mixed with 240 mL of chocolate milk and taken with a standard hospital breakfast, their peak ciclosporin levels rose by 31%, from 1120 to 1465 nanograms/mL, trough blood levels rose by 17%, from 228 to 267 nanograms/mL, and the AUC rose by 45%. Very considerable individual variations occurred.3

A study in 10 patients undergoing bone-marrow transplantation and given isocaloric and isonitrogenous parenteral nutrition with or without lipids found that ciclosporin pharmacokinetics are not affected by lipid-enriched admixtures.4

(b) Soft drinks

A lung transplant patient taking ciclosporin had large variations in his ciclosporin levels, which ranged between 319 and 761 nanograms/mL, on discharge from hospital, which were unexplained by changes in his current medication or ciclosporin dose changes. It was found that on the days when the ciclosporin levels were increased, the patient had drunk a citrus soft drink (Sun Drop) at breakfast. These fluctuations resolved when he stopped drinking the soft drink.5 However, a subsequent pharmacokinetic study in 12 healthy subjects found that neither Sun Drop nor another citrus soft drink, Fresca, had any significant effects on the pharmacokinetics of a single 2.5-mg/kg dose of ciclosporin. Both Sun Drop and Fresca were tested, and found to contain bergamotin 0.078 and 6.5 mg/L, respectively (note that ‘grapefruit’, (p.1034), contains about 5.6 mg/L). The authors note that factors such as genetic and disease-related variability in ciclosporin metabolism as well as changes in the bergamotin content between batches of the drinks may account for the contrasting results.6

Immunosuppressants 1033
Mechanism

The authors of the report of an interaction with a citrus soda drink confirmed with the manufacturers that it contained furanocoumarins such as bergamottin which are thought to inhibit CYP3A4, the major isoenzyme involved in the metabolism of ciclosporin.

Importance and management

The food and milk interactions are established, clinically important, and result in an increase in the bioavailability of ciclosporin. The situation should therefore be monitored if any changes are made to the diet of patients taking ciclosporin. Patients should be warned because increased ciclosporin levels are associated with increased nephrotoxicity. Lipid admixtures in parenteral nutrition do not appear to affect ciclosporin pharmacokinetics and it is speculated that they may protect against ciclosporin-induced nephrotoxicity. Close supervision and monitoring is required. There is insufficient evidence to allow extrapolation of the results to bone-marrow transplant recipients with risk factors such as dyslipidaemia, liver, or renal impairment.

The isolated report of an interaction between a citrus soft drink (containing furanocoumarins) and ciclosporin was not confirmed by a subsequent single-dose pharmacokinetic study in healthy subjects and therefore its significance is unclear. The case does highlight the influence diet can have on ciclosporin and it should be borne in mind should any unexpected changes in ciclosporin levels occur.

Clinical evidence, mechanism, importance and management

A considerable number of single and multiple dose studies in healthy subjects, transplant recipients, and other patients with haematological diseases have shown that if oral ciclosporin is taken with 150 to 250 mL (5 to 8 ozs) of grapefruit juice, the trough and peak blood levels and the bioavailability of the ciclosporin may be significantly increased. The increases reported vary considerably. Increases in trough blood levels range from 23 to 85%, increases in peak blood levels range from 0 to 69% and increases in AUCs range from 0 to 72%.

In one study the AUC of the microemulsion formulation of ciclosporin was increased by 38% (range 12 to 194%) by grapefruit juice but the maximum levels were unchanged. A further study with the microemulsion formulation found that both the peak levels and AUC were increased by grapefruit juice, but while increases of 39% and 60%, respectively, were observed in African-American patients, smaller increases of 8% and 44% were observed in Caucasian patients.

A study in 6 paediatric kidney transplant patients found that giving ciclosporin oral solution with grapefruit juice produced a significant increase (109%) in the 12-hour trough level although the AUC was not significantly changed. When ciclosporin was given as a microemulsion, grapefruit juice did not significantly affect the pharmacokinetics of ciclosporin. Grapefruit juice has no effect on ciclosporin levels when the ciclosporin is given intravenously.

Ciclosporin levels are unaffected by orange juice.

A study in 12 healthy subjects given a single 200-mg dose of ciclosporin found that pomelo juice significantly increased the AUC and maximum level of ciclosporin by about 19% and 12%, respectively, whereas cranberry juice did not have any significant effects on ciclosporin pharmacokinetics.

Mechanism

It is suggested that grapefruit juice inhibits the activity of the cytochrome P450 isoenzyme CYP3A in the gut wall and liver. Ciclosporin is primarily

Ciclosporin + Ganciclovir

Four patients given ciclosporin and ganciclovir developed an acute but reversible eye movement disorder.

Clinical evidence, mechanism, importance and management

In a USA hospital, 582 allogeneic bone marrow transplants were carried out between 1988 and 1994. All the patients were given ciclosporin and about 45% also had ganciclovir at some time during the first 3 months after the transplant. Four patients (0.7%) developed an acute eye movement disorder (unilateral or bilateral sixth nerve palsies) within 4 to 34 days of starting ganciclovir. Three of the 4 patients also had bilateral ptosis. The problem cleared 24 to 48 hours after withdrawal of both drugs from 3 patients, and the withdrawal of just ciclosporin from the other patient. Objective eye movement abnormality with diplopia occurred in one patient when both drugs were restarted, but not when ciclosporin alone was given.

The reason for this toxic reaction is not known but the authors of the report postulate a transient brain stem or neuromuscular dysfunction caused by both drugs. It is an uncommon reaction and reversible, so that concurrent use need not be avoided but both drugs should be stopped if it happens. The report cited here seems to be the only report of this interaction.

Ciclosporin + Grapefruit and other fruit juices

Grapefruit juice and pomelo juice, but not cranberry or orange juice, can increase the bioavailability of ciclosporin.

Clinical evidence

A considerable number of single and multiple dose studies in healthy subjects, transplant recipients, and other patients with haematological diseases have shown that if oral ciclosporin is taken with 150 to 250 mL (5 to 8 ozs) of grapefruit juice, the trough and peak blood levels and the bioavailability of the ciclosporin may be significantly increased. The increases reported vary considerably. Increases in trough blood levels range from 23 to 85%, increases in peak blood levels range from 0 to 69% and increases in AUCs range from 0 to 72%.
metabolised by CYP3A4 and so its levels rise. Pomelo is related to grapefruit and therefore potentially interacts by the same mechanism.

**Importance and management**

The interaction between grapefruit juice and ciclosporin is established and clinically important, and results in increases in the bioavailability of ciclosporin. Patients taking ciclosporin should be warned about drinking grapefruit juice because increased ciclosporin levels are associated with increased nephrotoxicity. In general, grapefruit juice should be avoided. It has been suggested\(^2\) that the interaction between grapefruit juice and ciclosporin could be exploited to save money. One group of authors has suggested that grapefruit juice is roughly as effective as diltiazem in raising ciclosporin blood levels, and has the advantage of being inexpensive, nutritious and lacking the systemic effects of diltiazem and ketoconazole which have been used in this way, see ‘Ciclosporin + Calcium-channel blockers’, p.1027 and ‘Ciclosporin + Azoles’, p.1023. However, it has also been pointed out that it may be risky to try to exploit this interaction in this way because the increases appear to be so variable and difficult, if not impossible, to control. This is because batches of grapefruit juice vary so much, and also considerable patient variation occurs with this interaction.\(^2\)\(^-\)\(^3\) The US manufacturers suggest that patients taking ciclosporin should avoid grapefruit juice, as well as the juice.\(^4\)

The significance of the single report of the small increases in ciclosporin bioavailability and blood levels seen with pomelo juice in healthy subjects is unclear.\(^5\) However, a similar interaction has been seen in a kidney transplant patient taking tacrolimus, see ‘Tacrolimus + Grapefruit and other fruit juices’, p.1079. There is insufficient evidence to recommend avoiding pomelo juice or pomelo fruit when taking ciclosporin but bear this potential interaction in mind. More study is needed.

One report (see Cimetidine above), where the effects of cimetidine and ranitidine were examined together, suggests that ranitidine raises creatinine levels in patients taking ciclosporin, without affecting ciclosporin levels.\(^1\) Similarly, several other reports say that ranitidine does not alter ciclosporin blood levels.\(^1\)\(^2\)\(^3\) One also notes that ranitidine does not alter creatinine levels and inulin clearance.\(^1\)\(^3\)

A report describes thrombocytopenia in a man taking ciclosporin after a kidney transplant who was given ranitidine.\(^1\)\(^6\) Another patient experienced hepatotoxicity while taking ciclosporin with ranitidine.\(^1\)\(^7\)

**Mechanism**

It is not clear why these reports are inconsistent, nor how the H\(_2\)-receptor antagonists might raise ciclosporin blood levels. It has also been suggested that any rise in serum creatinine levels could simply be because these H\(_2\)-receptor antagonists compete with creatinine for secretion by the kidney tubules, and therefore are not an indicator of nephrotoxicity.\(^8\)\(^9\)

**Importance and management**

Information about the possible interactions of ciclosporin and cimetidine, famotidine or ranitidine is inconsistent, but there appear to be very few reports of confirmed toxicity. Moreover the reported increases in serum creatinine levels seen with the H\(_2\)-receptor antagonists may not be a reflection of increased nephrotoxicity (see ‘Mechanism’). Thus there is little to suggest that concurrent use should be avoided, but good initial monitoring is advisable.

**Clinical evidence, mechanism, importance and management**

A stable kidney transplant patient taking ciclosporin 75 mg twice daily began to take alfalfa (*Medicago sativa*) and black cohosh (*Cimicifuga racemosa*) supplements on medical advice. Her serum creatinine rose from between about 97 to 124 micromol/L up to 168 micromol/L in 4 weeks and, to 256 micromol/L at 6 weeks with no associated change in her ciclosporin levels. Severe acute rejection with vasculitis was diagnosed and treated with corticosteroids and anti-T lymphocyte immunoglobulin. Alfalfa has been reported to cause worsening of lupus and immunosuppression and it was suggested that immunostimulation may have contributed to the acute rejection in this patient.\(^1\) The evidence of for this interaction is limited, but as the effects were so severe in this case it would seem prudent to avoid concurrent use.

---

**Ciclosporin + Herbal medicines; Berberine**

Berberine appears to increase the bioavailability and trough blood levels of ciclosporin.

**Clinical evidence, mechanism, importance and management**

A study in 6 kidney transplant patients looked at the effects of the Chinese herbal medicine berberine on the pharmacokinetics of ciclosporin. The patients were taking ciclosporin 3 mg/kg twice daily for an average of 12 days before berberine 200 mg three times daily for 12 days was added. The AUC and trough blood levels of ciclosporin were increased by 34.5% and 88.3%, respectively. The peak ciclosporin level was decreased but this was not statistically significant.\(^1\) A clinical study by the same authors in 52 kidney transplant patients stable taking ciclosporin and given berberine 200 mg three times daily for 3 months found that the ciclosporin trough levels were increased by 24.4% in the berberine-treated group, when compared with 52 similar patients taking ciclosporin without berberine. The ciclosporin levels in 8 patients after berberine was stopped.\(^1\)

A single-dose study in healthy subjects found conflicting results. Six subjects given a single 6-mg/kg dose of ciclosporin daily found that berberine 300 mg twice daily, taken for 10 days before the dose of ciclosporin, had no significant effects on the pharmacokinetics of ciclosporin. However, a separate study in another 6 subjects given a single 3-mg/kg dose of ciclosporin found that a single 300 mg 3 mg dose of berberine increased the AUC of ciclosporin by 19.2%.\(^2\)

The mechanism for the increase in ciclosporin levels is unclear. Although the increase is not sufficiently severe to suggest that concurrent use should be avoided, it may make ciclosporin levels less stable and therefore be undesirable (see ‘drug-herb interactions’).\(^3\) If concurrent use is undertaken it should be well monitored.

**Ciclosporin + Herbal medicines; Geum chiloense**

A single case report describes a marked and rapid increase in the serum ciclosporin levels of a man after he drank an infusion of *Geum chiloense*.

**Clinical evidence, mechanism, importance and management**

A 54-year-old kidney transplant patient taking ciclosporin, prednisone, azathioprine, diltiazem and nifedipine had a sudden and very marked rise in his ciclosporin levels from his usual range of 60 to 90 [mg/dL] up to a range of 469 to 600 [mg/dL]. He had been taking ciclosporin 2 to 3 mg/kg daily for 15 months since the transplant. His serum creatinine levels were found to be 115 micromol/L. It eventually turned out that about 2 weeks earlier he had started to drink an infusion of *Geum chiloense* (or *Geum quellyon*), a herbal remedy claimed to increase virility and to treat prostatitis. When the herbal remedy was stopped, his serum ciclosporin levels rapidly returned to their normal values. The reasons for this apparent interaction are not known.\(^1\)

---

**Ciclosporin + Herbal medicines; Alfalfa and Black cohosh**

An isolated report describes acute rejection and vasculitis with black cohosh and/or alfalfa in a renal transplant patient taking ciclosporin.
This appears to be the only case on record but it serves, along with reports about other herbs, to emphasise that herbal remedies may not be safe just because they are ‘natural’. In this instance the herbal remedy markedly increased the potential nephrotoxicity of the ciclosporin. Patients should be warned.

Ciclosporin + Herbal medicines; Quercetin

A study found that quercetin increased the bioavailability of ciclosporin.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects a single 300-mg dose of ciclosporin was given four times: alone, with oral quercetin 5 mg/kg, 30 minutes after oral quercetin 5 mg/kg, or after a 3-day course of quercetin 5 mg/kg twice daily. It was found that the AUC of ciclosporin was increased by 16% by the concurrent use of a single dose of quercetin, by 36% when given after single-dose quercetin, and by 46% when given after multiple-dose quercetin. These correlate with results from previous animal studies. Quercetin is a flavonoid, found in many foods and drinks as well as supplements such as ginkgo, and it has also been found to affect the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme involved in ciclosporin metabolism. Quercetin is also found in citrus fruits. Although the increase in ciclosporin levels is modest, and the interaction is not sufficiently severe to suggest that concurrent use should be avoided, it may make ciclosporin levels less stable as the quercetin content of different herbs and preparations is likely to vary. Concurrent use may therefore be undesirable. If concurrent use of ciclosporin and a quercetin-containing product is undertaken it should be well monitored.

Ciclosporin + Herbal medicines; Red yeast rice (Monascus purpureus)

Red yeast rice has been reported to cause rhabdomyolysis in a kidney transplant patient taking ciclosporin.

Clinical evidence, mechanism, importance and management

A kidney transplant patient taking ciclosporin 300 mg daily developed asymptomatic rhabdomyolysis when she started to take a herbal preparation of red yeast rice (Monascus purpureus) containing rice fermented with red yeast, beta-sitosterol, dansen root (Salvia miltiorrhiza) and garlic bulb (Allium sativum). Two months later, her creatine phosphokinase rose to 1050 units/L but reduced to 600 units/L 2 weeks after stopping the herbal preparation. It is thought that a component of the red yeast rice called monacolin K (identical to lovastatin) probably caused the muscle damage. This appears to be an isolated case but it would be expected called monacolin K (identical to lovastatin) probably caused the muscle damage.

Clinical evidence

A marked drop in ciclosporin blood levels was identified in one kidney transplant patient as being due to the addition of St John’s wort extract 300 mg three times daily. When the St John’s wort was stopped the ciclosporin levels rose. The authors of this report identified another 35 kidney and 10 liver transplant patients whose ciclosporin levels had dropped by an average of 49% (range 30 to 64%) after starting St John’s work. Two of them had rejection episodes. In addition, subtherapeutic ciclosporin levels in 7 kidney transplant patients were noted after the St John’s wort was added. Two patients subsequently developed chronic rejection, requiring a return to dialysis. Another case of subtherapeutic ciclosporin levels occurred in a kidney transplant patient during the concurrent use of a herbal tea containing St John’s wort. The patient’s levels remained subtherapeutic despite a ciclosporin dose increase from 150 to 250 mg daily. The levels recovered within 5 days of stopping the herbal tea and the ciclosporin dose was reduced to 175 mg daily.

These case reports are supported by a small study in which 11 renal transplant patients, with stable dose requirements for ciclosporin, were given St John’s wort extract (Jarsin 300) 600 mg daily for 14 days. Pharmacokinetic changes were noted 3 days after the St John’s wort was added. By day 10 the ciclosporin dose had to be increased from an average of 2.7 to 4.2 mg/kg daily in an attempt to keep ciclosporin levels within the therapeutic range. Two weeks after the St John’s wort was stopped, only 3 patients had been successfully re-stabilised on their baseline ciclosporin dose. Additionally, the pharmacokinetics of various ciclosporin metabolites were substantially altered.

Another study in 10 kidney transplant patients stable taking ciclosporin found that the content of hyperforin in the St John’s wort affected the extent of the interaction with ciclosporin. In patients taking St John’s wort with a high hyperforin content (hyperforin 7 mg; hypericin 0.45 mg) the reduction in the AUC0-12 of ciclosporin was 45% greater than that in patients taking St John’s wort with a low hyperforin content (hyperforin 0.1 mg; hypericin 0.45 mg). The maximum blood ciclosporin level and the trough ciclosporin level were also reduced by 36% and 45%, respectively, in the patients taking the higher hyperforin-containing St John’s wort preparation, when compared with the patients taking the preparation with a lower hyperforin content. The patients taking the high-hyperforin preparation required a mean ciclosporin dose increase of 65% whereas the patients taking the low-hyperforin preparation did not require any ciclosporin dose alterations.

Mechanism

St John’s wort is a known inducer of the cytochrome P450 isoenzyme CYP3A4 by which ciclosporin is metabolised. Concurrent use therefore reduces ciclosporin levels. It has also been suggested that St John’s wort affects ciclosporin reabsorption by inducing the drug transporter protein, P-glycoprotein, in the intestine.

Importance and management

An established and clinically important interaction. The incidence is not known, but all patients taking ciclosporin should avoid St John’s wort because of the potential severity of this interaction. Transplant rejection can develop within 3 to 4 weeks. It is possible to accommodate this interaction by lowering the ciclosporin dosage11 (possibly about doubled) but this raises the costs of an already expensive drug. Also, the varying content of natural products would make this hard to monitor. The advice of the CSM in the UK is that patients receiving ciclosporin should avoid or stop taking St John’s wort. In the latter situation, the ciclosporin blood levels should be well monitored and the dosage adjusted as necessary. The study described above suggests that increased monitoring will be needed for at least 2 weeks after the St John’s wort is stopped.

Marked reductions in ciclosporin blood levels and transplant rejection can occur within a few weeks of starting St John’s wort.
Ciclosporin + Melphalan

Melphalan appears to increase the nephrotoxic effects of ciclosporin.

Clinical evidence, mechanism, importance and management

A comparative study found that 13 out of 17 patients receiving bone marrow transplants and given ciclosporin 12.5 mg/kg daily with high-dose melphalan (single injection of 140 to 250 mg/m²) developed renal failure, compared with no cases of renal failure in 7 other patients given melphalan but no ciclosporin. In another study, one out of 4 patients given both drugs developed nephrotoxicity. The reasons are not understood. Renal function should be monitored closely on concurrent use.

Ciclosporin + Methotrexate

Previous or concurrent treatment with methotrexate may possibly increase the risk of liver and other toxicity in those given ciclosporin, but effective and valuable concurrent use has also been reported. Ciclosporin causes a moderate rise in serum methotrexate levels, but methotrexate does not appear to affect the pharmacokinetics of ciclosporin.

Clinical evidence

(a) Evidence of an interaction

A limited comparative study in patients with chronic plaque psoriasis suggested that the previous use of methotrexate, which can cause liver damage, possibly increases the risk of ciclosporin toxicity (higher ciclosporin blood levels and serum creatinine levels, hypertension). This was confirmed by another study in 4 patients with resistant psoriasis in whom ciclosporin 5 mg/kg daily given with methotrexate 2.5 mg every 12 hours for three doses at weekly intervals increased the blood levels of both drugs, and increased the adverse effects (nausea, vomiting, mouth ulcers). Rises in creatinine levels and liver enzymes (AST, ALT) also occurred.

An open-label pharmacokinetic study in 26 patients with rheumatoid arthritis taking methotrexate 7.5 to 22.5 mg weekly with ciclosporin 1.5 mg/kg every 12 hours for 14 days, found that the AUC of the weekly dose of methotrexate increased by 26%, whereas the plasma levels of its major metabolite (7-hydroxymethotrexate), which is much less active and may be associated with toxicity, were reduced by 80%. Another study in patients with rheumatoid arthritis found that the pharmacokinetics of ciclosporin after the first dose did not differ between those who had been receiving intramuscular methotrexate 10 mg each week for 6 months and those not receiving methotrexate.

(b) Evidence of concurrent use without toxicity

A pilot study described the effective use of ciclosporin and methotrexate for the control of acute graft-versus-host disease in bone marrow transplant patients, with the ciclosporin dosage reduced by 50% to 1.5 mg/kg/day during the first 2 weeks. The methotrexate dosages were 10 to 15 mg/m² on days 1, 3, 6, and 11 after grafting. Hepatotoxicity appeared to be reduced. Another study in three bone marrow transplant patients found that low-dose methotrexate (15 mg/m² on day 1, and 10 mg/m² on days 3, 6 and 11) given with ciclosporin did not significantly affect clinical care and no interaction of clinical significance was seen.

Mechanism

Not understood.
Importance and management

The reports cited here give an inconsistent picture. On the one hand there is the strong recommendation by the authors of the second study that combined use should be avoided, even in patients with severe unresponsive psoriatic arthritis, whereas it seems from the other studies in patients with rheumatoid arthritis, or those undergoing bone marrow transplant, that concurrent use can be valuable, effective and apparently safe. Patients receiving ciclosporin should be routinely monitored for renal effects, and those receiving methotrexate routinely monitored for hepatotoxicity. If both drugs are used concurrently it may be worthwhile increasing the frequency of this monitoring to aid rapid detection of any adverse effects.

3. Fox RI, Morgan SL, Smith HT, Robbins BA, Choc MG, Baggott JE. Combined oral ciclosporin and methotrexate: mechanism, importance and management

In a single-dose study, methoxsalen increased the bioavailability of ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that a single 40-mg dose of methoxsalen significantly increased the AUC and peak plasma levels of a single 200-mg dose of ciclosporin by about 14% and 8%, respectively. In two patients the AUCs increased by 1.8-fold and 2.7-fold, respectively. The half-life and time to peak levels were not affected. As methoxsalen absorption is subject to high interindividual variation, this particular study was unable to detect a significant difference in methoxsalen pharmacokinetics although the AUC and peak levels tended to be reduced by concurrent ciclosporin. 1

Methoxsalen may act by reducing the absorption of ciclosporin. Further study is required to see if this interaction is clinically significant. However, bear this interaction in mind in patients taking ciclosporin if levels are high. In a single-dose study, methoxsalen increased the bioavailability of ciclosporin.

3. Fox RI, Morgan SL, Smith HT, Robbins BA, Choc MG, Baggott JE. Combined oral ciclosporin and methotrexate: mechanism, importance and management

Ciclosporin + Methoxsalen

On the basis of an experimental study in 9 patients it was concluded that the dosage of midazolam needs no adjustment in those taking ciclosporin. Midazolam also appears to have no effect on ciclosporin pharmacokinetics.1

Clinical evidence, mechanism, importance and management

The concurrent use of ciclosporin and minoxidil can cause excessive hairiness (hypertrichosis).

Clinical evidence, mechanism, importance and management

Ciclosporin + Minoxidil

The concurrent use of ciclosporin and minoxidil can cause excessive hairiness (hypertrichosis).

Clinical evidence, mechanism, importance and management

Six male kidney transplant patients taking ciclosporin (blood levels of 100 to 200 nanograms/mL) were given methyldopa, a diuretic and minoxidil 15 to 40 mg daily for intractable hypertension. After 4 weeks of treatment all of them complained of severe and unpleasant hypertrichosis (excessive hairiness). Two months after stopping the minoxidil the hypertrichosis had significantly improved.1 Both ciclosporin and minoxidil cause hypertrichosis and it would seem that their effects may be additive. The authors of the report point out that this is not a life-threatening problem, but it limits the concurrent use of these drugs in both men and women.1

Ciclosporin + Modafinil

Ciclosporin serum levels were reported to be reduced by modafinil in one patient.

Clinical evidence, mechanism, importance and management

A kidney transplant patient, stabilised for 9 years taking ciclosporin 200 mg daily, developed Gélineau’s syndrome (narcoleptic syndrome) and was given modafinil 200 mg daily. Within a few weeks her ciclosporin blood levels were noted to have fallen, and it was necessary to raise her ciclosporin dosage stepwise to 300 mg daily before her blood
levels were back to their former values.\textsuperscript{1} This is the first reported case of an interaction between ciclosporin and modafinil, and its general importance is unknown. However, the manufacturers state that in interaction studies modafinil induced the cytochrome P450 isoenzyme CYP3A4, the major enzyme involved in the metabolism of ciclosporin,\textsuperscript{2} which would suggest that the interaction may be of general importance.

---

### Ciclosporin + Muromonab-CD3

**Muromonab-CD3 increases ciclosporin blood levels.**

**Clinical evidence, mechanism, importance and management**

When muromonab-CD3 5 mg daily for 10 days was given to 10 kidney transplant patients to treat acute rejection, their mean trough ciclosporin levels on day 8 were higher than before the muromonab-CD3 was started, despite a 50\% reduction in the ciclosporin dosage. When the muromonab-CD3 was withdrawn, the ciclosporin dosage needed to be increased again.\textsuperscript{1} The reasons are not understood. It is clearly necessary to titrate the dosage of ciclosporin downwards if muromonab-CD3 is given to prevent an excessive rise in ciclosporin levels with the attendant risks of renal toxicity.

---

### Ciclosporin + NNRTIs

The ciclosporin levels of one patient dramatically decreased following the addition of efavirenz.

**Clinical evidence**

A patient was diagnosed as HIV-positive 3 years after a kidney transplant, for which he was taking ciclosporin. He was started on efavirenz 600 mg daily, lamivudine and zidovudine, and 7 days later, after an initial rise, his ciclosporin level dropped from about 203 to 80 nanograms/mL. A nadir of 50 nanograms/mL was reached one month later.\textsuperscript{1}

**Mechanism**

Efavirenz induces the cytochrome P450 isoenzyme CYP3A4. Ciclosporin is extensively metabolised by CYP3A4, so concurrent use decreases ciclosporin levels.

**Importance and management**

There appears to be only one report of a reduction in ciclosporin levels with efavirenz. However, as subtherapeutic levels of ciclosporin may have significant consequences, including transplant rejection, it would be prudent to monitor ciclosporin levels closely in patients given efavirenz.

---

### Ciclosporin + NRTIs

No change in ciclosporin levels was seen in a study in 6 kidney transplant patients taking ciclosporin when lamivudine 100 to 150 mg daily was added to treat chronic hepatitis B.\textsuperscript{1} Another study in 15 kidney transplant patients also found that lamivudine 50 to 100 mg daily did not affect ciclosporin levels.\textsuperscript{2}

---

**Ciclosporin + NSAIDs, Aspirin or Paracetamol (Acetaminophen)**

NSAIDs sometimes reduce renal function in individual patients, which is reflected in serum creatinine level rises and possibly in changes in ciclosporin levels, but concurrent use can also be uneventful. Diclofenac serum levels can be doubled by ciclosporin. There is an isolated report of colitis in a child treated with ciclosporin and diclofenac or indomethacin.

**Clinical evidence**

(a) **Aspirin**

No pharmacokinetic interaction was found when ciclosporin was given with aspirin 960 mg three times daily in healthy subjects.\textsuperscript{1}

(b) **Diclofenac**

A study in 20 patients with rheumatoid arthritis given ciclosporin and diclofenac found that 7 of them had a high probability of an interaction (risks in serum creatinine levels and blood pressures), and 9 possibly had an interaction.\textsuperscript{2} A kidney transplant patient taking ciclosporin, digoxin, furosemide, prednisolone, and spironolactone had a marked rise in serum creatinine levels immediately after starting to take diclofenac 25 mg three times daily. A fall in serum ciclosporin levels from 409 to 285 nanograms/mL also occurred.\textsuperscript{3} Increased nephrotoxicity was seen in another patient taking ciclosporin for idiopathic uveitis when given diclofenac 150 mg daily.\textsuperscript{4}

A 6-month study in 20 patients with severe rheumatoid arthritis given diclofenac 100 to 200 mg with ciclosporin 3 mg/kg daily found that the AUC of diclofenac was doubled and serum creatinine levels raised from 71 to 88.4 micromol/L. The overall pattern of adverse events and laboratory abnormalities were similar to those in patients with rheumatoid arthritis treated with ciclosporin and other NSAIDs. It was suggested that it would be prudent to start with low doses of diclofenac and to monitor well.\textsuperscript{5} A study in 24 healthy subjects found that diclofenac 50 mg every 8 hours for 8 days caused no changes in the pharmacokinetics of ciclosporin, but there was some inconclusive evidence that diclofenac serum levels were increased.\textsuperscript{6}

A child with rheumatoid arthritis taking ciclosporin 10 mg/kg daily developed colitis when diclofenac was given. The NSAID was stopped and her symptoms resolved while the ciclosporin was continued.\textsuperscript{7}

(c) **Dipyrone (Metamizole sodium)**

A placebo-controlled, crossover study in 6 kidney and 2 heart transplant patients taking ciclosporin found that while they were taking dipyrone 500 mg three times daily for 4 days the pharmacokinetics of the ciclosporin (AUC, trough and peak blood levels, elimination half-life) were unchanged, but the time to reach maximum blood levels was slightly prolonged, from 2.1 to 3.8 hours. It is not known what the effects of more prolonged use might be.\textsuperscript{8}

(d) **Indomethacin**

A study in 16 healthy subjects found that indomethacin 100 mg twice daily for 9 days reduced the maximum blood levels of a single 300-mg dose of ciclosporin by 18\% and slowed its absorption (time to maximum concentration increased by 30 minutes) but the extent of absorption was not changed, indicating the absence of a clinically relevant pharmacokinetic interaction. Further, the pharmacokinetics of indomethacin were not affected by ciclosporin.\textsuperscript{9} A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 6\% in those taking indomethacin 50 mg four times daily, but this was not considered to be clinically important.\textsuperscript{10} An experimental study in healthy subjects found that ciclosporin 10 mg/kg twice daily for 4 days had no effect on effective renal plasma flow (ERPF) or the glomerular filtration rate (GFR), but when indomethacin 50 mg twice daily was added the ERPF fell by 32\% and the GFR by 37\%.\textsuperscript{11}

A child with rheumatoid arthritis on ciclosporin 10 mg/kg daily developed colitis when indomethacin was given. The NSAID was stopped and her symptoms resolved the ciclosporin was continued.\textsuperscript{7}

(e) **Ketoprofen**

A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 2.3\% in those taking ketoprofen 50 mg four times daily, but this was not considered to be clin-
ically important.10 Another report describes increased serum creatinine levels in a patient with rheumatoid arthritis who took ciclosporin and ketoprofen.12

(f) Mefenamic acid
The ciclosporin blood levels in a renal transplant patient doubled, accompanied by rise in creatine levels from 113 to 168 micromol/L within a day of starting to take mefenamic acid. Levels fell to normal within a week of stopping the mefenamic acid.13

(g) Naproxen
In 11 patients with rheumatoid arthritis taking ciclosporin, naproxen and sulindac increased serum creatinine levels by 24% and reduced renal function (glomerular filtration rate reduced from 98 mL/minute at baseline to 67 mL/minute while taking an NSAID and ciclosporin). All patients had a clinical improvement in their rheumatoid arthritis.14

(h) Paracetamol (Acetaminophen)
A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 3.5% in those taking paracetamol 650 mg four times daily, but this was not considered to be clinically important.10

(i) Piroxicam
Piroxicam is reported to have increased the serum creatinine levels of a patient with rheumatoid arthritis by an unknown amount (but classed as a significant adverse event). This resolved when the piroxicam was withdrawn.12 A study in healthy subjects given piroxicam 20 mg daily for 11 days and a single 300-mg dose of ciclosporin on day 10 found no clinically relevant pharmacokinetic interaction.9

(j) Sulindac
A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 2.6% in those taking sulindac 100 mg four times daily, but this was not considered to be clinically important.10

A patient with a kidney transplant had a rise in serum creatinine levels when sulindac was used. Ciclosporin blood levels fell and rose again when the sulindac was stopped.3 Another report states that the ciclosporin levels of a woman with a kidney transplant were more than doubled within 3 days of her starting to take sulindac 150 mg twice daily.15 In 11 patients with rheumatoid arthritis taking ciclosporin, both sulindac and naproxen increased serum creatinine levels by 24% and reduced renal function (glomerular filtration rate reduced from 98 mL/minute at baseline to 67 mL/minute while taking an NSAID and ciclosporin). All patients had a clinical improvement in their rheumatoid arthritis.14

Another report describes a patient with rheumatoid arthritis taking ciclosporin who developed increased serum creatinine levels when given ketoprofen, but not when given sulindac.12

Mechanism
Uncertain. One idea is that intact kidney prostacyclin synthesis is needed to maintain the glomerular filtration rate and renal blood flow in patients given ciclosporin, which may possibly protect the kidney from the development of ciclosporin-induced nephrotoxicity. If NSAIDs that inhibit prostaglandin production in the kidney are given, the nephrotoxic effects of the ciclosporin manifest themselves, possibly independently of changes in serum ciclosporin levels.3 A study in rats found that indometacin and ciclosporin together can cause rises in serum creatinine levels that are much greater than with either drug alone.16

The occurrence of colitis in a child receiving ciclosporin and either diclofenac or indometacin appeared to be independent of changes in ciclosporin levels and may be a result of additive effects of both drugs.7

Importance and management
Information about the NSAIDs listed here is sparse and limited, but the overall picture appears to be that concurrent use in rheumatoid arthritis need not be avoided but renal function should be very well monitored. The manufacturers of ciclosporin also specifically recommend that patients with rheumatoid arthritis taking ciclosporin and an NSAID should have their hepatic function measured as well as renal function, because hepatotoxicity is a potential adverse effect of both drugs.17 It has been suggested that gastrointestinal symptoms should also be carefully evaluated. It is clearly difficult to generalise about what will or will not happen if any particular NSAID is given but in the case of diclofenac it has been recommended that doses at the lower end of the recommended range should be used at the start because its serum levels can be doubled by ciclosporin.

16. Whiting PH, Burke MD, Thomson AW. Drug interactions with ciclosporine. Immunosuppressants 1041

Ciclosporin + Opioids

An isolated report describes neuropsychosis in a patient who was given intravenous ciclosporin and morphine. A single case report describes a patient taking ciclosporin who developed opioid withdrawal on stopping low-dose, transdermal fentanyl.

Clinical evidence, mechanism, importance and management
A patient who underwent renal transplantation was given ciclosporin 6 mg/kg daily by intravenous infusion over 2 hours and intravenous methylprednisolone postoperatively. He also received patient-controlled analgesia (PCA) as bolus doses of morphine 0.5 mg to a total dose of 13 mg on the first day and 11 mg on the second day. On the third day he developed insomnia, anxiety, amnesia, aphasia and severe confusion. The mor-
phine was discontinued and the symptoms subsided after treatment with propofol, diazepam and haloperidol. It was suggested that ciclosporin may have decreased the excitation threshold of neuronal cells, which potentiated the dysphoric effects of morphine.1

A patient taking ciclosporin following a stem cell transplant developed opioid withdrawal symptoms when transdermal fentanyl 25 micrograms/hour was discontinued. The authors suggested that elevation of fentanyl levels due to inhibition of the cytochrome P450 isoenzyme CYP3A4 by ciclosporin during concurrent use may have been a possible cause, as withdrawal symptoms are not usual with this dose of fentanyl. However, they also note that other factors may have played a role, such as the physical and mental status of the patient after the stem cell
transplant. Further, ciclosporin does not usually appear to interact with other drugs by inhibiting CYP3A4.

These appear to be isolated cases and almost certainly not of general importance.

**Ciclosporin + Orlistat**

The absorption of ciclosporin is significantly reduced by orlistat. In one case, orlistat appeared to have less effect on the microemulsion formulation of ciclosporin (*Neoral*) than the oil formulation (*Sandimmun*). Nevertheless, an episode of acute graft rejection (said to be non-significant) has been reported with the microemulsion formulation.

**Clinical evidence**

In a heart transplant patient taking ciclosporin (*Sandimmun*), orlistat 120 mg three times daily reduced the trough blood levels of ciclosporin by 47%, to 52 nanograms/mL. The Eur to levels and the AUC of ciclosporin were increased by 86% and 75%, respectively.1 Another heart transplant patient taking ciclosporin (*Neoral*) had a nonsignificant acute rejection episode on routine endocardial biopsy, with trough ciclosporin levels of 38 nanograms/mL, 24 days after starting to take orlistat. Ciclosporin trough levels increased to about 90 to 110 nanograms/mL when the orlistat was stopped.2 In a further patient taking ciclosporin (*Sandimmun*) 250 mg daily, orlistat 360 mg daily reduced the ciclosporin levels from 150 to 50 nanograms/mL. Increasing the dose of ciclosporin did not result in an increased level, so the patient was given Neoral instead. Adequate levels of 160 nanograms/mL were finally achieved with ciclosporin (*Neoral*) 375 mg daily.3 Details of this patient are also briefly given elsewhere.4 Another report describes 6 transplant recipients who developed subtherapeutic ciclosporin trough levels after also taking orlistat.5 Another heart transplant patient had a progressive reduction in her ciclosporin (*Sandimmune*) level when she started to take orlistat. Note that this patient was also reported to have severe diarrhoea secondary to poor adherence to a low-fat diet when taking orlistat, which may have contributed to the low levels seen.6

**Mechanism**

Orlistat inhibits pancreatic lipase and prevents the absorption of dietary fat and lipophilic molecules such as ciclosporin. Absorption of ciclosporin from the oil suspension formulation (*Sandimmun*) is more dependent on the lipid absorption stage and thus may be more affected by orlistat than the microemulsion form (*Neoral*).1

**Importance and management**

Information appears to be limited to these reports, but the interaction seems to be established. It has been suggested that the effects of the interaction may be reduced by using the microemulsion formulation of ciclosporin (*Neoral*) (which has generally replaced the corn oil suspension). Monitoring is required if the two drugs are used together, either in the standard or microemulsion form because there is a risk of subtherapeutic levels even with the microemulsion preparation.2 Some authors recommend avoidance of the combination.3 The UK manufacturers of orlistat do not recommend concurrent use, but if such use is unavoidable more frequent ciclosporin monitoring is recommended.1 The US manufacturers recommend taking ciclosporin at least 2 hours before or 2 hours after orlistat, and that ciclosporin levels should be monitored more frequently in these patients.6

**Ciclosporin + Oxybutynin**

Oxybutynin did not appear to affect ciclosporin levels in two children.

**Clinical evidence, mechanism, importance and management**

In a retrospective analysis, one child with a kidney transplant taking ciclosporin had no change in his ciclosporin level and dosage over the 2 months before and the 2 months after he started oxybutynin 2 mg twice daily. Another patient had no change in ciclosporin levels and dosage over the 3 months before and 3 months after stopping oxybutynin 5 mg twice daily.1 This analysis was prompted by evidence suggesting oxybutynin may induce the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of ciclosporin. Although the evidence is limited, it suggests that oxybutynin is unlikely to have an important effect on ciclosporin levels.

**Ciclosporin + Pancreatic enzymes**

Pancreatic enzyme extracts do not increase the bioavailability of ciclosporin in cystic fibrosis patients.

**Clinical evidence, mechanism, importance and management**

A study in heart-lung transplant patients with cystic fibrosis found that they needed almost five times the oral dose of ciclosporin of other patients, confirming other studies in these patients that had shown a very much reduced bioavailability of oral ciclosporin. This is probably a reflection of the generally poor digestion and absorption in cystic fibrosis patients. The addition of pancreatic enzymes (Creon) was not found to improve this poor ciclosporin bioavailability. No adverse effects were reported.1

**Ciclosporin + Prazosin**

Preliminary studies show that prazosin causes a small reduction in the glomerular filtration rate in kidney transplant patients taking ciclosporin.

**Clinical evidence, mechanism, importance and management**

A study in 8 patients with kidney transplants found that prazosin 1 mg twice daily for one week did not alter their ciclosporin blood levels, and arterial blood pressures and renal vascular resistance were reduced. However, the glomerular filtration rate (GFR) was reduced by about 10% (from 47 to 42 mL/minute).1 Previous studies in kidney transplant patients taking azathioprine, prednisone and prazosin found no reduction in GFR.2 There would seem to be no strong reasons for totally avoiding prazosin in patients taking ciclosporin, but the authors of the report point out that the fall in GFR makes prazosin a less attractive antihypertensive than a calcium-channel blocker.

**Ciclosporin + Probucol**

Probucol reduces blood ciclosporin levels by about 40%.
Clinical evidence
A study in 6 heart transplant patients taking ciclosporin found that the concurrent use of probucol 500 mg every 12 hours decreased trough whole blood ciclosporin levels from 139 to 81 nanograms/mL and the AUC₀₋₉ by 28%. The clearance was increased by 60% and volume of distribution also increased.¹

Another group of workers similarly found that 9 out 10 kidney transplant patients had a reduction in their trough blood ciclosporin levels while taking probucol.²

Mechanism
Not understood. Evidence from in vitro and animal studies suggest that probucol may form complexes with ciclosporin in the gut, preventing absorption. The studies also found that probucol does not affect ciclosporin absorption via P-glycoprotein-mediated transport.³

Importance and management
Information appears to be limited to these studies, but the interaction appears to be well established. The ciclosporin dosage may need to be increased if probucol is added. The dosage may need to be adjusted and the patient appropriately monitored.

Ciclosporin + Propafenone

In an isolated report, propafenone caused a 60% increase in the ciclosporin levels of a patient.

Clinical evidence
A heart transplant patient taking ciclosporin, azathioprine and prednisolone developed ventricular tachycardia 9 months after transplantation, for which he was given propafenone 600 or 750 mg daily. After the first day, his ciclosporin level had risen from about 160 to 190 nanograms/mL, and after 5 days the levels had reached around 260 nanograms/mL. Over the same time period his serum creatinine rose from 168 to 212 micromol/L. His ciclosporin dose was reduced from 240 mg daily to a final dose of 200 mg daily after which his renal function and ciclosporin levels were re-established at about the level before propafenone was started.¹

Mechanism
The authors suggest that propafenone interferes with the metabolism of ciclosporin by affecting hepatic cytochrome P450, or that propafenone may enhance the absorption of ciclosporin.

Importance and management
Information appears to be limited to this one report, the general importance of which is unknown.

Ciclosporin or Tacrolimus + Potassium compounds

Ciclosporin and tacrolimus can cause or worsen pre-existing hyperkalaemia. The concurrent use of potassium compounds should be closely monitored.

Clinical evidence, mechanism, importance and management
Both ciclosporin and tacrolimus can cause hyperkalaemia.¹ ² Tacrolimus has been reported in one study in 34 liver transplant patients to cause hyperkalaemia (defined in this study as potassium greater than 4.5 mmol/L) in 21% of patients, even when the trough level was within therapeutic range.³ Another study in kidney transplant patients found that the incidence of hyperkalaemia was higher in tacrolimus treated patients, when compared with ciclosporin treated patients.⁴

Hyperkalaemia can in itself be a sign of worsening renal function but may be exacerbated by ciclosporin or tacrolimus. This can be worsened further by the use of potassium supplements.

The manufacturers of tacrolimus recommend that patients should have a high potassium intake, such as in supplements.¹ The manufacturers of ciclosporin however recommend potassium monitoring with concurrent use of any potassium supplement or a potassium-rich diet.²

Ciclosporin + Protease inhibitors

Protease inhibitors significantly increase the levels of ciclosporin. Ciclosporin may increase the time to maximum nelfinavir levels.

Clinical evidence
(a) Fosamprenavir
A HIV-positive patient taking ciclosporin 250 to 350 mg twice daily (to maintain a therapeutic ciclosporin trough level of 300 to 400 nanograms/mL) was restarted on his usual HAART regimen of tenofovir, lamivudine and fosamprenavir 1.4 g twice daily on day 12 post-liver transplantation. Within 2 days, the ciclosporin level had increased to 600 nanograms/mL, requiring a ciclosporin dose reduction to 100 mg twice daily.¹

(b) Nelfinavir
A pilot study in 7 HIV-positive subjects taking nelfinavir 1.25 g twice daily found that a single 4-mg/kg oral dose of ciclosporin increased the time to maximum serum level for nelfinavir from 2.6 to 3.2 hours. The AUC of nelfinavir was also increased but this was not significant. In the same study, a single 2-mg/kg intravenous dose of ciclosporin given over 2.5 hours had little effect on the pharmacokinetics of oral nelfinavir. Nelfinavir did not significantly affect the pharmacokinetics of either oral or intravenous ciclosporin.²

(c) Ritonavir-boosted regimens
Three HIV-positive patients who had undergone liver transplantation required reductions in their ciclosporin doses when they started taking ritonavir-boosted HAART. One patient taking ciclosporin 150 mg twice daily had an increase in his ciclosporin levels to 900 nanograms/mL when ritonavir-boosted HAART was started, and needed a dose reduction of 95% to maintain a usual ciclosporin trough level of 75 to 150 nanograms/mL. A second patient also required a similar reduction. The third patient needed a dose reduction of 80% when taking ritonavir-boosted lopinavir, but no further ciclosporin dose alteration was needed when his treatment was changed to ritonavir-boosted indinavir.³

(d) Saquinavir
An HIV-positive patient taking lamivudine and zidovudine, and ciclosporin for a kidney transplant, started taking saquinavir 1.2 g three times daily. Within 2 days he started to complain of fatigue, headache and gastrointestinal discomfort. On investigation his ciclosporin level was found to have risen from a range of 150 to 200 nanograms/mL up to 380 nanograms/mL, and his saquinavir AUC was increased 4.3-fold (by comparison with subjects not taking ciclosporin). His ciclosporin dose was reduced from 150 mg twice daily to 75 mg twice daily, and his saquinavir dose was reduced to 600 mg three times daily, which resulted in ciclosporin levels similar to those achieved previously.⁵

Mechanism
All protease inhibitors can inhibit the cytochrome P450 isoenzyme CYP3A4 to varying degrees, see ‘Antivirals’, (p.772). Ciclosporin is ex-
tensively metabolised by CYP3A4, so any inhibition of this isoenzyme is likely to increase ciclosporin levels. Ciclosporin and the protease inhibitors are substrates for P-glycoprotein, which may explain the raised neflinavir and saquinavir levels.

**Importance and management**

The increase in ciclosporin levels seen with ritonavir may occur irrespective of whether it is used as an antiretroviral in its own right or as a pharmacokinetic enhancer with other antiretrovirals (usually in a lower dose of 100 mg twice daily). The inhibition of ciclosporin metabolism by other protease inhibitors, either alone or in combination with ritonavir, may lead to significant increases in ciclosporin levels. Therefore, ciclosporin levels should be carefully monitored and the dose adjusted accordingly during concurrent use, bearing in mind that large dose reductions may be required in some patients, as seen with ritonavir. It is also important to reduce or alter the ciclosporin dose should the protease inhibitor be stopped or changed to avoid ciclosporin toxicity. The clinical significance of the effects of ciclosporin on neflinavir pharmacokinetics is unclear, and further study is needed.

### Ciclosporin + Pyrazinamide

Pyrazinamide does not normally appear to interact with ciclosporin but one isolated report suggests that it may possibly have contributed to the effects of rifampicin in one patient, which resulted in lowered ciclosporin levels. Another patient developed toxic myopathy attributed to the use of pyrazinamide with ciclosporin.

**Clinical evidence, mechanism, importance and management**

A 12-year-old girl with a kidney transplant taking ciclosporin and prednisolone had a rejection episode while taking rifampicin and isoniazid, apparently due to the fall in serum ciclosporin levels caused by the rifampicin. The rejection settled when the rifampicin was replaced by pyrazinamide. Other patients taking ciclosporin have been given pyrazinamide combined with ethambutol and/or streptomycin without any apparent interaction problems. However, an anecdotal report suggested that when pyrazinamide was given with rifampicin and isoniazid it appeared to add to the effects of the rifampicin causing an additional reduction in ciclosporin blood levels. Another report attributed the development of toxic myopathy in a kidney transplant patient to the concurrent use of pyrazinamide and ciclosporin.

There would therefore seem to be no reason for avoiding pyrazinamide in patients taking ciclosporin, but be aware of these rare complications.

### Ciclosporin + Quinine

An isolated case suggests that quinine reduces ciclosporin levels.

**Clinical evidence, mechanism, importance and management**

A man with a kidney transplant and mild cerebral falciparum malaria had a gradual decrease in his ciclosporin blood levels, from 328 to 107 nanograms/mL, over 7 days when he was given quinine 600 mg every 8 hours, and a gradual rise when the quinine was stopped. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the...
case of an unexpected response to treatment. The effects of lower quinine
doses used for cramps are unclear.

1. Tan HW, Ch‘ng SL. Drug interaction between cyclosporine A and quinine in a renal transplant

### Ciclosporin + Retinoids

An increase in ciclosporin blood levels occurred in one patient
given etretinate, but studies have not found this effect. In two pa-
tients taking isotretinoin and ciclosporin, rises in ciclosporin lev-
eels occurred, although another patient taking both drugs had no
alteration in ciclosporin levels.

#### Clinical evidence

**(a) Etretinate**

In one case, a woman with generalised pustular psoriasis who had been
taking ciclosporin 200 mg daily had a considerable rise in her ciclosporin
blood levels to 540 micrograms/L when the dosage was raised to 300 mg
daily and etretinate 50 mg daily was added. An interaction was suspected
as contributing to this effect because it was found possible to reduce the
ciclosporin dosage gradually to 150 mg daily (accompanied by a fall in
the trough ciclosporin blood levels to 168 micrograms/L), without any loss in
the control of the disease. However, only a modest ciclosporin dosage re-
duction was needed in another study when etretinate was given.

Other reports suggest successful and uncomplicated concurrent use.

There was no improvement when a patient with erythrodermic psoriasis
producing the dose of either drug resulted in exacerbation of symptoms. An-
with etretinate 700 micrograms/kg daily cleared the psoriasis by 90%
was given ciclosporin 5 to 10 mg/kg daily, but ciclosporin 5 mg/kg daily
other 5 patients with plaque-type psoriasis had a relapse when the
etretinate was stopped, and they also recommend that ciclosporin is taken at least 1 hour
before ciclosporin dosage in 3 instances before isotretinoin was start-

**Ciclosporin + Sevelamer**

One study suggests sevelamer does not appear to alter ciclosporin
levels, but a report describes markedly reduced ciclosporin levels in a patient who took sevelamer.

#### Clinical evidence, mechanism, importance and management

The pharmacokinetics of ciclosporin were unchanged in a study in 18 kid-
ney transplant patients taking ciclosporin, (with 9 patients also taking mycophenolate)
after they took sevelamer as a single 1.6- or 1.2-g dose and when sevelamer was given in the same dose, three times daily for
4 days. Eight of the patients were children (average age 12 years). How-
ever, the findings in this study have been criticised by other authors, who, in contrast, report a case of reduced ciclosporin levels in a liver transplant
patient. The patient had been stable taking ciclosporin 60 mg daily, but when she was given sevelamer 806 mg three times daily a dose increase to
85 mg daily was needed to maintain ciclosporin levels. This may be due to binding of sevelamer with ciclosporin in the gut preventing ciclosporin
absorption. The manufacturers of sevelamer recommend close monitor-
ing of ciclosporin levels with concurrent use or when sevelamer is stopped, and they also recommend that ciclosporin is taken at least 1 hour before or 3 hours after sevelamer.

**Ciclosporin + Sibutramine**

Ciclosporin is predicted to raise sibutramine levels. One case re-
port describes an increase in ciclosporin levels when a patient was changed from orlistat to sibutramine.

#### Clinical evidence, mechanism, importance and management

A kidney transplant patient taking ciclosporin 100 mg twice daily took or-
listat for 27 months with no problems or changes in her ciclosporin levels
or dosage reported. As orlistat was unsuccessful for weight reduction in this patient, sibutramine 10 mg daily was given instead. One week later
her trough ciclosporin level had increased from 79 to 152 nanograms/mL and her ciclosporin daily dose was reduced by 25 mg. Her ciclosporin lev-
el was still raised one week later at 162 nanograms/mL and her ciclosporin daily dose was again reduced by 25 mg. No increase in blood pressure or
serum creatinine occurred. Sibutramine is metabolised by the cytochrome P450 isoenzyme
CYP3A4 although it is not known to have any effects on this isoenzyme. Ciclosporin is also metabolised by CYP3A4 and the changes in levels seen

**Mechanism Uncertain.** An in vitro study using human liver microsomes found that concentrations of 100 micromol of acitretin, etretinate and isotretinoin in-
hibited the total ciclosporin metabolism and total primary ciclosporin me-
tabolite production to the same extent (32 to 45%). These figures suggest that the retinoids may inhibit ciclosporin metabolism. However, another in
vitro study using human liver microsomes did not find that etretinate in-
hibits the metabolism of ciclosporin.

**Importance and management**

The overall picture seems to be that etretinate has only a modest effect, or
no effect at all, on ciclosporin blood levels in most patients. Nevertheless,
this possible interaction is worth bearing in mind because of the possibility of
isolated cases of raised ciclosporin levels. There seems to be no marked
therapeutic advantage in using both drugs together for psoriasis. From the
cases presented, it is unclear if isotretinoin alters ciclosporin levels. In ad-
dition, it has been suggested that serum lipids should be monitored be-
cause both drugs can cause an increase. Acitretin (the major metabolite
of etretinate) probably behaves like etretinate, although this needs confir-
mation.

ful use of isotretinoin in a patient on cyclosporine: apparent lack of toxicity. Int J Dermatol
may therefore have been due to competition for metabolism. In contrast to what was seen in this case, the manufacturers predict that inhibitors of CYP3A4 (they name ciclosporin, but note that this drug does not usually interact by inhibiting this isoenzyme) may lead to an increase in levels of the active metabolite of sibutramine, but no effects on ciclosporin levels are expected.2

This appears to be the only case report of an increase in ciclosporin levels with sibutramine.1 However, orlistat has been reported to reduce ciclosporin absorption, and therefore levels, see ‘ orlistat’, (p.1042), so there is a possibility that the increase in ciclosporin levels was due to stopping orlistat rather than starting sibutramine, but this was not investigated.2

Ciclosporin + Somatostatin analogues

Octreotide causes a marked reduction in the blood levels of ciclosporin and inadequate immunosuppression may result. Lanreotide is predicted to interact similarly.

Clinical evidence

A diabetic man with kidney and pancreatic segment transplants was successfully immunosuppressed with azathioprine, methylprednisolone and ciclosporin. When he was also given subcutaneous octreotide 100 micrograms twice daily to reduce fluid collection around the pancreatic graft, his trough ciclosporin blood levels fell below the assay detection limit of 50 nanograms/mL. Serum creatinine increased dramatically, which was interpreted as a selective rejection episode of the kidney transplant. Nine other diabetics similarly treated with octreotide for peripancreatic fluid collection and fistulas after pancreatic transplantation also had significant falls in their ciclosporin blood levels within 24 to 48 hours, in 3 of them to undetectable levels.1 A similar interaction was seen in another patient.2

Mechanism

Uncertain. A suggestion is that the octreotide reduces the intestinal absorption of the ciclosporin.1,2

Importance and management

The interaction between octreotide and ciclosporin is established and clinically important, although the documentation is limited. The authors of one report recommend that before giving octreotide the oral dosage of ciclosporin should be increased on average by 50% and the serum levels monitored daily.1 The manufacturers of lanreotide say that, as with other somatostatin analogues, it may reduce the absorption of ciclosporin from the gut.3 As yet there appear to be no reports of this interaction in practice; however, it would be prudent to monitor the outcome of the use of lanreotide with ciclosporin.

Ciclosporin + SSRI s and related antidepressants

Four cases of raised ciclosporin levels have been seen in patients taking nefazodone and ciclosporin, one with raised creatinine levels and tremor, and one with raised liver enzymes. A small study found no evidence of an interaction between fluoxetine and ciclosporin although one case of increased ciclosporin levels has been seen with fluoxetine. Fluvoxamine may inhibit the metabolism of ciclosporin and one case of increased ciclosporin levels has been reported with fluvoxamine. The serotonin syndrome has been seen in a patient taking ciclosporin and sertraline. Limited evidence suggests that citalopram and sertraline do not alter ciclosporin levels.

Clinical evidence

(a) Citalopram

In 5 transplant patients the pharmacokinetics of ciclosporin were not significantly affected by citalopram 10 to 20 mg daily.1

(b) Fluoxetine

A small, retrospective study in 9 liver transplant and 4 heart transplant patients found no evidence that fluoxetine 5 to 20 mg daily increased ciclosporin blood levels.2 However, the ciclosporin blood levels of a heart transplant patient were doubled by fluoxetine 20 mg daily for 10 days. They fell when the ciclosporin dosage was reduced and needed to be increased again when the fluoxetine was stopped.3

(c) Fluvoxamine

A patient had increased ciclosporin blood levels and serum creatinine levels and fine tremor 2 weeks after starting fluvoxamine 100 mg daily, and the ciclosporin dosage was subsequently reduced by 33%.4

(d) Sertraline

A 53-year-old man taking ciclosporin following a renal transplant developed the serotonin syndrome 5 days after starting to take sertraline 50 mg daily. Ciclosporin is known to increase serotonin turnover within the brain, and so the reaction was attributed to an interaction between sertraline and ciclosporin.5 One report briefly mentions that a patient taking ciclosporin who had antidepressant medication switched from nefazodone to sertraline, because sertraline did not affect ciclosporin levels.6

(e) Nefazodone

A kidney transplant patient had a 70% rise in trough serum ciclosporin levels within 3 days of starting to take nefazodone 25 mg twice daily.7 Another kidney transplant patient had a two- to threefold rise in ciclosporin levels associated with raised creatinine levels and marked generalised tremors after starting nefazodone 100 mg twice daily. The patient was eventually stabilised on a 50% lower dose of ciclosporin.8 Similarly, a cardiac transplant patient taking ciclosporin had a tenfold increase in ciclosporin levels shortly after the addition of nefazodone 150 mg twice daily. Levels returned to baseline over 6 days after nefazodone was stopped.9 A patient taking nefazodone developed significantly raised liver enzymes AST and ALT one month after kidney transplantation. His ciclosporin level was high, at 614 nanograms/mL, and both ciclosporin and nefazodone were stopped. He had previously taken nefazodone unevenly, and subsequently took ciclosporin unevenly, so the raised liver enzymes were attributed to a pharmacokinetic interaction between the two drugs.8 However, note that nefazodone has generally been withdrawn due to its adverse effects on the liver.

Mechanism

Fluvaxamine and nefazodone are inhibitors of the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme by which ciclosporin is metabolised. Concurrent use can therefore lead to increased ciclosporin levels. Fluvoxamine may interact similarly. Citalopram and sertraline do not usually significantly inhibit CYP3A4 and would therefore not be expected to interact.

Importance and management

Although the evidence is limited, it appears that nefazodone can cause a marked rise in ciclosporin levels, with an increase in adverse effects. Alternative antidepressants should probably be used, or concurrent therapy very well monitored. Similar caution would seem prudent with fluvoxamine, and possibly fluoxetine. Citalopram, and sertraline do not appear to alter ciclosporin levels and may therefore be suitable alternatives. Serotonin syndrome is a rare adverse effect, usually associated with the use of more than one serotoninergic drug (see ‘The serotonin syndrome’, (p.9)).

Ciclosporin + Sucrose polyesters

Sucrose polyesters (e.g. Olestra) may reduce the bioavailability and peak levels of ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 7 kidney transplant patients aged 9 to 18 years, found that the addition of sucrose polyesters (Olestra), in a single 0.35-g/kg dose (maximum of 16 g) reduced the ciclosporin AUC and peak levels by almost 19% and 27%, respectively. Ciclosporin trough levels and elimination rate were not affected by Olestra. The reduced bioavailability was thought to be due to Olestra reducing the absorption of ciclosporin. Olestra is marketed as a non-absorbable, non-caloric fat ingredient in snack foods. The authors note that Olestra is mainly consumed by children and adolescents, with the age group of 13 to 17-year-olds being reported to eat 16.2 g of Olestra per snack, and therefore this interaction could be of particular significance for young transplant patients taking ciclosporin.1 However, note that changes in the AUC of ciclosporin of this size are very modest.

Ciclosporin + Sulfasalazine

An isolated report describes elevated ciclosporin levels in a kidney transplant patient that developed when sulfasalazine was stopped.

Clinical evidence

A patient with a kidney transplant was taking azathioprine, ciclosporin, prednisone and sulfasalazine 1.5 g daily. After initial adjustments the dose of ciclosporin remained at 480 mg daily for 8 months. The dose of prednisone was reduced and treatment stopped at 8 months, and azathioprine was stopped at 12 months without any need to adjust the ciclosporin dosage. Sulfasalazine was stopped 13.5 months after transplantation and the mean ciclosporin level increased from 205 nanograms/mL to 360 nanograms/mL within 5 days, and to 389 nanograms/mL after 10 days. The ciclosporin dosage was reduced over the following 2 months from 9.6 mg/kg to 5.6 mg/kg to maintain blood levels at about 200 nanograms/mL.1

Mechanism

Not understood. The time course of the interaction, noted after 5 days probably excludes decreased absorption. It is possible that the interaction is due to induction of the cytochrome P450 enzymes.

Importance and management

Information appears to be limited to this isolated case report. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Ciclosporin + Terbinafine

Terbinafine causes a small but usually clinically unimportant reduction in ciclosporin serum levels.

Clinical evidence, mechanism, importance and management

After taking terbinafine 250 mg daily for 6 to 7 days the mean AUC of a single 300-mg dose of ciclosporin was decreased by 13% and the maximum blood level was reduced by 14% in a study in 20 healthy subjects. It was suggested that as Sandimmun was used in the study, inter- and intra-individual variations in ciclosporin absorption caused these differences, rather than any drug interaction.1,2 Another study in 11 patients with kidney, heart or lung transplants found that terbinafine 250 mg daily for 12 weeks caused a small but clinically irrelevant decrease in serum ciclosporin levels.3 Another study in 30 kidney transplant patients taking ciclosporin and given terbinafine 250 mg daily for 6 to 12 weeks found no significant interaction and none of the patients required ciclosporin dose changes.4 Four kidney transplant patients taking ciclosporin were given terbinafine 250 mg daily for fungal skin and nail infections. Ciclosporin levels were reduced during concurrent treatment in all patients. However, in 3 of the patients ciclosporin levels remained within the therapeutic range and therefore no dose adjustment was made. One patient required an increase in the ciclosporin dose to maintain levels within the therapeutic range, and then a reduction in dose on stopping terbinafine.5 These studies broadly confirm previous in vitro work with human liver microsomal enzymes, which found that terbinafine either does not inhibit ciclosporin metabolism or only causes modest inhibition.6–8 In general, the changes in the

Clinical evidence

A study in 120 heart transplant patients found that sulfinpyrazone 200 mg daily was effective in the treatment of hyperuricaemia. The mean uric acid over 4 to 8 months fell by 22%, from 0.51 to 0.4 mmol/L, but unexpectedly the mean trough ciclosporin levels fell by 39%, from 183 to 121 micrograms/L, despite a 7.7% increase in the ciclosporin daily dosage. Two of the patients developed rejection: one after 4 months of taking sulfinpyrazone when the ciclosporin levels fell to 50 micrograms/L, and the other after 7 months of taking sulfinpyrazone, when the ciclosporin levels fell to 20 micrograms/L.1

Another report describes a patient who needed unusually high doses of ciclosporin while taking sulfinpyrazone,2 while yet another report describes increased ciclosporin levels in a patient taking sulfinpyrazone. In this latter case there is the possibility that it may have been an artefact due to interference with the assay method.3

Mechanism

Not understood.

Importance and management

Information appears to be limited to these reports but the interaction would seem to be established and clinically important. If sulfinpyrazone is added to established treatment with ciclosporin, be alert for the need to raise the ciclosporin dosage. The mean fall in trough ciclosporin levels seen in the major study cited was 39%.1 This study does comment on how quickly this interaction develops but the two cases of transplant rejection occurred after 4 months and 7 months, which implies that it can possibly be slow. Long-term monitoring would therefore be a prudent precaution. The authors of this report say that sulfinpyrazone is an effective alternative to allopurinol and no additional adverse effects occur including myelotoxicity when it is used with azathioprine.

Ciclosporin + Sucrose polyesters

Sulfinpyrazone can reduce ciclosporin levels and episodes of transplant rejection have resulted.
pharmacokinetics of ciclosporin appear to be clinically unimportant. However, patients whose ciclosporin levels are at the lower end of the therapeutic range should be closely monitored if they are given terbinafine.3

Clinical evidence

The ciclosporin blood levels of a patient with nephrotic syndrome were roughly halved on two occasions when he was given ticlopidine 500 mg daily.2 Another two patients with kidney transplants had similar falls (one patient on two occasions) when ticlopidine 250 mg daily was given.2,3

Twelve heart transplant patients were given ticlopidine 250 mg twice daily. The mean whole blood trough ciclosporin levels were noted to be halved but the mean ciclosporin dosage was not altered over a 3-month period. The neutrophil, platelet and whole blood leucocyte counts and haemoglobin levels were not significantly altered, but adverse effects included epistaxis (1 patient), haematuria (1 patient), which both necessitated a 50% dosage reduction, and neutropenia (1 patient), which resolved when the ticlopidine was withdrawn.4

A later study by the same group in 20 heart transplant patients given ticlopidine 250 mg daily found that the bioavailability of the ciclosporin was not clearly altered by ticlopidine, although one patient was withdrawn from the study after 3 days because of a 60% fall in ciclosporin levels, attributed to poor compliance rather than an interaction. No clinically significant adverse haematological, biochemical or ECG or echocardiography changes occurred.5

Mechanism

Not understood.

Importance and management

Information appears to be limited to the reports cited. It appears that the occasional patient may unpredictably have marked reductions in ciclosporin blood levels. For this reason close monitoring of ciclosporin levels is needed, particularly when ticlopidine is first added, so that any problems can be quickly identified and any dosage alterations made as needed.

Ciclosporin + Ticlopidine

Three case reports describe marked falls in ciclosporin blood levels, and one study noted that trough ciclosporin levels were halved by ticlopidine. However, another study reported that ticlopidine did not affect ciclosporin bioavailability.

Clinical evidence

The ciclosporin blood levels of a patient with nephrotic syndrome were

Clinical evidence, mechanism, importance and management

To find out if the concurrent use of trimetazidine and ciclosporin was associated with any adverse effects, 12 kidney transplant patients taking ciclosporin were given trimetazidine 40 mg twice daily for 5 days. No changes in the pharmacokinetics of the ciclosporin were seen, and there were no alterations in interleukin-2 concentrations or soluble interleukin-2 receptors.1 An associated study by the same group of workers using two models (the lymphoproliferative response of normal human lymphocytes to phytohaemagglutinin and a delayed mouse hypersensitivity model) similarly found that trimetazidine did not interfere with the effects of ciclosporin.2 It was concluded on the basis of these two studies that the concurrent use of ciclosporin and trimetazidine need not be avoided.

Ciclosporin + Vitamins

In a single-dose study, the ciclosporin AUC was increased by vitamin E, while in another study vitamin E decreased the ciclosporin AUC. Ciclosporin levels were also reduced by vitamin C and vitamin E with or without betacarotene.

Clinical evidence and mechanism

Ten healthy subjects were given a single 10-mg/kg oral dose of ciclosporin with and without a 0.15 mL/kg oral dose of vitamin E (d-alpha tocopheryl polyethylene glycol 1000 succinate: Liqui-E). The AUC of the ciclosporin increased by 60%, and it was suggested that absorption was increased due to improved solubilisation and micelle formation within the gut, or that decreased intestinal metabolism occurred.1 In contrast, another study in 12 healthy subjects found that vitamin E 800 units daily for 6 weeks reduced the AUC of a single 5-mg/kg dose of ciclosporin by 21%.2

A study in 10 kidney transplant patients taking ciclosporin found that the addition of an antioxidant vitamin supplement for 6 months containing vitamin C 500 mg, vitamin E 400 units and betacarotene (vitamin A precursor) 6 mg daily reduced the ciclosporin blood level by 24%. An associated improvement in renal function, indicated by an increase in glomerular filtration rate (GFR) of 17%, was also seen and may have been associated with reduced ciclosporin levels. The reason for the reduction is unclear.3 A study in 56 kidney transplant patients taking ciclosporin with vitamin C 1000 mg daily and vitamin E 300 mg daily found that ciclosporin levels were significantly lower in the vitamin-treated group when compared with a placebo group. A reduction in serum creatinine was also seen.4

Importance and management

The clinical significance of these studies is unclear as there appear to be no published case reports of any adverse effects due to this interaction. However, in some patients, changes in ciclosporin levels may significantly affect ciclosporin immunosuppression, and dose modification may be required. Patients should be questioned about their intake of vitamin sup-
plements before starting or when taking ciclosporin, particularly if a sudden or unexplained reduction in stable ciclosporin levels occurs. More study is needed, particularly with regard to the concurrent use of standard, commercially available multivitamin preparations.

4. de Vries APJ, Oterdoom LH, Gans ROB, Bakker SJL. Supplementation with anti-oxidants for an extended period.1 Another study found a fourfold increase in dexamethasone clearance in 10 patients taking aminoglutethimide 1 g daily.2

### Corticosteroids + Antimicrobial Therapy

Corticosteroids + Aminoglutethimide

The effects of dexamethasone, but not hydrocortisone, can be reduced or abolished by aminoglutethimide.

#### Clinical evidence

(a) Dexamethasone

Aminoglutethimide 500 to 750 mg daily reduced the half-life of dexamethasone 1 mg from 264 to 120 minutes in 6 patients.3 In another 22 patients it was found that larger doses of dexamethasone (1.5 to 3 mg daily) compensated for the increased dexamethasone metabolism caused by aminoglutethimide and complete adrenal suppression was achieved over a prolonged period.4 Another study found a fourfold increase in dexamethasone clearance in 10 patients taking aminoglutethimide 1 g daily.2

A patient, dependent on dexamethasone due to brain oedema caused by a tumour, deteriorated rapidly, with headache and lethargy, when aminoglutethimide was also given. The problem was solved by withdrawing the aminoglutethimide and temporarily increasing the dexamethasone dosage from 6 to 16 mg daily.3

(b) Hydrocortisone

One study found that aminoglutethimide did not affect the response to hydrocortisone, and that hydrocortisone 40 mg was adequate replacement therapy in patients taking aminoglutethimide 1 g daily. In this study, aminoglutethimide did not affect the half-life of 1H-prednisolone, which suggests that it does not affect hydrocortisone metabolism.2 Hydrocortisone 30 mg daily is normally adequate replacement in patients taking aminoglutethimide.4

#### Mechanism

Aminoglutethimide is an enzyme inducer and it seems likely that it interacts by increasing the metabolism and clearance of dexamethasone by the liver, thereby reducing its effects.5

#### Importance and management

Information is limited but the interaction between dexamethasone and aminoglutethimide is established. The reduction in the serum corticosteroid levels can be enough to reduce or even abolish the effects of corticosteroid replacement therapy1 or to cause loss of control of a disease condition.3 This has been successfully accommodated by increasing the dosage of the dexamethasone. Hydrocortisone is routinely used with aminoglutethimide as replacement therapy, and would seem to be a suitable alternative to dexamethasone, where clinically appropriate. Other synthetic corticosteroids are predicted to interact in the same way as dexamethasone, but this needs confirmation.

Corticosteroids + Antithyroid drugs

Prednisolone clearance is increased by the use of carbimazole or thiamazole.
Clinical evidence
A comparative study was conducted in:
A. 8 women taking levothyroxine with thiamazole 2.5 mg daily or carbi-
mazol 5 mg daily for Graves’ ophthalmology,
B. 6 women taking levothyroxine who had undergone subtotal thyroid-
ectomy, and
C. 6 other healthy women.
All were euthyroid. It was found that the clearance of a 540 microgram/kg
Dose of intravenous prednisolone in those in group A was much greater
than in groups B and C (0.37, 0.24 and 0.2 L/h.kg respectively). After
6 hours the plasma prednisolone levels in group A were only about 10% of
those in the healthy women (group C) and was undetectable after 8
hours, whereas total and unbound prednisolone levels were much higher
and measurable over the 10 hour study period in groups B and C.1
In another group of previously hyperthyroid patients, now euthyroid be-
cause of carbimazole treatment, the total prednisolone clearance was
0.4 L/hour.1

Mechanism
Not established. It seems possible that the thiamazole and carbimazole
increase the metabolism of the prednisolone by the liver microsomal en-
zymes, thereby increasing its clearance.

Importance and management
Direct information seems to be limited to this study, although the authors
point out that there is a clinical impression that higher doses of prednisolo-
ne are needed in patients with Graves’ disease. Be alert for the need to use
higher doses of prednisolone in patients taking either thiamazole or carbi-
mazol. Also note that a hypothyroid state may increase corticosteroid ef-
facts, and thus corticosteroids are cautioned in hypothyroid patients.

Corticosteroids + Aprepitant
In the short-term, aprepitant increases the plasma levels of dexam-
ethasone and methylprednisolone.

Clinical evidence
(a) Dexamethasone
In a crossover study in 20 subjects, aprepitant 125 mg on day one, and
80 mg on days 2 to 5 given with a standard dexamethasone regimen
(20 mg on day one, and 8 mg on days 2 to 5) increased the dexamethasone
AUC by 2.2-fold. When the same dose of aprepitant was given with a re-
duced-dose dexamethasone regimen (12 mg on day one, and 4 mg on days
2 to 5), the AUC of dexamethasone was similar to that seen with the stand-
ard dexamethasone regimen given alone. All regimens in this study also
included intravenous ondansetron 32 mg on day one.1

(b) Methylprednisolone
In a crossover study in 10 subjects, aprepitant 125 mg on day one, and
80 mg on days 2 and 3, given with a methylprednisolone regimen (125 mg
intravenously on day one, and 40 mg orally on days 2 and 3), increased the
AUC of methylprednisolone by 1.3-fold on day one and 2.5-fold on
day 3.1

Mechanism
Aprepitant is a moderate inhibitor of the cytochrome P450 isoenzyme
CYP3A4, and probably raises levels of these corticosteroids in the short-
term by inhibiting their metabolism via CYP3A4. However, if the corti-
coesteroids were given longer term, at later time points within 2 weeks after
starting aprepitant, an inductive effect on CYP3A4 may occur; see ‘Ben-
zodiazepines + Aprepitant’, p.721 for a more detailed explanation.

Importance and management
An established interaction of clinical importance. The manufacturer recom-
Mend that the usual dose of dexamethasone should be reduced by
about 50% when given with aprepitant (although note that the dose given
in the manufacturers dexamethasone/aprepitant antiemetic regimen ac-
counts for the interaction). In clinical studies a dexamethasone regimen of
12 mg on day one and 8 mg on days 2 to 4 was used, and this is the rec-
ommended regimen. The manufacturer recommends that the usual dose of
intravenous methylprednisolone should be reduced by 25%, and the usual
oral dose by 50%, when given with aprepitant. However, the manufacturer
also notes that during continuous treatment with methylprednisolone, cor-
ticosteroid levels would be expected to decrease at later time points within
2 weeks of starting aprepitant and the effect is expected to be greater if
methylprednisolone is given orally rather than intravenously.

1. Legler UF. Impairment of prednisolone disposition in patients with Graves’ disease taking me-

Corticosteroids + Azaoles; Itraconazole
There is some evidence to suggest that itraconazole can increase the
levels and/or effects of inhaled budesonide, the active metab-
olite of ciclesonide, deflazacort, dexamethasone and methylpred-
isolone, and, to a lesser extent, prednisolone and prednisone. A
few case reports describe the development of secondary Cushing’s syndrome in patients taking itraconazole and budesonide,
fluticasone and deflazacort.

Clinical evidence
(a) Budesonide
A 70-year-old patient receiving long-term treatment for asthma, which in-
cluded inhaled budesonide 1.2 to 1.6 mg daily and diltiazem, developed
Cushing’s syndrome after taking itraconazole 200 mg twice daily for
8 weeks for a fungal infection of the skin and subcutaneous tissues. Corti-
coesteroid levels may already have been increased by the use of ‘diltiazem’,
(p.1054), with the effects becoming more pronounced after starting irra-
conazole. Budesonide and itraconazole were discontinued but she subse-
quently required long-term oral hydrocortisone for secondary adrenal
insufficiency. A recurrence of the fungal infection was treated with vori-
conazole 200 mg twice daily, which appeared not to interact with the oral
hydrocortisone.5

Two other reports describe the development of Cushing’s syndrome in
patients with cystic fibrosis given inhaled budesonide, and then itracon-
azole for bronchopulmonary aspergillosis.2 One patient was also taking
carbimazole, which may have contributed to the increased budesonide
levels (see also ‘Corticosteroids + Macrolides’, p.1056). The other patient
was a 4-year-old boy who developed Cushing’s syndrome 2 weeks after
starting treatment with itraconazole 200 mg daily and inhaled budesonide
400 micrograms daily.3

In a double-blind, randomised, crossover study, 10 healthy subjects were
given 1 mg of inhaled budesonide over a period of 2 minutes after taking
itraconazole 200 mg daily for 5 days. The AUC of budesonide was
increased 4.2-fold by the itraconazole, and the plasma cortisol levels of the
patients were suppressed, indicating an increased budesonide effect.4 An-
other study compared the results of the ACTH (tetracosactide) test in 25
patients taking itraconazole 400 to 600 mg daily and high-dose inhaled
budesonide 800 micrograms to 1.6 mg daily with patients receiving either
drug alone. Adrenal insufficiency was detected in 44% of those treated
with both drugs, but in none of the patients taking itraconazole or budeso-
nide alone.5

(b) Ciclesonide
The manufacturer notes that giving itraconazole with ciclesonide may
increase serum levels of the active metabolite of ciclesonide (seen with ke-
toconazole) and that the risk of adverse effects such as Cushing’s syn-
drome may be increased.6

(c) Deflazacort
A patient with cystic fibrosis taking deflazacort developed Cushing’s syn-
drome soon after starting itraconazole 200 mg twice daily. The effects
gradually disappeared when the itraconazole was stopped.7

February 2007.

1050 Chapter 29
(d) Dexamethasone

A study in 8 healthy subjects found that itraconazole 400 mg for one day and then 200 mg daily for the next 3 days, increased the AUC of a single 48-mg dose of methylprednisolone by more than 2.5-fold.11 Other studies in healthy subjects have found that itraconazole decreases the clearance, and increases the elimination half-life and AUC of both oral and inhaled budesonide. Enhanced adrenal suppression also occurred.11,17

A man with a lung transplant taking methylprednisolone, ciclosporin and azathioprine was given itraconazole 200 mg twice daily to treat a suspected Aspergillus fumigatus infection. Three weeks later signs of corticosteroid toxicity developed, namely myopathy (confirmed by electromyography) and diabetes mellitus. Ten days after stopping the itraconazole the muscle force had improved and the daily dose of insulin had decreased from 120 to 20 units.14

(g) Prednisolone or Prednisone

Six patients with allergic bronchopulmonary aspergillosis (3 with underlying cystic fibrosis and 3 with severe asthma) were given itraconazole 200 mg twice daily for 1 to 6 months. Four of the patients also taking systemic prednisone were able to reduce the corticosteroid dosage by 44% (from 43 to 24 mg daily) without any clinical deterioration.15

Another study found no clinically significant pharmacokinetic interaction between itraconazole (400 mg on day one then 200 mg daily for 3 days) and a single 60-mg dose of prednisone in healthy subjects.15

A study in 10 healthy subjects found that itraconazole 200 mg daily for 4 days increased the AUC of a single 20-mg oral dose of prednisolone by 24%, but this was considered to be of limited clinical significance.16

Mechanism

It seems probable that the itraconazole inhibits the metabolism of these corticosteroids by the cytochrome P450 isoenzyme CYP3A4 in the liver leading to higher levels and therefore increased effects. The active metabolite of ciclesonide is also metabolised by CYP3A4.6 Prednisolone is less likely than methylprednisolone to interact with CYP3A4 inhibitors.16

Importance and management

These interactions appear to be established. There is currently too little data to assess the incidence, but it would be prudent to monitor the outcome of adding itraconazole to any patient taking deflazacort, dexamethasone or methylprednisolone, being alert for the need to reduce the steroid dosage. The manufacturers of ciclesonide suggest that the concurrent use of itraconazole should be avoided unless the benefits outweigh the risks.16

Adrenal function should also be monitored in patients receiving inhaled budesonide or fluticasone given itraconazole, as Cushing’s syndrome has been reported in a few patients during concurrent use. Itraconazole appears to interact with prednisone and prednisolone to a lesser extent, but the effects may still be clinically important in some patients. Information about other corticosteroids is lacking but good monitoring seems advisable with all of them.1

Ketoconazole reduces the metabolism and clearance of methylprednisolone. Ketoconazole may increase levels of the active metabolite of ciclesonide. Ketoconazole modestly increases the systemic effect of inhaled budesonide and possibly fluticasone, and markedly increases the AUC of oral budesonide. The situation with prednisone and prednisolone is uncertain: studies have shown some moderate pharmacokinetic effects, but this does not appear to alter the action of either drug.

Clinical evidence

(a) Budesonide

Sixteen healthy subjects were given a single 1-mg inhaled dose of budesonide after taking ketoconazole 200 mg daily for 2 days. Plasma cortisol levels and urinary cortisol excretion were used as a measure of how much budesonide was absorbed systemically, and ketoconazole was found to cause a 37% decrease in the AUC_0-24 of cortisol.1

Another study in 8 healthy subjects found that the AUC of a single 3-mg oral dose of budesonide was increased 6.5-fold when it was given with the last dose of ketoconazole 200 mg daily for 4 days. When budesonide was given 12 hours before the last dose of ketoconazole, the AUC was increased 3.8-fold.2

(b) Ciclesonide

The manufacturer notes that the use of ketoconazole with ciclesonide increase the serum levels of the active metabolite of ciclesonide 3.5-fold and that an increased risk of adverse effects such as cushingoid syndrome cannot be excluded.3

(c) Fluticasone

Sixteen healthy subjects were given a single 500-microgram inhaled dose of fluticasone after taking ketoconazole 200 mg daily for 2 days. Plasma cortisol levels and urinary cortisol excretion were used as a measure of how much fluticasone was absorbed systemically, and it was found that ketoconazole had no effect on fluticasone absorption.1 However, the manufacturers of fluticasone cite a study in which the exposure to fluticasone was increased by 150% by ketoconazole, which resulted in reductions in plasma cortisol levels.4
In 6 healthy subjects ketoconazole 200 mg daily for 6 days increased the mean AUC of a single 20-mg intravenous dose of methylprednisolone by 135% and decreased the clearance by 60%. The 24-hour cortisol AUC was reduced by 44%. These findings were confirmed in another study by the same group of workers. In 10 healthy subjects ketoconazole 200 mg daily for 6 to 7 days caused a 50% rise in the levels of both total and unbound prednisolone, following a dose of either oral prednisone or intravenous prednisolone. In contrast, two other studies found that ketoconazole 200 mg daily for 6 days did not affect either the pharmacokinetics or the pharmacodynamics of prednisolone, as measured by the suppressive effects on serum cortisol, blood basophil and helper T-lymphocyte values of prednisolone.

Mechanism
Ketoconazole inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and liver so that the metabolism of some corticosteroids is reduced and therefore their levels increase. The active metabolite of ciclesonide is also metabolised by CYP3A4, and it may therefore be similarly affected.

Importance and management
The interaction between methylprednisolone and ketoconazole appears to be established and clinically important. A 50% reduction in the dose of methylprednisolone was recommended by the authors of one study. It has been pointed out that increased corticosteroid serum levels have an increased immunosuppressive effect, which may be undesirable in those with a fungal infection needing treatment with ketoconazole. The situation with prednisone and prednisolone is as yet uncertain, and more study is needed. The study using inhaled budesonide indicates that ketoconazole increases the systemic effect of inhaled budesonide. Some manufacturers recommend that if the combination cannot be avoided the interval between giving the two drugs should be as great as possible; in addition, a significant interaction may occur with oral budesonide: the effects of ketoconazole on budesonide may be reduced by about half by separating the administration of the two drugs by 12 hours. The manufacturers suggest reducing the oral budesonide dose if adverse effects occur.

The situation with inhaled fluticasone is less clear, with one study finding an effect and another finding no effect. The manufacturers of fluticasone suggest that caution is warranted and where possible long-term monitoring is needed and another finding no effect. The manufacturers of fluticasone propionate and budesonide recommend separating the time of administration.

Voriconazole increases plasma levels of prednisolone but not to a clinically significant extent. A case report notes that voriconazole appears not to interact with oral hydrocortisone.

Clinical evidence
In healthy subjects, voriconazole 200 mg twice daily for 30 days increased the maximum plasma levels and AUC of a single 60-mg dose of prednisolone by 11% and 34%, respectively. A patient who developed Cushing’s syndrome and secondary adrenal insufficiency during treatment with itraconazole and inhaled budesonide was given oral hydrocortisone replacement. The patient was then also given voriconazole 200 mg twice daily for 3 months without any apparent effects on the hydrocortisone.

Mechanism
Voriconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but its inhibitory effects are much less than those of itraconazole. Therefore voriconazole is less likely than ‘itraconazole’, but its inhibitory effects are much less than those of itraconazole. Voriconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but its inhibitory effects are much less than those of itraconazole. Voriconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but its inhibitory effects are much less than those of itraconazole.

Importance and management
No dosage adjustment of the corticosteroid is said to be necessary if voriconazole is given with prednisolone, and this also appears to be the case if voriconazole is given with hydrocortisone.

Corticosteroids + Barbiturates
The therapeutic effects of systemic dexamethasone, methylprednisolone, prednisone and prednisolone are decreased by phenobarbital. Other barbiturates, including primidone, probably interact similarly.

Clinical evidence
(a) Dexamethasone
A 14-year-old girl with congenital adrenal hyperplasia taking dexamethasone rapidly became over-treated (weight gain, signs of hypercortisolism) when treatment with phenobarbital was withdrawn. The patient was then also given dexamethasone and primidone for petit mal seizures.

(b) Methylprednisolone
Phenobarbital increased the clearance of methylprednisolone in asthmatic children by 209%.

(c) Prednisone or Prednisolone
Three prednisone-dependent patients with bronchial asthma taking prednisone 10 to 40 mg daily had a marked worsening of their symptoms within a few days of starting to take phenobarbital 120 mg daily. There was a deterioration in their pulmonary function tests (FEV₁) and a rise in eosinophil counts, all of which improved when the phenobarbital was stopped. The prednisone clearance was increased by the phenobarbital.

A group of 75 children with kidney transplants taking azathioprine and prednisone, the incidence of graft failure was increased in those taking phenobarbital 60 to 120 mg daily. Two of the 11 epileptic children were also taking phenytoin 100 mg daily. Another study in renal
transplant patients found that prednisolone elimination is increased by phenobarbital. 6
Nine patients with rheumatoid arthritis taking prednisolone 8 to 15 mg daily had strong evidence of clinical deterioration (worsening joint tenderness, pain, morning stiffness, fall in grip strength) when they took pheno- barbital for 2 weeks (plasma levels 0 to 86.2 micromol/L). The prednisolone half-life fell by 25%.7
In contrast, the prednisone requirements of children were unaltered when they took a compound preparation containing phenobarbital 24 mg daily.8

Mechanism
Phenobarbital is a recognised potent liver enzyme inducer that increases the metabolism of corticosteroids, thereby reducing their effects. Pharmaco- kinetic studies have shown that phenobarbital reduces the half-lives of these corticosteroids and increases their clearances by 40 to 209%.3,4,9 Primidone interacts in a similar way because it is metabolised in the body to phenobarbital.1

Importance and management
The interaction between the corticosteroids and phenobarbital is well doc- umented, well established and of clinical importance. Concurrent use need not be avoided but the outcome should be monitored. Increase the corticosteroid dosage as necessary. The extent of the increase is variable. Dexamethasone, hydrocortisone,10 methylprednisolone,3,6 prednisolone,4,5 and prednisone11 are all known to be affected. Prednisone and prednisolone appear to be less affected than methylprednisolone and may be preferred.3 Be alert for the same interaction with other corticosteroids and other bar- biturates, which also are enzyme-inducers, although direct evidence seems to be lacking. The dexamethasone adrenal suppression test may be expect- ed to be unreliable in those taking phenobarbital, just as it is with pheny- toin, another potent enzyme-inducer. See ‘Corticosteroids + Phenytin’, p.1059.

3. Falliers CJ. Corticosteroids and phenobarbital in asthma. J Clin Endocrinol Metab

Corticosteroids + Caffeine
The results of the dexamethasone suppression test can be falsified by the acute ingestion of caffeine but chronic caffeine use does not appear to have an effect.

Clinical evidence, mechanism, importance and management
In one study, 22 healthy subjects and 6 depressed patients were given a single 480-mg dose of caffeine or placebo at 2 pm following a single 1-mg dose of dexamethasone given at 11 pm the previous evening. Caffeine significantly increased the cortisol levels following the dexamethasone dose; cortisol levels taken at 4 pm were about 146 nanomol/L with caf- feine, compared with about 64 nanomol/L with placebo.1 Thus the equiva- lent of about 4 to 5 cups of coffee may effectively falsify the results of the dexamethasone suppression test. However, in a study in 121 patients with depression, there was no correlation between chronic low to high intake of caffeine (6 mg to 2.3 g daily) and cortisol levels at 8 am, 4 pm or 11 pm on the day after a 1-mg dose of dexamethasone given at 11 pm the previous evening. It was suggested that chronic caffeine intake produces tolerance to the effects of acute caffeine on the hypothalamic-pituitary-adrenal (HPA) axis.2

Corticosteroids + Carbamazepine
The clearance of dexamethasone, methylprednisolone and pred- nisolone is increased in patients taking carbamazepine, and the results of the dexamethasone suppression test may be invalid in those taking carbamazepine.

Clinical evidence
A study in 8 patients receiving long-term treatment with carbamazepine found that the elimination half-life of prednisolone was about 45 minutes shorter, and the clearance was 42% higher, than in 9 healthy subjects not taking carbamazepine.1

A study in asthmatic children found that carbamazepine increased the clearance of prednisolone by 79% and increased the clearance of meth- ylprednisolone by 342%.2 A patient taking carbamazepine and valproate required high-dose prednisolone (20 to 60 mg daily) for polymyalgia

Corticosteroids + Bile-acid binding resins
Colestyramine and possibly colestipol reduce the absorption of oral hydrocortisone. Colesterylamine does not appear to affect prednisolone absorption.

Clinical evidence
(a) Colesterylamine
In 10 healthy subjects, colesterylamine 4 g reduced the AUC of a 50-mg oral dose of hydrocortisone by 43%. Peak levels were reduced and delayed (by about 50 minutes).1 Two of the subjects were given both 4 g and 8 g of colesterylamine, and their AUCs were reduced by 47% and 59% by the 4-g dose and by 97% and 86% by the 8-g dose.1
In contrast, an 8-g dose of colesterylamine did not affect the bioavailability of prednisolone in 2 patients receiving long-term prednisolone.2
(b) Colestipol
A man with hypopituitarism taking hydrocortisone 20 mg each morning and 10 mg each evening became lethargic, ataxic, and developed head- aches (all signs of hydrocortisone insufficiency) within 4 days of starting to take colestipol 15 g three times daily for hypercholesterolaemia. He re-
rheumatics. It was noted that when carbamazepine was discontinued her response to prednisolone improve, allowing the dose to be reduced to 20 mg then 10 mg daily.3

A report describes two patients suspected of having Cushing’s syndrome because the overnight suppression test with dexamethasone 1 mg had not suppressed their cortisol levels. Further investigation found no clinical evidence of Cushing’s syndrome and the false-positive test results were attributed to the fact that both patients were taking carbamazepine 400 mg three times daily at the time of the test. The test was repeated in one patient 3 weeks after carbamazepine was stopped and it indicated normal cortisol suppression.4 A study in 8 healthy subjects found that, in the presence of carbamazepine 800 mg daily, the dosage of dexamethasone needed to suppress cortisol secretion (as part of the dexamethasone adrenal suppression test) was increased two to fourfold.5 A further study found that it took 2 to 13 days for false-positive results to occur after carbamazepine was started, and 3 to 12 days to recover when the carbamazepine was stopped.6

Mechanism

Carbamazepine induces liver enzymes, which results in the increased metabolism of the steroids.

Importance and management

Information is limited but the interaction appears to be established. Patients taking carbamazepine are likely to need increased doses of dexamethasone, methylprednisolone or prednisolone. Prednisolone is less affected than methylprednisolone and is probably preferred. The same interaction seems likely with other corticosteroids but more study is needed to confirm this. Note that hydrocortisone and prednisone are affected by another potent enzyme inducer, ‘phenobarbital’, (p.1052), and would therefore also be expected to interact with carbamazepine.

Corticosteroids + Diltiazem

Diltiazem increases the AUC of intravenous and oral methylprednisolone, but the clinical significance of this is unclear.

Clinical evidence

In a study, 5 healthy subjects were given diltiazem 180 mg daily for 4 days, with and without intravenous methylprednisolone 300 micrograms/kg (based on ideal body-weight) on day 5. Diltiazem increased the AUC of methylprednisolone by 50%, prolonged its half-life by 37% and reduced the methylprednisolone clearance by 33%. Although the morning cortisol concentration was only 12% of that during the placebo phase, overall the suppressive effects of methylprednisolone on cortisol excretion were unchanged.1 Another similar study in which patients were given diltiazem and a single 16-mg oral dose of methylprednisolone found much larger effects: the AUC of methylprednisolone was increased 2.6-fold, and the morning cortisol excretion was only 12% of that in the absence of diltiazem,2 suggesting an enhanced effect.

Mechanism

Diltiazem is an inhibitor of the cytochrome P450 isoenzyme CYP3A4. As methylprednisolone is metabolised by CYP3A4 any inhibition of its activity would be expected to raise methylprednisolone levels.1,2 It has been suggested that P-glycoprotein may also play a role.1,2 Inhibition of intestinal/hepatic CYP3A4 may increase the oral bioavailability of methylprednisolone, which could contribute to the pharmacokinetic differences seen in the interaction when methylprednisolone is given orally rather than intravenously.

Importance and management

Information about the interaction between diltiazem and methylprednisolone seems limited to these two studies, but the effect of concurrent use is clear. However, the clinical significance of the raised methylprednisolone levels has not been established. Monitoring for an increase in the adverse effects of methylprednisolone, as suggested by one of the authors, seems a prudent measure.1

Corticosteroids + Diuretics; Potassium-depleting

Since both corticosteroids and the loop or thiazide diuretics can cause potassium loss, severe depletion is possible if they are used together.

Clinical evidence, mechanism, importance and management

There seem to be no formal clinical studies about the extent of the additive potassium depletion that can occur when potassium-depleting diuretics and corticosteroids are given together but an exaggeration of the potassium loss undoubtedly occurs (e.g. seen with hydrocortisone and furosemide). One study looking at hypokalaemia with potassium-depleting diuretics found that corticosteroids were a significant risk factor for hypokalaemic events; 19.9% of patients taking a potassium-depleting diuretic developed hypokalaemia, whereas 31.1% of patients taking a potassium-depleting diuretic and a corticosteroid developed hypokalaemia.2 Hypokalaemia in patients taking potassium-depleting diuretics should be corrected before a corticosteroid is started. Concurrent use should be well monitored and the potassium intake increased as appropriate to balance this loss.

The greatest potassium loss occurs with the naturally occurring corticosteroids such as cortisone and hydrocortisone. Corticoterop (ACTH), which is a pituitary hormone, and tetracosactrin (a synthetic polypeptide) stimulate corticosteroid secretion by the adrenal cortex and can thereby indirectly cause potassium loss. Fludrocortisone also causes potassium loss. The synthetic corticosteroids (glucocorticoids) have a less marked potassium-depleting effect and are therefore less likely to cause problems. These include betamethasone, dexamethasone, prednisolone, prednisone and triamcinolone.

The potassium-depleting diuretics (i.e. loop diuretics or thiazide and related diuretics) are listed in ‘Table 26.1’, (p.944). Acelotazolamide, a weak diuretic, has also been predicted to cause hypokalaemia in the presence of corticosteroids. However, hypokalaemia seen with acetzolamide is rarely clinically significant, and therefore the risks are lower

Corticosteroids + Ephedrine

Ephedrine increases the clearance of dexamethasone.

Clinical evidence, mechanism, importance and management

Nine asthmatic patients had a 40% increase in the clearance and a similar reduction in the half-life of dexamethasone when they were given ephedrine 100 mg daily for 3 weeks.1 This would be expected to reduce the overall effects of dexamethasone, but this requires confirmation. Be alert
for any evidence that the dexamethasone effects are reduced if both drugs are given. It is not clear whether other corticosteroids behave similarly.

---

**Corticosteroids + Fluoxetine**

Fluoxetine does not affect the pharmacokinetics of prednisolone or its effects on cortisol suppression.

**Clinical evidence, mechanism, importance and management**

In healthy subjects, fluoxetine 20 mg daily for 5 days then 60 mg daily for 9 days did not significantly affect the pharmacokinetics of a single 40-mg dose of prednisolone succinate, given as an intravenous bolus, or the duration of cortisol suppression.1 Fluoxetine is a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6 but it also inhibits other isoenzymes including CYP3A4 and thus may inhibit the metabolism of corticosteroids that are CYP3A4 substrates. However, prednisolone is less likely than other corticosteroids, such as methylprednisolone, to interact with CYP3A4 inhibitors.2 No clinically important interaction is likely if prednisolone and fluoxetine are given concurrently. The situation with other corticosteroids that may be more likely to interact is not known. More study is needed.

---

**Corticosteroids + Glycyrrhizin (Liquorice)**

Glycyrrhizin can reduce the clearance of prednisolone.

**Clinical evidence, mechanism, importance and management**

A study in 6 healthy subjects found that after taking 50-mg oral doses of glycyrrhizin every 8 hours for 4 doses, followed by a bolus injection of prednisolone hemisuccinate 96 micrograms/kg, the AUC of total prednisolone was increased by 50% and the AUC of free prednisolone was increased by 55%.1 This confirms the findings of two previous studies in which the glycyrrhizin was given orally,1 or by intravenous infusion,2 and one study where the route of administration is not clear.2 A study that included 4 patients taking hydrocortisone found glycyrrhizin also increased the corticosteroid AUC and half-life.3

The probable reason for this reaction is that glycyrrhizin inhibits the metabolism of prednisolone by the liver. In one of the studies it was also found that glycyrrhizin increased the effects of prednisolone in some patients with rheumatoid arthritis and polyarteritis nodosa.4

The clinical importance of these observations is uncertain, but some increase in effects may be beneficial whereas excess effects may be toxic. Concurrent use should be well monitored.

---

**Corticosteroids + Grapefruit juice**

Grapefruit juice increases plasma levels of methylprednisolone and is predicted to increase plasma levels of rectal budesonide. Grapefruit juice does not affect the pharmacokinetics of prednisone or prednisolone.

**Clinical evidence, mechanism, importance and management**

(a) Budesonide

One of the manufacturers of rectal budesonide predict that grapefruit juice will increase budesonide levels and therefore advise that concurrent use should be avoided. Even though budesonide plasma levels are higher after rectal use than after oral or inhaled use, this seems a very cautious approach.1

(b) Methylprednisolone

In a crossover study, 10 healthy subjects were given either double-strength grapefruit juice 200 mL, or water, three times daily for 2 days. On day 3, grapefruit juice 200 mL of water was given with, and 30 and 90 minutes after, a single 16-mg dose of methylprednisolone. Grapefruit juice increased the AUC and peak plasma level of methylprednisolone by 75% and 27%, respectively. The time to reach peak levels was increased from 2 to 3 hours and the elimination half-life was increased by 35%. Plasma cortisol levels after methylprednisolone was given with grapefruit juice or water were not significantly different, although grapefruit juice slightly decreased plasma cortisol levels before the morning dose of methylprednisolone. As the effects on plasma cortisol levels were slight this interaction is unlikely to be of clinical significance in most patients’ although the authors note that in some sensitive subjects large amounts of grapefruit juice might enhance the effects of oral methylprednisolone.2

---

**Corticosteroids + H2-receptor antagonists**

Cimetidine does not interact with prednisolone, prednisone or dexamethasone, and ranitidine does not interact with prednisone.

**Clinical evidence, mechanism, importance and management**

Prednisone is a pro-drug, which must be converted to prednisolone within the body to become active. A double-blind crossover study in 9 healthy subjects found that cimetidine 300 mg every 6 hours or ranitidine 150 mg twice daily for 4 days did not significantly alter the pharmacokinetics of prednisolone after a single 40-mg oral dose of prednisone.1 Another double-blind, crossover study found that cimetidine 1 g daily only caused minor changes in plasma prednisolone levels following a 10-mg dose of enteric-coated prednisolone.2 Similarly, another study found that cimetidine 600 mg twice daily for 7 days had no effect on the pharmacokinetics of a single 8-mg intravenous dose of dexamethasone sodium phosphate.3

There would therefore seem to be no reason for avoiding concurrent use. Information about other corticosteroids appears to be lacking, but no interaction is anticipated.

---

**Corticosteroids + Hormonal contraceptives and Sex hormones**

The serum levels of prednisone, prednisolone, cloprednol, methylprednisolone and possibly other corticosteroids are increased by oral contraceptives. In theory, both the therapeutic and toxic effects would be expected to be increased, but in practice it is uncertain whether these changes are important. Fluocortolone and oral budesonide levels were not affected by oral contracept-
tives. Prasterone did not affect the pharmacokinetics of prednisone or the effects of prednisolone on cortisol secretion. Progesterone appears not to affect the metabolism of prednisolone.

**Clinical evidence**

(a) Oral contraceptives

1. **Budesonide.** In 20 women taking an oral contraceptive (ethinylestradiol/desogestrel) the plasma levels of oral budesonide 4.5 mg daily for 7 days, and cortisol suppression were no different, when compared with 20 women not taking an oral contraceptive.1

2. **Cloprednol.** The clearance of cloprednol 20 mg was decreased by about one-third in 7 women taking an oral contraceptive (ethinylestradiol/norethisterone), when compared with women not taking an oral contraceptive.2

3. **Flucortolone.** A study in 7 women found that the pharmacokinetics of flucortolone 20 mg were unaffected by an oral contraceptive (ethinylestradiol/norethisterone).3

4. **Methylprednisolone.** A study in two groups of 6 patients found that the clearance of methylprednisolone was decreased to about half in the group taking oral contraceptives, when compared with the group not taking oral contraceptives. The oral contraceptive group were less sensitive to the suppressive effects of methylprednisolone on the secretion of cortisol, and had more suppression of basophils, but no changes in the T-helper cell response patterns.4

5. **Prednisolone or prednisone.** In a placebo-controlled study, 20 healthy women took an oral contraceptive (ethinylestradiol/desogestrel 30/150 micrograms) for at least 4 months before being given prednisolone 20 mg daily for 7 days. The prednisolone AUC and steady-state levels were 2.3-fold higher, when compared with those in 20 women not taking oral contraceptives.5 Several other studies have found similar results, with the prednisolone AUC increasing 1.6- to 6-fold,5,6 and the clearance reducing by about 35 to 85%5-10 in the presence of oral contraceptives containing ethinylestradiol or mestranol and various progestogens such as levonorgestrel, norgestrel and norethisterone. Similarly, a 2.3-fold increase in the AUC of prednisolone and a 45% decrease in its clearance was seen when prednisone was given to women taking an oral contraceptive.11

(b) Prasterone

In a study in 14 healthy women, prasterone 200 mg daily for one menstrual cycle (approximately 28 days) did not affect the pharmacokinetics of a single 20-mg dose of prednisone or its inhibition of cortisol secretion.12

(c) Progesterone

Intravenous and oral prednisolone was given to 6 post-menopausal women before and after they took progesterone 5 mg for 2 months. The pharmacokinetics of the prednisolone were not significantly altered.13

**Mechanism**

Not understood. The possibilities include a change in the metabolism of the corticosteroids, or in their binding to serum proteins.11 The absence of an interaction with progesterone suggests that the oestrogenic component of the oral contraceptives is possibly responsible for any interaction.13

**Importance and management**

It is established that the pharmacokinetics of some corticosteroids are affected by oral contraceptives, but the clinical importance of any such changes is not known. The therapeutic and adverse effects would be expected to be increased but there appear to be no clinical reports of adverse reactions arising from concurrent use. In fact the authors of one study9 concluded that women can be dosed similarly with methylprednisolone irrespective of oral contraceptive use. However, until more is known it would be prudent to bear this interaction in mind when using any corticosteroid and oral contraceptive together. Only prednisone, prednisolone, cloprednol and methylprednisolone have been reported to interact and other corticosteroids possibly behave similarly, the exception apparently being flucortolone and oral budesonide. Progesterone appears not to interact with prednisolone.

**Corticosteroids + Macrolides**

Troleandomycin and, to a lesser extent, clarithromycin and erythromycin can reduce the clearance of methylprednisolone, thereby increasing both its therapeutic and adverse effects. A patient receiving long-term clarithromycin developed Cushing’s syndrome after starting treatment with inhaled budesonide. There appears to be no pharmacokinetic interaction between erythromycin and inhaled ciclesonide. Similarly, prednisolone appears not to be affected by macrolides, except possibly in those also taking enzyme-inducers such as phenobarbital. Isolated case reports describe the development of acute mania and psychosis in two patients, apparently due to an interaction between prednisolone and clarithromycin.

**Clinical evidence**

(a) Budesonide

A 40-year-old woman with cystic fibrosis given clarithromycin 500 mg twice daily for 4 years for a *Mycobacterium abscessus* infection developed Cushing’s syndrome with adrenal suppression 6 weeks after starting to use inhaled budesonide 400 micrograms daily. A slow rise in morning free cortisol levels was found 4 weeks after stopping budesonide, but she died 8 weeks later of severe respiratory failure.1

(b) Ciclesonide

In a crossover study, healthy subjects were given a single 500-mg dose of erythromycin and inhaled ciclesonide 640 micrograms, alone or together. Concurrent use did not alter the pharmacokinetics of either drug.2

(c) Methylprednisolone

1. **Azithromycin.** A review by the manufacturers briefly mentions that azithromycin did not alter the pharmacokinetics of methylprednisolone.3

2. **Clarithromycin.** A study in 6 asthmatic patients found that clarithromycin 500 mg twice daily for 9 days reduced the clearance of a single dose of methylprednisolone by 65% and resulted in significantly higher plasma methylprednisolone levels.4

3. **Erythromycin.** A study in 9 asthmatic patients aged 9 to 18 found that after taking erythromycin 250 mg four times daily for a week, the clearance of methylprednisolone was decreased by 46% (range 28 to 61%) and the half-life was increased by 47%, from 2.34 to 3.45 hours.5

4. **Troleandomycin.** A pharmacokinetic study in 4 children and 6 adult corticosteroid-dependent asthmatics found that troleandomycin 14 mg/kg daily for one week increased the half-life of methylprednisolone by 88%, from 2.46 to 4.63 hours, and reduced the total body clearance by 64%. All 10 had cushingoid symptoms (cushingoid facies and weight gain), which resolved when the methylprednisolone dosage was reduced, without any loss in the control of the asthma.6 Another study found that the dose of methylprednisolone could be reduced by 50% in the presence of troleandomycin, without loss of disease control.7 Other studies have found similar effects.8-11 However, a randomised, placebo-controlled 2-year study found that although troleandomycin modestly reduced the required dose...
of methylprednisolone, this did not reduce corticosteroid-related adverse effects. A case report describes a fatal varicella infection attributed to the potentiation of steroid effects by troleandomycin.

(d) Prednisolone or Prednisone

1. Clarithromycin. A 30-year-old woman with no history of mental illness was treated for acute sinusitis with prednisone 20 mg daily for 2 days, followed by 40 mg for a further 2 days and clarithromycin 1 g daily. After 5 days she stopped taking both drugs (for unknown reasons), but a further 5 days later she was hospitalised with acute mania (disorganised thoughts and behaviour, pressured speech, increased energy, reduced need for sleep and labile effect). She spontaneously recovered after a further 5 days and had no evidence of psychiatric illness 4 months later. A 50-year-old man with emphysema was given prednisone 20 mg daily to improve dyspnoea. After about 2 weeks he was also given clarithromycin 500 mg twice daily for purulent bronchitis. Shortly afterwards his family noticed psychiatric symptoms characterised by paranoia, delusions and what was described as dangerous behaviour. He recovered following treatment with low-dose methylprednisolone dosage was possible within 2 weeks.

2. Troleandomycin. A study found that prednisolone clearance was not affected by troleandomycin in 3 patients, but was reduced by about 50% by troleandomycin in one patient who was also taking phenobarbital, which is an enzyme inducer.

Mechanism

What is known suggests that clarithromycin, erythromycin and troleandomycin can inhibit the metabolism of methylprednisolone. The volume of distribution is also decreased.

Importance and management

Information about the clarithromycin or erythromycin interactions with methylprednisolone is much more limited than with the interaction between troleandomycin and methylprednisolone, but they all appear to be established and of clinical importance. The effect should be taken into account during concurrent use and appropriate dosage reductions made to avoid the development of corticosteroid adverse effects. The authors of one study suggest that this reduction should be empirical, based primarily on clinical symptomatology. Another group found that a 68% reduction in methylprednisolone dosage was possible within 2 weeks.

Troleandomycin appears to have a greater effect than erythromycin or clarithromycin. Prednisolone seems not to interact with troleandomycin and may be a non-interacting alternative, except possibly in those taking enzyme-inducers (e.g. phenobarbital).

The evidence for the interaction leading to psychosis between prednisone and clarithromycin is limited and its general importance is uncertain, but prescribers should be aware of the reports of psychosis if both drugs are used together. Note that psychosis is a rare adverse effect of high-dose corticosteroids given alone.

One case report indicates that clarithromycin may enhance the effects of inhaled budesonide and although the authors suggest that prolonged use of clarithromycin and the terminal condition of the patient may have been factors, they advise close monitoring if the combination is used. Note that rectal budesonide produces higher plasma levels than the oral or inhaled use. The manufacturers of one UK rectal preparation advise that potent inhibitors of CYP3A4 (they name clarithromycin) should be avoided. However, given the evidence available, this seems a very cautious approach.

In general the concurrent use of corticosteroids and macrolides need not be avoided, but it would seem prudent to monitor for corticosteroid adverse effects and suspect an interaction if symptoms occur. 1

Corticosteroids + Mifepristone

The UK manufacturers of mifepristone say that the efficacy of corticosteroids (included inhaled corticosteroids) is expected to be reduced in the 3 to 4 days following the use of mifepristone, because of the antiglucocorticoid activity of mifepristone. Patients taking corticosteroids should be monitored during this time, and consideration given to increasing the corticosteroid dose. However, the US manufacturers contraindicate the use of mifepristone in those receiving long-term corticosteroid therapy.

Corticosteroids + Nefazodone

Nefazodone inhibits the metabolism of methylprednisolone and prolongs its effects on cortisol suppression.

Clinical evidence

In healthy subjects, nefazodone for 9 days (initial dose of 100 mg, increased to 150 mg, then 200 mg, twice daily) increased the AUC of a single 0.6-mg/kg intravenous dose of methylprednisolone by twofold and increased its half-life from 2.28 to 3.32 hours. Methylprednisolone clearance was decreased from 28.7 to 14.6 L/hour. The duration of cortisol suppression after methylprednisolone alone was 23.3 hours, which increased to more than 32 hours when nefazodone was also given.

Mechanism

Nefazodone probably inhibits methylprednisolone metabolism by cytochrome P450 isoenzyme CYP3A4.

Importance and management

At clinically relevant doses nefazodone decreases methylprednisolone clearance and significantly prolongs methylprednisolone induced cortisol...
suppression. Care is recommended during concurrent use. Note that ne-
fazodone has been generally withdrawn from the market.

Corticosteroids or NSAIDs alone may be risk factors for gastrointestinal bleeding and ulceration. The concurrent use of NSAIDs and corticosteroids increases the risk of gastrointestinal bleeding and probably ulceration. Ibuprofen, indometacin and naproxen may increase the levels of free prednisolone, and plasma levels of diclofenac are modestly increased by triamcinolone.

Clinical evidence, mechanism, importance and management

(a) Gastrointestinal bleeding and ulceration

A retrospective study of more than 20,000 patients who had received corticosteroids found that the incidence of upper gastrointestinal bleeding was no greater than in the control group who had not received corticosteroids (bleeds occurred in 95 patients compared with 91 patients). However, the risk of bleeding was increased if the patients were also taking aspirin or other NSAIDs. This is consistent with the results of another study in patients taking prednisone and indometacin.

A case control study reviewed 1415 patients aged 65 years or older, hospitalised between 1984 and 1986 for peptic ulcer or upper gastrointestinal haemorrhage of unknown cause, and 7063 control patients. The relative risk for the development of peptic ulcer disease was estimated to be 2 in those taking oral corticosteroids, and 4.4 in those taking corticosteroids with NSAIDs. It was estimated that patients taking corticosteroids with NSAIDs have a 15-fold greater risk for peptic ulcer disease than patients taking neither drug. Another study compared 1121 patients aged 60 or over who were admitted to hospital with bleeding peptic ulcers, with 989 control patients, to investigate factors other than NSAIDs that may have contributed to the risk of bleeding. The risk was threefold greater for the use of corticosteroids alone, but when corticosteroids were used with NSAIDs, the risk was tenfold greater.

NSAIDs alone increase the risk of gastrointestinal adverse effects. Most patients with NSAID-associated ulcers are elderly: this is because there is a greater prevalence of ulcer disease in the elderly, and they are more likely to be taking NSAIDs and be sensitive to them. A history of ulcer disease is a further risk factor. Corticosteroids alone are reported not to be a risk factor in some studies, while other studies found they were a risk factor for gastrointestinal adverse effects. However, several studies have found that the risk of gastrointestinal adverse effects is increased by the combined use of corticosteroids and NSAIDs and caution with concurrent use has been suggested. It may be prudent to consider the use of gastroprotection in patients taking NSAIDs and corticosteroids, especially if they are elderly.

Consider also *Aspirin or other Salicylates + Corticosteroids or Cortico-
tropin*, p. 136.

(b) Pharmacokinetic interactions

A patient with rheumatoid arthritis taking *prednisolone* 5 to 10 mg daily with an NSAID (aspirin 700 mg to 2.8 g daily, ibuprofen 400 mg to 1.2 g daily, or naproxen 250 to 500 mg daily) intermittently, developed osteonecrosis of the upper third of the femoral head that was attributed to increased free levels of *prednisolone* due to displacement by the NSAID. A study in 11 patients with stable rheumatoid disease regularly taking a corticosteroid found that *indometacin* 75 mg or naproxen 250 mg twice daily for 2 weeks did not alter the total plasma levels of a single 7.5-mg dose of *prednisolone* but the amount of unbound (free) *prednisolone* increased by 30 to 60%. The probable reason is that these NSAIDs displace both administered and endogenous corticosteroids from their plasma protein binding sites, although the clinical relevance of this change is unclear. In a double-blind, crossover study 12 healthy subjects were given *rofecoxib* 250 mg daily or placebo for 14 days, with a single 30-mg dose of either intravenous *prednisolone* or oral *prednisone* on days 10 and 14. *Rofecoxib* did not affect the pharmacokinetics of the corticosteroids, even in a dose 10 times greater than that used clinically.

In a double-blind, crossover study in healthy subjects given a single intramuscular dose of *diclofenac sodium* 75 mg alone and with triamcinolone diacetate 40 mg, the maximum plasma levels of *diclofenac* were increased by 24% by *triamcinolone*. This was possibly due to an increased rate of absorption but this is unlikely to be of clinical relevance. Other pharmacokinetic parameters of *diclofenac* were not significantly changed. The majority of these pharmacokinetic interactions seem unlikely to be of clinical significance, but they may well contribute to the adverse effects of both drugs, particularly the corticosteroids. No particular action appears to be necessary to account for these pharmacokinetic effects.

6.

Omeprazole had no effect on oral budesonide or prednisone pharmacokinetics in healthy subjects, but an isolated and unexplained report describes a reduction in the effects of prednisone in a patient taking omeprazole.

Clinical evidence, mechanism, importance and management

A placebo-controlled, randomised study in 18 healthy subjects found that omeprazole 40 mg daily had no effect on the pharmacokinetics of a single 40-mg dose of *prednisone*. This contrasts with an isolated and unexplained report of a patient suffering from pemphigus who was given *prednisone* 1 mg/kg daily with a week later, ranitidine 200 mg daily for a gastric ulcer. Four weeks later, when the skin lesions were well controlled, it was decided to replace the ranitidine with omeprazole 40 mg daily.

It would seem that adverse interactions between oral budesonide or prednisone and omeprazole are unlikely, but the isolated case should be borne in mind in the event of an unexpected response to treatment.

### Corticosteroids + Phenytoin

The therapeutic effects of dexamethasone, methylprednisolone, prednisolone, prednisone (and probably other glucocorticoids) and fludrocortisone can be markedly reduced by phenytoin. One study suggested that dexamethasone may modestly increase serum phenytoin levels, but another study and two case reports of patients with brain metastases suggest that an important decrease can occur. The results of the dexamethasone adrenal suppression test may prove to be unreliable in those taking phenytoin.

**Clinical evidence**

(a) Reduced corticosteroid levels

A comparative pharmacokinetic study in 6 neurological or neurosurgical patients taking oral dexamethasone and phenytoin found that the average amount of dexamethasone that reached the general circulation was a quarter of that observed in 9 other patients taking dexamethasone alone (mean oral bioavailability fractions of 0.21 and 0.84, respectively). Another report describes patients who needed increased doses of dexamethasone while taking phenytoin. The fludrocortisone dosages of two patients required 4-fold and 10- to 20-fold increases, respectively, in the presence of phenytoin. Renal allograft survival is decreased in patients taking prednisone and phenytoin, due (it is believed) to a reduction in the immunosuppressive effects of the corticosteroid.

Several studies suggest that phenytoin may affect the half-life and clearance of a number of corticosteroids. These are shown in ‘Table 29.2’, (see above).

(b) Interference with the dexamethasone adrenal suppression test

A study in 7 patients found that phenytoin 300 to 400 mg daily reduced the plasma cortisol levels in response to dexamethasone from 22 to 19 microgram%, compared with a reduction from 18 to 4 microgram% in the absence of phenytoin. Other studies confirm that plasma cortisol and urinary 17-hydroxycorticosteroids are suppressed far less than might be expected with small doses of dexamethasone (500 micrograms every 6 hours for 8 doses), but with larger doses (2 mg every 6 hours for 8 doses) suppression was normal. However, one case describes a patient in whom even 16 mg of dexamethasone failed to cause cortisol depression while she was taking phenytoin, but when she was re-tested in the absence of phenytoin only 1 mg of dexamethasone was needed to elicit a response.

(c) Serum phenytoin levels increased or decreased

A study into epilepsy prophylaxis post-trauma found that the serum phenytoin levels in those taking dexamethasone 16 to 150 mg (mean 63.6 mg) was 40% higher than those taking phenytoin alone (17.3 micrograms/mL compared with 12.5 micrograms/mL). The phenytoin was given as a loading dose of 11 mg/kg intravenously and then 13 mg/kg intramuscularly.

Conversely, a retrospective study of 40 patient records (diagnosis unspecified) indicated that dexamethasone reduced serum phenytoin levels: the serum phenytoin levels of 6 patients receiving fixed doses of phenytoin were halved by dexamethasone. Another report describes a patient with brain metastases who required over 8 mg/kg of phenytoin (600 mg) to achieve therapeutic phenytoin levels in the presence of dexamethasone 16 mg. When the dexamethasone was increased to 28 mg daily he experienced seizures, and an increase in his phenytoin dose from 600 mg to 1 g only resulted in an increase in his levels from 13.9 to 16.4 micrograms/mL. Another patient, also with a brain metastasis, needed a large dose of phenytoin (greater than 10 mg/kg) while taking dexamethasone. He had an almost fourfold rise in serum phenytoin levels when dexamethasone was stopped.

**Mechanism**

Phenytoin is a potent liver enzyme inducer that increases the metabolism of the corticosteroids so that they are cleared from the body more quickly, reducing both their therapeutic and adrenal suppressant effects.

**Importance and management**

The fall in serum corticosteroid levels is established and of clinical importance in systemic treatment, but it seems unlikely to affect the response to steroids given topically or by inhalation, intra-articular injection or enema. The interaction can be accommodated in several ways:

- Increase the corticosteroid dosage proportionately to the increase in clearance (see ‘Table 29.2’, (see above)). With prednisolone an average increase of 100% (range 58 to 260% in 5 subjects) proved effective.
- A fourfold increase may be necessary with dexamethasone, and much greater increases have been required with fludrocortisone.
- Exchange the corticosteroid for another that is less affected (see ‘Table 29.2’, (see above)). A switch from dexamethasone to equivalent doses of methylprednisolone has been reported to be effective but another report found that methylprednisolone was more affected than prednisolone.
- In another case the exchange of dexamethasone 16 mg daily for prednisone 100 mg daily was successful.
- Exchange the phenytoin for another antiepileptic: barbiturates (including primidone) and carbamazepine, are also enzyme-inducers, but valproate is a possible non-interacting alternative where clinically appropriate. However, remember that corticosteroids should only be given to epileptics with care and good monitoring because of the risk that they will exacerbate the disease condition.

The effects of phenytoin on the dexamethasone adrenal suppression test can apparently be accommodated by using larger than usual doses of dexamethasone (2 mg every 6 hours for 8 doses) or by an overnight test using 50 mg of hydrocortisone.
The reports on the changes in serum phenytoin levels are inconsistent (both increases and decreases have been seen). The effects of concurrent use should be closely monitored.

**Clinical evidence**

An HIV-positive 32-year-old man who had been using inhaled or intranasal fluticasone when ritonavir was also given. Ritonavir may reduce the clearance of prednisone, and ritonavir or nefilavir may increase levels of the active metabolite of ciclesonide. Dexamethasone may reduce the levels of indinavir and saquinavir.

**Mechanism**

Ritonavir, and all protease inhibitors, inhibit the cytochrome P450 isoenzyme CYP3A4 to varying degrees. Fluticasone is metabolised by this isoenzyme and therefore the protease inhibitors cause its plasma levels to rise. The active metabolite of ciclesonide is also metabolised by CYP3A4, and is therefore similarly affected.

**Importance and information**

Information and management are limited but the interaction between ritonavir and fluticasone appears to be an established and clinically important. The incidence is not known. Patients using these two drugs should be very well monitored for any signs of corticosteroid overdose. The problem may take months to manifest itself. It has been suggested that if an inhaled corticosteroid is required by a patient taking ritonavir, a corticosteroid with less systemic availability should be given at the lowest effective dose. The manufacturers of the fluticasone inhaled, and nasal spray advise against their concurrent use with ritonavir unless the potential benefit is considered to outweigh the risk of systemic corticosteroid adverse effects. Ritonavir may increase the levels of prednisone and some manufacturers of betamethasone, budesonide, ciclesonide, or dexamethasone predict a similar interaction with ritonavir or nefilavir.

Corticosteroids + Rifampicin (Rifampin)

The effects of systemic cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisone and prednisolone can be markedly reduced by rifampicin, but aldosterone appears not to be affected. Rifabutin and rifapentine are predicted to interact similarly, all to be it a lesser extent.

Clinical evidence

(a) Aldosterone

Seven patients with Addison’s disease due to tuberculosis had no changes in the pharmacokinetics of intravenous aldosterone after being given rifampicin 600 mg daily for 6 days.1

(b) Cortisone and fludrocortisone

A patient with Addison’s disease taking cortisone and fludrocortisone had typical signs of corticosteroid overdosage when the rifampicin he was taking was replaced by ethambutol,2 suggesting that the rifampicin reduces the levels of these corticosteroids. Another Addisonian patient needed an increase in her dosage of cortisone from 37.5 to 50 mg daily, plus fludrocortisone 100 micrograms daily, when rifampicin 450 mg daily was started.3 When rifampicin was added to prednisolone or dexamethasone and fludrocortisone it caused an Addisonian crisis in two patients.4

(c) Dexamethasone

Rifampicin markedly increases the clearance of dexamethasone.5,6 See also under (b) above.

(d) Hydrocortisone

A metabolic study in an Addisonian patient taking hydrocortisone found that rifampicin shortened its half-life and reduced its AUC.7

(e) Methylprednisolone, Prednisone or Prednisolone

A child with nephrotic syndrome taking prednisolone, and accidentally given a BCG vaccine, was given rifampicin and isoniazid to prevent possible dissemination of the vaccine. When the nephrotic condition did not respond, the prednisolone dosage was raised from 2 to 3 mg/kg daily without any evidence of corticosteroid overdosage. Later when the rifampicin and isoniazid were withdrawn, remission of the nephrotic condition was achieved with the original dosage of prednisolone.8 A number of other reports describe a reduction in the response to prednisone, prednisolone or methylprednisolone in patients given rifampicin.9-17 Pharmacokinetic studies in patients have shown that the AUC of prednisolone is reduced by about 60% by rifampicin, and its half-life is decreased by 40 to 60%.11,15,18

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of the corticosteroids by the liver,10,15 thereby decreasing their levels and reducing their effects.

Importance and management

The interactions between the corticosteroids and rifampicin are established, well documented and clinically important. The need to increase the dosages of cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone and prednisone should be expected if rifampicin is given. It has been suggested that as an initial adjustment the dosage of prednisolone should be increased two to threefold, and reduced proportionately if the rifampicin is withdrawn.10,11,18,20 The dosage increases needed for other corticosteroids await assessment. In the case of prednisolone the interaction develops maximally by 14 days and disappears about 14 days after withdrawal of the rifampicin.21 There seems to be no direct information about other glucocorticoids but be alert for them to be similarly affected. It is not clear whether any of the topically applied corticosteroids will interact with rifampicin but any clinically significant interaction would be expected to be very rare. The systemic corticosteroids are usually considered as contraindicated, or only to be used with great care, in patients with active or quiescent tuberculosis. There does not seem to be any information regarding the other rifamycins, rifabutin (a weak enzyme inducer) and rifapentine (a moderate enzyme inducer). However, the UK manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including corticosteroids,22,22 and therefore some caution is probably prudent.

Sucrafate

Sucrafate appears not to interact with prednisone.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects sucrafate 1 g every 6 hours had no significant effect on the pharmacokinetics of a single 20-mg dose of prednisone; however, the peak plasma levels were delayed by about 45 minutes when the drugs were given at the same time, but not when the sucrafate was given 2 hours after the prednisone.1 No particular precautions are likely to be needed in patients given both drugs. Information about other corticosteroids is lacking.

Corticosteroids + Vaccines; Live

Patients who are immunised with live vaccines while receiving immunosuppressive doses of corticosteroids may develop generalised, possibly life-threatening, infections.

Clinical evidence, mechanism, importance and management

The use of corticosteroids can reduce the number of circulating lymphocytes and suppress the normal immune response, so that concurrent immunisation with live vaccines can lead to generalised infection. It is suggested that prednisone in doses of greater than 10 to 15 mg daily will suppress the immune response, whereas 40 to 60-mg doses on alternate days probably does not, although this is debated.

A patient with lymphosarcoma and hypogammaglobulinaemia, taking prednisone 15 mg daily, developed a generalised vaccinal infection
when she was given smallpox vaccine. A fatal vaccinal infection developed following smallpox vaccination in another patient taking cortisone. This type of problem can be controlled with immunoglobulin to give cover against a general infection while immunity develops, and this has been successfully used in steroid-dependent patients needing smallpox vaccination.

The principles applied to smallpox may be generally applicable to other live attenuated vaccines (e.g. measles, mumps, rubella, poliomyelitis, BCG), but no studies seem to have been done to establish what is safe. It is generally accepted that patients taking immunosuppressants should not be given live vaccines. Problems with topical or inhaled steroids in normal situations may be a factor in fatal infection.

Dexamethasone does not affect the pharmacokinetics of valspodar. Valspodar modestly increases the AUC of dexamethasone.

Clinical evidence, mechanism, importance and management

In a crossover study healthy fasting subjects were given single doses of dexamethasone 8 mg and valspodar 400 mg either alone or together. Dexamethasone had no effect on the pharmacokinetics of valspodar. The AUC of dexamethasone was increased by 24% by valspodar. This change is modest and therefore dosage alterations are probably not required if concurrent use is of a short duration.

Corticosteroids + Zileuton

No clinically relevant pharmacokinetic interaction occurs between prednisone and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, crossover study, 16 healthy subjects were given zileuton 600 mg every 6 hours for a week, with either a 40-mg dose of prednisone or placebo on day 6. The pharmacokinetics of both drugs were slightly altered but this was not considered to be clinically relevant. The prednisone half-life increased from 2.8 to 2.9 hours, while the zileuton AUC and the time to achieve maximum serum levels were decreased by 13% and 26%, respectively. It was concluded that concurrent use carries a minimal risk of a clinically important pharmacokinetic interaction.

No special precautions would appear to be needed.

Daclizumab + Miscellaneous

No adverse drug interactions appear to have been reported with daclizumab, although its use with another antilymphocyte antibody in transplant patients receiving intensive immunosuppression may be a factor in fatal infection.

Clinical evidence, mechanism, importance and management

The manufacturers of daclizumab say that because it is an immunoglobulin, no metabolic drug interactions (i.e. those mediated by inhibitory or inducing effects on cytochrome P450 enzymes) would be expected, and none seems to have been reported. The manufacturers say that daclizumab has been given in clinical studies with the following drugs without any adverse interactions: aciclovir, azathioprine, antithymocyte immune globulin, cyclosporin, corticosteroids, ganciclovir, mycophenolate, mycophenolate mofetil and tacrolimus.

However, in one clinical study in heart transplant patients taking cyclosporin, mycophenolate, and corticosteroids, use of daclizumab with another antilymphocyte (such as muromonab-CD3 or antithymocyte immunoglobulin) appeared to be associated with a higher incidence of fatal infection: 8 of 40 patients died, compared with 2 of 37 who received an antilymphocyte and placebo. The manufacturer suggests that concurrent use of daclizumab with another antilymphocyte antibody in patients receiving intensive immunosuppression may be a factor leading to fatal infection. Caution may be warranted, and more study is needed.

Etanercept + Miscellaneous

An increased risk of serious infection and neutropenia is reported if etanercept is given with anakinra. A higher incidence of malignancies has been reported in patients with Wegener’s granulomatosis when given both cyclophosphamide and etanercept. No clinically significant pharmacokinetic interactions occur between etanercept and methotrexate. Etanercept did not affect the pharmacodynamics of warfarin. A reduced neutrophil count may occur in patients treated with etanercept and sulfasalazine. No interactions have been found when etanercept was given with salicylates (other than sulfasalazine), corticosteroids, or NSAIDs. Live vaccines should not be given to patients taking etanercept.

Clinical evidence, mechanism, importance and management

(a) Anakinra

In a study in patients with active rheumatoid arthritis taking etanercept and anakinra for up to 24 weeks, serious infections occurred in 7% of patients, compared with none in patients taking etanercept alone. Neutropenia occurred in 2% of patients taking both drugs. Infections are very common adverse effects of treatment with etanercept but serious infections are reported to be uncommon (occurring in about 1% of etanercept- and placebo-treated groups in clinical studies). Further, the combination of etanercept with anakinra has not increased clinical benefit and the manufacturers say that concurrent use is not recommended.

(b) Cyclophosphamide

The US manufacturers say that etanercept is not recommended in patients receiving cyclophosphamide. They state that in a study in patients with Wegener’s granulomatosis, the addition of etanercept to standard treatment, including cyclophosphamide, was associated with a higher incidence of non-cutaneous solid malignancies.

(c) Methotrexate

A double-blind study in 98 patients with rheumatoid arthritis receiving subcutaneous etanercept 25 mg twice weekly, or etanercept with oral methotrexate (median weekly dose of 20 mg) were randomly selected for a pharmacokinetic study from 682 patients in a clinical study. The pharmacokinetics of etanercept were not altered by concurrent methotrexate and no dosage adjustment is required during concurrent use.

(d) Sulfasalazine

A study in patients taking sulfasalazine found that when etanercept was also given, patients had a decrease in neutrophil counts, when compared to other groups of patients receiving either drug alone. The clinical significance is not known.
As no data are available on the secondary transmission of infection by live vaccines in patients receiving etanercept, the manufacturers recommend that live vaccines should not be given.1,2

(f) Other drugs

The UK manufacturers note that no interactions have been found when etanercept was given with corticosteroids, salicylates (except sulfasalazine, see under (e) above), NSAIDs or other analgesics.2

Everolimus + Itraconazole

Itraconazole significantly increases everolimus levels. A case report describes reduced everolimus clearance in a patient also given itraconazole. Pharmacokinetic modelling suggests that fluconazole will not interact with a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given a single 1-mg dose of everolimus on day 4 of an 8-day course of ketoconazole 200 mg twice daily. Ketoconazole increased the AUC, peak blood level and half-life of everolimus by 15-fold, 3.9-fold, and 1.9 fold, respectively.1 Similarly, a patient taking everolimus with ciclosporin and prednisone had a 74% decrease in everolimus clearance when itraconazole was given. However, in 16 patients, pharmacokinetic modelling suggested that everolimus clearance was reduced by a non-significant 7% when fluconazole was given.2 More study is needed to confirm this finding.

Patients who are given ketoconazole, and possibly any azole that is also a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, such as itraconazole, should have their everolimus levels monitored closely and dose adjustments made as required.1

Everolimus + Azoles

Ketoconazole significantly increases everolimus levels. A case report describes reduced everolimus clearance in a patient also given itraconazole. Pharmacokinetic modelling suggests that fluconazole will not interact with a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given a single 1-mg dose of everolimus on day 4 of an 8-day course of ketoconazole 200 mg twice daily. Ketoconazole increased the AUC, peak blood level and half-life of everolimus by 15-fold, 3.9-fold, and 1.9 fold, respectively.1 Similarly, a patient taking everolimus with ciclosporin and prednisone had a 74% decrease in everolimus clearance when itraconazole was given. However, in 16 patients, pharmacokinetic modelling suggested that everolimus clearance was reduced by a non-significant 7% when fluconazole was given.2 More study is needed to confirm this finding.

Patients who are given ketoconazole, and possibly any azole that is also a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, such as itraconazole, should have their everolimus levels monitored closely and dose adjustments made as required.1

Everolimus + Ciclosporin

Ciclosporin increases the AUC of everolimus. Everolimus appears to have no significant effects on ciclosporin levels.

Clinical evidence

(a) Effects on ciclosporin

In a placebo-controlled study in 54 kidney transplant patients taking ciclosporin (93% also taking prednisone), everolimus 0.75 mg to 10 mg daily in single or divided doses in 44 patients had no consistent, clinically significant effect on ciclosporin levels, when compared with the 10 patients given placebo, although because of wide interpatient variability, there is a possibility that a significant interaction could occur in some patients.1 Another study in 101 kidney transplant patients taking ciclosporin and prednisone with everolimus 0.5 to 2 mg twice daily for 1 year also found no evidence that everolimus affected ciclosporin pharmacokinetics.2

(b) Effects on everolimus

The possibility of a drug interaction was assessed in a crossover study in 24 healthy subjects who were given a single 2-mg dose of everolimus, alone and with single doses of ciclosporin, either Neoral (microemulsion) 175 mg or Sandimmune (corn oil suspension) 300 mg. Neoral increased the peak levels and AUC of everolimus by 82% and 168% respectively. Sandimmune did not affect the peak levels of everolimus but increased its AUC by 74%.3

Mechanism

Not fully understood. Both everolimus and ciclosporin are metabolised by the cytochrome P450 isoenzyme CYP3A4 and both are substrates of P-glycoprotein. Competition via one or both of these pathways in the liver or gut wall may contribute to the interaction.3

Importance and management

Information on the effects on everolimus levels when it is used with ciclosporin appear to be limited to the single-dose study.3 However, it has been suggested if ciclosporin (either Neoral or Sandimmune) is removed from an everolimus/ciclosporin regimen, a two- to threefold decrease in everolimus exposure could be expected. Monitoring is recommended.1 Note that sirolimus (of which everolimus is a derivative) interacts similarly, see ‘Sirolimus + Ciclosporin’, p.1072.

It would appear that, in general, everolimus has no clinically significant effects on the pharmacokinetics of ciclosporin.

Everolimus + Macrolides

Erythromycin increases everolimus levels. Other macrolides probably interact similarly.

Clinical evidence, mechanism, importance and management

Sixteen healthy subjects were given a single 4-mg dose of everolimus before and on day 5 of a 9-day course of erythromycin 500 mg three times daily. The peak blood levels and AUC of everolimus were increased twofold and 4.4-fold, respectively, and its half-life was prolonged by 39%. Erythromycin probably inhibited the metabolism of everolimus by the cytochrome P450 isoenzyme CYP3A4. There was wide inter-subject variability in the levels of erythromycin and therefore they could not be correlated with the extent of the interaction with everolimus. The authors recommend that appropriate everolimus dose reductions based on frequently monitored blood levels should be made when patients are given erythromycin.1 Other macrolides that inhibit CYP3A4 (such as clarithromycin and telithromycin, but not azithromycin) would be expected to interact similarly, and therefore concurrent use of these drugs with everolimus should also be monitored.

Everolimus + Rifampicin (Rifampin)

Rifampicin reduces the bioavailability and increases the clearance of everolimus.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects were given a single 4-mg dose of everolimus before and after taking rifampicin 600 mg daily for 7 days. Rifampicin increased the clearance of everolimus by 172%, and increased its AUC and peak blood levels by 63% and 58%, respectively, although there was a large inter-individual variation in the AUC. Induction of both cytochrome P450 isoenzymes CYP3A4 and P-glycoprotein (everolimus is metabolised by CYP3A4 and is a substrate for P-glycoprotein) by rifampicin may have increased metabolism and reduced the bioavailability of everolimus.1

Immunosuppressants 1063

Vaccines, live
known to interact. Monitor concurrent use for everolimus efficacy, anticipating the need to increase the dose of everolimus.

**Everolimus + Verapamil**

Increased levels of both everolimus and verapamil can occur on concurrent use.

**Clinical evidence, mechanism, importance and management**

A study in 16 healthy subjects given a single 2 mg dose of everolimus before and on day 2 of a 6-day course of verapamil 80 mg three times daily found that verapamil increased the AUC and peak blood level of everolimus by 3.5-fold and 2.3-fold, respectively. Everolimus also increased the plasma levels of verapamil by 2.3-fold.1

Verapamil is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme primarily involved in the metabolism of everolimus, and inhibits P-glycoprotein, a transporter for which everolimus is a substrate. Therefore concurrent use raises everolimus levels. It is not known exactly why verapamil levels are raised. This appears to be the only evidence for an interaction, but it is in line with the way these drugs are known to interact. If both drugs are given it would seem prudent to monitor everolimus blood levels as well as monitor for adverse effects due to verapamil, such as hypotension, flushing and oedema, and adjust the dose of both drugs as needed.

**Immunosuppressants + Vaccines**

The body’s immune response is suppressed by immunosuppressants such as ciclosporin, mycophenolate, sirolimus, and tacrolimus. The antibody response to vaccines may be reduced, although even partial protection may be of benefit. In general, the use of live attenuated vaccines is considered contraindicated because of the possible risk of generalised infection. Inactivated vaccines may be used.

**Clinical evidence**

(a) *Diphtheria, tetanus, and inactivated polio vaccines*

In organ transplant recipients taking immunosuppressants, tetanus vaccines1,2 and inactivated polio vaccines1 produced protective antibody titres. The response to diphtheria vaccine was lower than in healthy controls1 and the antibody titre had fallen below the protective level by 12 months in 38% of patients in one study,1 and 24% in another.2 Note that live polio vaccines are not recommended in immunosuppressed patients (see *Live vaccines*, below).

(b) *Hepatitis vaccines*

The antibody response to hepatitis *B* vaccine is generally poor in patients taking immunosuppressants after organ transplantation,3,4 although one research group reported a sustained antibody response in half of their patients,5 and an overall 85% seroconversion rate was seen in one study in children (aged between 4 and 16 years).6 In this latter study,6 children receiving *ciclosporin* monotherapy had a higher seroconversion rate (100%) than those receiving *ciclosporin* and *corticosteroids* (84%) and those receiving *ciclosporin, azathioprine*, and *corticosteroids* (66%).

The antibody response to hepatitis *A* vaccine in patients taking immunosuppressants after organ transplant is variable,7,8 and declines quicker than in healthy controls.7 In renal transplant recipients, there is some evidence that the response is inversely related to the number of immunosuppressant drugs.8

(c) *Influenza vaccine*

A number of studies have been published on the efficacy of influenza vaccination in organ transplant recipients taking immunosuppressants. Many have found a reduction in the proportion of patients developing a protective antibody titre compared with healthy control subjects,9,10 whereas some have found no reduction.11 A few studies have looked at the effects of individual drugs in the immunosuppressive regimen. In one comparative study in 59 kidney transplant patients, 21 patients taking *ciclosporin* and prednisone had a significantly lower immune response to influenza vaccine (inactivated trivalent) than 38 patients taking azathioprine and prednisone or 29 healthy subjects taking no drugs. All of the immune response measurements were reduced by 20 to 30% in those taking *ciclosporin*.13 In another study, 13 patients taking mycophenolate, *ciclosporin*, and prednisolone had a marked reduction in antibody response to influenza vaccine, when compared with 25 patients taking *ciclosporin, azathioprine* and prednisolone.14 In yet another study, patients receiving *ciclosporin* had lower antibody responses when compared with patients receiving tacrolimus.15 Patients given a higher dose of prednisolone per kg had a reduced antibody response to influenza vaccine in one study, and those given a daily dose had a reduced response, when compared with those given an alternate day schedule.16

Confirmation of the practical importance of the reduced antibody titre in some patients is described in a case report of a heart transplant patient taking *ciclosporin* who did not respond to influenza vaccination while taking *ciclosporin* and prednisone. He had two episodes of influenza, one serologically confirmed, and it was later shown that vaccination had not resulted in seroconversion.17 Similarly, a patient taking tacrolimus after a liver transplant developed influenza A myocarditis despite prophylactic vaccination.18

(d) *Live vaccines*

The use of live vaccines in patients receiving corticosteroids has caused generalised infection, see ‘Corticosteroids + Vaccines; Live’, p.1061. Similarly, the use of live vaccines in patients taking other immunosuppressants is not recommended: probably as a consequence of this there are few published reports about the use of live vaccines with immunosuppressants. One study found that measles vaccine was effective in 7 of 18 children under 3 years old after liver transplantation, and that there were no complications directly attributable to the vaccine.19

(e) *Pneumococcal vaccines*

Good responses to pneumococcal vaccines in patients taking immunosuppressant drugs after organ transplantation have been seen,20 but protective antibody titres may not persist as long as in healthy subjects.21

**Mechanism**

Immunosuppression by these drugs diminishes the ability of the body to respond immunologically both to transplants and to vaccination.

**Importance and management**

These are established and clinically important interactions. The UK Department of Health22 recommends the following:

- Live vaccines: patients taking immunosuppressant drugs such as ciclosporin, methotrexate, cyclophosphamide, leflunomide, and cytokine inhibitors should not be given live vaccines during or for up to 6 months after treatment has stopped, as they can cause severe or fatal infections.
- Inactivated vaccines: ideally should be given at least 2 weeks before immunosuppressive therapy is started.
- Bone marrow transplant patients may lose their antibodies against most diseases and should be considered for re-immunisation under specialist supervision.

The proportion of patients developing protective antibody titres to vaccines is often reduced in patients taking immunosuppressants. Nevertheless, for many vaccines, the reduced response seen is still considered clinically useful, and, for example, in the case of kidney transplant patients,23 and in patients who are immunosuppressed (either by drugs or disease), influenza vaccination is actively recommended.22,23 Pneumococcal vaccine should also be given to these patients. If a vaccine is given, it may be prudent to monitor the response, so that alternative prophylactic measures can be considered where it is considered inadequate. For influenza vaccine, one suggestion is that if patients remain unprotected after a single vaccination and a booster dose, amantadine 200 mg daily should be given during an influenza epidemic. It will protect against influenza A but not B infection.24 Note that, even where effective antibody titres are produced, these may not persist as long as in healthy subjects, and more frequent booster doses may be required.

There appears to be little published experience of the use of live vaccines in patients receiving immunosuppressants (apart from ‘corticosteroids’,
Infliximab + Miscellaneous

Live vaccines should not be given to patients undergoing treatment with infliximab. Serious infection and neutropenia is predicted to occur if infliximab is given with anakinra. Infliximab may increase serum levels of azathioprine metabolites, and a rare T-cell lymphoma has been reported in adolescents and young adults treated with infliximab and also given azathioprine or mercaptopurine. Serum levels of infliximab appear to be unaffected by aminosalicylates, corticosteroids, ciprofloxacin or metronidazole.

Clinical evidence, mechanism, importance and management

(a) Anakinra

Infliximab inhibits the activity of tumour necrosis factor (TNFα). In clinical studies the use of anakinra with another TNFα inhibitor, ‘etanercept’, (p.1062) has been associated with an increased risk of serious infection and neutropenia and no additional benefit, when compared to the use of these drugs alone.1,2 As a result of this the manufacturers of infliximab note that similar toxicity may occur if anakinra is given with infliximab and therefore advise against concurrent use.1,2

(b) Azathioprine or Mercaptopurine

In 32 patients with Crohn’s disease taking azathioprine (mean dose 2.81 mg/kg) and with stable levels of 6-tygouanine nucleotides (the active metabolites of azathioprine), infusions of infliximab 5 mg/kg over 2 hours resulted in a significant increase in 6-tygouanine nucleotide levels in 21 patients after 1 to 3 weeks, when compared to pre-infusion levels. The leukocyte count was significantly decreased and mean corpuscular volume increased. Significant increases in 6-tygouanine nucleotides were associated with good toleration and favourable response to infliximab. These changes were transient: levels returned to normal 3 months later.3 Although this study suggests that concurrent use did not result in adverse effects the manufacturers report that rare post-marketing cases of an aggressive and usually fatal hepatosplenic T-cell lymphoma have been reported in adolescent and young adult patients with Crohn’s disease treated with infliximab. All cases occurred in patients also receiving azathioprine or mercaptopurine. A causal relationship is unclear.1,2

(c) Vaccines (live)

As no data are available on the response to vaccination with live vaccines or on the secondary transmission of infection by live vaccines in patients receiving anti-TNF therapy, the manufacturers recommend that live vaccines should not be given concurrently with infliximab.1,2

(d) Miscellaneous

The manufacturers note that serum levels of infliximab appear to be unaffected by baseline use of medications to treat Crohn’s disease including aminosalicylates, ciprofloxacin, corticosteroids and metronidazole.2

The manufacturers say that clinically significant interaction occurs be-
tween leflunomide and cimetidine.1,2

The manufacturers say that corticosteroids may continue to be used if
leflunomide is given.1,2

The manufacturers advise caution if leflunomide is given with phenytoin
or tolbutamide.1 The reason is that the active metabolite of leflunomide
(A771726) has been shown by in vitro studies to be an inhibitor of the cy-
tochrome P450 isoenzyme CYP2C9, which is concerned with the metab-
of these two drugs. If this inhibition were to occur in vivo it could possibly
lead to a decrease in their metabolism and an increase in their tox-
icity. Although so far there appear to be no clinical reports of an inter-
action, the manufacturers made a similar prediction with warfarin, another
CYP2C9 substrate, which has, in isolated cases, been borne out in prac-
tice. See ‘Coumarins + Leflunomide’, p.423.

The manufacturers say that the concurrent use of leflunomide and other
DMARDS (they list azathioprine, chloroquine, hydroxychloroquine,
intramuscular or oral gold and penicillamine) has not yet been studied but
they say that combined use is not advisable because of the increased risk
of serious adverse reactions (haemo- or hepatotoxicity). As the active me-

leflunomide inhibits the activity of the cytochrome P450 isoenzyme
CYP2C9 in vitro and might therefore be expected to increase the serum
levels of NSAIDs that are metabolised by this isoenzyme (e.g.
diclofenac, ibuprofen) but the manufacturers say that no safety problems were seen in
clinical studies with leflunomide and NSAIDs. No special precautions
would seem to be needed if any of these or any other NSAID drugs are given
concurrently.1,2

When a single dose of leflunomide was given to subjects after taking mul-
tiple dose rifampicin, the peak levels of the active metabolite of leflun-
omide (A771726) were increased by 40% but the AUC was unchanged.1,2

The reasons are not understood. There would seem to be no reason for
avoiding concurrent use, but the manufacturers advise caution as A771721
levels may build up over time.2 It may be prudent to increase the frequency of
leflunomide monitoring if these two drugs are used together.

A 68-year-old woman who had been taking leflunomide 10 mg daily for
about 4 months was started on itraconazole 300 mg daily for a fungal in-
fection. About one month later her leflunomide dose was increased to
20 mg daily, and liver function tests were normal. The following month,
she developed abdominal pain, vomiting, and weakness. Despite sympto-
matic treatment and washout with colestyramine, fatal fulminant hepatic
failure occurred. The authors of the report attribute the reaction to additive
hepatotoxicity between the leflunomide and itraconazole.3 This interac-
tion serves to highlight the concerns about the use of other hepatotoxic
drugs, see (a) and (h).

No pharmacokinetic interaction was seen in patients taking methotrexate
(mean dose 17.2 mg per week) with leflunomide 100 mg daily for 2 days
as a loading dose followed by 10 to 20 mg daily.4 However, elevated liver
enzyme levels have been seen following concurrent use.1 By March 2001,
the European Agency for the Evaluation of Medicinal Products was aware of
129 cases of serious hepatic reactions in patients taking leflunomide,
and 78% of these were in patients concurrently treated with hepatotoxic
medications. In patients with elevated liver function tests, 58% were also
being treated with methotrexate and/or NSAIDS.5 Because of the possible
risks of additive or synergistic liver toxicity or haematotoxicity, particu-
larly when used long-term, the UK manufacturers say that the concurrent
use of methotrexate is not advisable.1 The US manufacturers say that if
concurrent use is undertaken, chronic monitoring should be increased to
monthly intervals.2 Close liver enzyme monitoring is also recommended if
switching between these drugs, and colestyramine or activated charcoal
washout should be performed when switching from leflunomide to meth-
отrexate.1,2

Leflunomide inhibits the activity of the cytochrome P450 isoenzyme
CYP2C9 in vitro and might therefore be expected to increase the serum
levels of NSAIDs that are metabolised by this isoenzyme (e.g. diclofenac,
ibuprofen) but the manufacturers say that no safety problems were seen in
clinical studies with leflunomide and NSAIDs. No special precautions
would seem to be needed if any of these or any other NSAID drugs are given
concurrently.1

When a single dose of leflunomide was given to subjects after taking mul-
tiple dose rifampicin, the peak levels of the active metabolite of leflun-
omide (A771726) were increased by 40% but the AUC was unchanged.1,2
The reasons are not understood. There would seem to be no reason for
avoiding concurrent use, but the manufacturers advise caution as A771721
levels may build up over time.2 It may be prudent to increase the frequency of
leflunomide monitoring if these two drugs are used together.

A 75-year-old man with rectal cancer was given a 28-day course of te-
gafur/uracil 200 mg three times daily and calcium folinate 30 mg daily.
Treatment was withheld because of an episode of minor duodenal bleed-
ing and 3 months later he was given leflunomide 100 mg daily for 3 days
followed by 20 mg daily to treat rheumatoid arthritis. A further two cour-
teses of tegafur/uracil (separated by 7 days) was given because of tumour
progression, after which the patient had increasing numbness of the lower
extremities, diagnosed as polynuropathy. He also had severe diarrhoea
and hand-foot syndrome. Tegafur is a prodrug of fluorouracil. Uracil pre-
vents fluorouracil degradation by inhibiting dihydroxymimidine dehydro-
genase. Both tegafur/uracil and leflunomide may cause neurotoxicity. As
these symptoms had not occurred when tegafur/uracil had been given
without leflunomide, it was suggested that leflunomide may increase
fluorouracil toxicity by increasing its conversion to fluorouracil mono-
phosphate, or by enhancing the effect of uracil by additional inhibition of
dihydroxymimidine dehydrogenase.6 This is an isolated case and its general
importance is unclear.

A 68-year-old woman who had been taking leflunomide 10 mg daily for
about 4 months was started on itraconazole 300 mg daily for a fungal in-
fection. About one month later her leflunomide dose was increased to
20 mg daily, and liver function tests were normal. The following month,
she developed abdominal pain, vomiting, and weakness. Despite sympto-
matic treatment and washout with colestyramine, fatal fulminant hepatic
failure occurred. The authors of the report attribute the reaction to additive
hepatotoxicity between the leflunomide and itraconazole.3 This interac-
tion serves to highlight the concerns about the use of other hepatotoxic
drugs, see (a) and (h).

No pharmacokinetic interaction was seen in patients taking methotrexate

concurrent use is undertaken, chronic monitoring should be increased to
monthly intervals.2 Close liver enzyme monitoring is also recommended if
switching between these drugs, and colestyramine or activated charcoal
washout should be performed when switching from leflunomide to meth-
отrexate.1,2

Muromonab-CD3 + Indomethacin

One report suggested that indomethacin may possibly increase the
incidence of encephalopathy and psychosis in patients given
muromonab-CD3.

Clinical evidence, mechanism, importance and management

A study of patient records found that 4 out of a total of 55 kidney trans-
plant patients (7.3%) given muromonab-CD3 and indomethacin 50 mg
orally or rectally every 6 to 8 hours for 48 to 72 hours developed serious
encephalopathy and psychosis compared with only two out of 173 patients
(1.2%) who had received muromonab-CD3 without indomethacin.1 This
appears to be an isolated report, and its general significance is unknown.
Indomethacin has been used to reduce the adverse effects of muromonab-
CD3, and in one analysis concurrent use was associated with reduced fe-
ver, headache, and gastrointestinal disturbances.2 Muromonab-CD3 alone
is associated with encephalopathy and other CNS adverse effects, and the
manufacturer warns that patients should be closely monitored for these ef-
effets.2

tion, November 2004.

Mycophenolate + Allopurinol

No clinically relevant interactions have been seen between myco-
phenolate mofetil and allopurinol.

Clinical evidence, mechanism, importance and management

A study in 5 kidney transplant patients with gouty arthritis, who
were switched from azathioprine to mycophenolate mofetil 2 g daily (to
avoid the risk of an azathioprine/allopurinol interaction), found that no adverse
effects occurred when they were given allopurinol 100 or 200 mg daily.
On average, 10 weeks after the switch had taken place, uricaemia had fall-

en by 21%, mean serum creatinine levels were only slightly raised, by 12%, and white cell counts were unchanged.1 Another study in 19 kidney transplant patients taking mycophenolate 2 g daily, ciclosporin and prednisolone also found a significant reduction in uricaemia without any adverse effects on white cell count, after allopurinol 100 mg daily was also taken, for 60 to 60 days.2

No special precautions would therefore seem necessary if allopurinol is used with mycophenolate, although the authors of both studies suggest that long-term randomised studies are needed to confirm safety.

Mycophenolate + Antacids

An aluminium/magnesium hydroxide antacid reduced the ab-
sorption of mycophenolate in one study, but the clinical relevance
of this is uncertain.

Clinical evidence, mechanism, importance and management

When 10 mL of an aluminium/magnesium hydroxide antacid (Maalox
TC) was given four times daily to 10 patients with a single 2-g dose
of mycophenolate mofetil, the AUC of mycophenolic acid (the active form
of the drug) was reduced by 17% and the maximum plasma concentration
of mycophenolic acid was reduced by 38%.1 The clinical importance
of this reduction has not been assessed, but the authors of the report suggest
that since 80% of transplant patients receive antacids, in practice, this
interaction is of no great significance. The US manufacturers say that al-
uminium/magnesium antacids can be used in patients taking
mycophenolate, but that they should not be given simultaneously.2 With
many other (but not all) antacid interactions, a 2-hour separation is usu-
ally sufficient to avoid an interaction. It would seem prudent to check that the
immunosuppressant effects of mycophenolate remain adequate in the
presence of this or any other antacid.

tober 2005.

Mycophenolate + Azathioprine

The manufacturers have recommended that mycophenolate
mofetil should not be given with azathioprine because they say
that concurrent use has not been studied,1,2 and both drugs have
the potential to cause bone marrow suppression.1

tics, March 2006.

Mycophenolate + Ciclosporin or Tacrolimus

Ciclosporin reduces the levels of mycophenolic acid. Tacrolimus
may increase mycophenolic acid levels in some patient groups,
but the clinical significance of this is unclear.

Clinical evidence

(a) Mycophenolate with Ciclosporin or Tacrolimus

A study in 78 kidney transplant patients taking corticosteroids with myco-
ophenolate 1 g two or three times daily, and also taking either ciclosporin (68 patients) or tacrolimus (10 patients), found lower trough levels of the active metabolite, mycophenolic acid, and higher levels of the glucuronide metabolite in patients taking ciclosporin during the first 3 months post-
transplant, when compared with those taking tacrolimus. Of interest is that
of the 11 patients changed from ciclosporin to tacrolimus during the study,
5 patients subsequently required mycophenolate dose reductions because of
adverse effects.3 Another study found that despite a higher dose of myco-
ophenolate, patients also taking ciclosporin had a 50% lower trough myc-
ophenolic acid level when compared with those taking mycophenolate with
tacrolimus.2 Other studies have found similar results.2,3,4 In another study,
12 stable kidney transplant patients taking ciclosporin (Neoral) were
given enteric-coated mycophenolate sodium (Myfortic) 720 mg
twice daily for 14 days. After pharmacokinetic assessment, they were then
changed over to tacrolimus with the same dose and formulation of myco-
phenolate sodium. This study found that when tacrolimus was given
the mycophenolic acid AUC was 20% greater than when ciclosporin was tak-
en, but maximum concentration of mycophenolic acid was 24% greater
with ciclosporin than with tacrolimus.6 However, a recent study in 22 kid-
ney transplant patients taking mycophenolate found that neither
ciclosporin (13 patients) nor tacrolimus (9 patients) affected the plasma
levels of mycophenolic acid. Levels of the glucuronide metabolite were
increased by ciclosporin but not tacrolimus.7 The manufacturers report
that in one study in renal transplant patients receiving ciclosporin and
mycophenolate mofetil, the AUC of mycophenolic acid was increased by
about 30% when ciclosporin was replaced by tacrolimus.8

(b) Mycophenolate with Ciclosporin

There are reports that the trough levels of the active metabolite of myco-
ophenolate, mycophenolic acid, may be reduced in the presence of
ciclosporin.9 In a study, 52 kidney transplant patients were given myco-
phenolate mofetil 1 g twice daily with ciclosporin and prednison. Six
months after transplantation 19 patients continued triple therapy, 19
discontinued ciclosporin and 14 discontinued prednison. Three months
later, patients in whom ciclosporin had been discontinued had higher
trough mycophenolic acid levels compared with the other groups of
patients. Discontinuing ciclosporin resulted in almost a doubling of myco-
phenolic acid trough levels.10 Other studies note similar effects on my-
cophenolic acid levels in adult11 and paediatric patients.12

A study in 33 children taking ciclosporin with prednisolone and 15 chil-
dren additionally taking mycophenolate mofetil found that the ciclosporin
levels 2 hours after the ciclosporin dose, was significantly reduced in
those patients taking mycophenolate.13 Another study in children found
similar results.14

(c) Mycophenolate with Tacrolimus

A study in stable kidney transplant patients taking tacrolimus long-term
found that the addition of mycophenolate mofetil resulted in a increase in
the tacrolimus AUC, but this was not considered significant.15 Another
study in renal transplant patients found no change in tacrolimus levels
when mycophenolate was given.8 However a 20% increase in tacrolimus
levels has been reported in a study in liver transplant patients given myco-
ophenolate 1.5 g twice daily.8

Mechanism

Mycophenolate is hydrolysed to its active drug, mycophenolic acid. This
then undergoes glucuronidation by uridine diphosphate glucuronosyl-
transferase (UGT) to form an inactive glucuronide metabolite. This me-
tabolite is then either excreted in urine or undergoes enterohepatic recirculation, where it is converted back into the active form, mycophenol-
ic acid. Ciclosporin is thought to inhibit the enterohepatic conversion of
the glucuronide metabolite back to the active metabolite, mycophenolic
acid, leading to lower levels of the mycophenolic acid.8

Tacrolimus may inhibit uridine diphosphate glucuronosyltransferase (UGT) which metabolises mycophenolic acid to the glucuronide metabo-
lite,1,7 and may also interfere with the enterohepatic recycling of the glu-
curonide metabolite.8

Importance and management

The addition of mycophenolate mofetil to ciclosporin has been found to
reduce the incidence of rejection episodes in kidney transplant patients16
and it is licensed for combined use.8 From the studies above, ciclosporin
appears to reduce the levels of the active metabolite, mycophenolic acid,
and increase the levels of the glucuronide metabolite (which is associated
with mycophenolate adverse effects). The UK manufacturers point out
that as efficacy studies were conducted in patients using ciclosporin, myco-
ophenolate and corticosteroids, the finding that ciclosporin reduces the
mycophenolic acid AUC by 19% to 38% does not affect the recommended
dose requirements.8 They also state that ciclosporin pharmacokinetics are
not affected by mycophenolate.8 However, this is in contrast to the studies
in children reported above. It has also been observed that the use of triple therapy with corticosteroids, ciclosporin and mycophenolate mofetil rather than with azathioprine makes it possible to use a lower dose of ciclosporin. However, other studies have noted that adjusting ciclosporin doses affects mycophenolic acid levels, and therefore the overall effect on immunosuppression needs careful monitoring. The significance of the reported increases in mycophenolic acid levels with concurrent tacrolimus is not clear, and the manufacturers note that the benefit of concurrent use with tacrolimus has not been established. There are also inherent problems in interpretation of the results of studies comparing ciclosporin or tacrolimus with mycophenolate. It has been suggested that the changes in mycophenolic acid trough levels are because tacrolimus increases mycophenolic acid levels; however, another interpretation may be that the differences in mycophenolic acid trough levels and AUCs seen are because ciclosporin decreases mycophenolic acid exposure.

Patients taking either ciclosporin or tacrolimus with mycophenolate should have their immunosuppressive response closely monitored, particularly if changing from ciclosporin to tacrolimus or vice versa, and dose adjustment of mycophenolate should be considered if patients develop mycophenolate-related adverse effects on switching from ciclosporin to tacrolimus.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that metronidazole 500 mg three times daily for 5 days reduced the AUC of a single 1-g oral dose of mycophenolate mofetil given two hours after the antibacterial on day 4 by 19%. The AUC of the glucuronide metabolite was also reduced, by 27%. When norfloxacin 400 mg twice daily was also given, the AUC of mycophenolate and its glucuronide metabolite were reduced by 33% and 41%, respectively. This interaction was thought to be due to interference of the enterohepatic recirculation of mycophenolate by the antibiotics.1 There appear to be no further clinical reports of an interaction between metronidazole and mycophenolate. The changes with metronidazole alone were modest, and possibly of minor clinical significance, but the larger reductions seen when norfloxacin was also given suggest that some caution may be prudent. Monitor the outcome of concurrent use to ensure that mycophenolate remains effective.

Mycophenolate + Miscellaneous

Co-trimoxazole appears to have no effect on the bioavailability of mycophenolic acid. Probencid increased the AUC of the glucuronide metabolite of mycophenolate threefold in animals. However, as there appear to be no clinical reports of this interaction, the clinical significance of this is unclear. Further study is needed.1

Mycophenolate + Polycarbophil calcium

Polycarbophil calcium reduces the bioavailability of mycophenolate.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects given a single 1-g dose of mycophenolate alone or with polycarbophil calcium 2.4 g found that the AUC and peak serum levels of mycophenolic acid were reduced by about 51% and 69%, respectively. The authors suggest that this interaction was probably the result of reduced absorption due to chelate-complex formation between mycophenolate and the calcium ions, which they demonstrated in an in vitro study. It was concluded that mycophenolate and polycarbophil calcium should not be taken at the same time.1 A suitable interval was not specified, but a separation of 2 hours has been suggested with ‘antacids’, (p.1067), which interact by a similar mechanism. Further study is needed.

Mycophenolate + Quinolones

Norfloxacin may reduce the bioavailability of mycophenolate mofetil.

Clinical evidence, mechanism, importance and management

A study in 11 healthy subjects found that norfloxacin 400 mg twice daily reduced the AUC of a single 1-g oral dose of mycophenolate mofetil given two hours after the antibacterial on day 4 by 10%. The AUC of the glucuronide metabolite was also reduced by 10%. When norfloxacin 400 mg twice daily was also given, the AUC of mycophenolate and its glucuronide metabolite were reduced by 33% and 41%, respectively. This interaction was thought to be due to interference of the enterohepatic recirculation of mycophenolate by the antibiotics.1 There appear to be no further clinical reports of an interaction between these antibacterials and mycophenolate. The changes with norfloxacin alone were modest, and unlikely to be of clinical significance, but the larger reductions seen when metronidazole was also given suggest that some caution may be prudent. Monitor the outcome of concurrent use to ensure that mycophenolate remains effective. There is no information about the use of other quinolones and metronidazole given with mycophenolate, but, if the mechanism is correct, until more information is available, it would be prudent to assume that they will interact similarly.

Mycophenolate + Rifampicin (Rifampin)

Rifampicin reduces the levels of mycophenolic acid (the active metabolite of mycophenolate) and increases the levels of the metabolite associated with mycophenolate adverse effects.

Clinical evidence

A heart-lung transplant patient taking tacrolimus 7 mg twice daily and mycophenolate mofetil 1 g twice daily was given rifampicin 600 mg daily, pyrazinamide 1 g daily, isoniazid 300 mg daily and pyridoxine 250 mg weekly for suspected mycobacterial infection. As expected, the tacrolimus dose needed to be substantially increased when rifampicin was started, and the rifampicin dose was reduced to 450 mg daily to try to minimise the interaction. However, the mycophenolate mofetil dose also needed to be increased to 6 g daily without achieving an adequate level (target trough plasma level of 2.5 micrograms/mL). Rifampicin was then stopped and the patient continued taking isoniazid and pyrazinamide. Pharmacokinetic analysis of mycophenolate, before and 13 days after rifampicin was stopped, found that the dose-corrected trough level of mycophenolic acid increased 18-fold and the AUC0.12 increased by 221%.

A subsequent study by the same authors in 8 kidney transplant patients taking mycophenolate 750 mg to 1 g twice daily found that rifampicin 600 mg daily for 8 days decreased the AUC0.12 and peak levels of mycophenolic acid by 17.5% and 18.5%, respectively. Glucuronide levels were increased and the AUC0.12 and peak levels of the acyl glucuronide metabolite, which has been associated with an increase in mycophenolate adverse effects, was significantly increased by 193% and 121%, respectively.1

Mechanism

The exact mechanism of this interaction is unknown. Mycophenolate is a pro-drug and is metabolised to its active form, mycophenolic acid, which undergoes glucuronidation by uridine diphosphate-glucuronosyltransferases (UGTs) in the liver, kidney and intestine to its inactive 7-O-glucuronide metabolite. The authors of these reports suggest that rifampicin induces intestinal, kidney and liver glucuronidation of mycophenolic acid by UGT and reduces its enterohepatic recirculation and absorption.1 2

Importance and management

These appear to be the only reports of an interaction between rifampicin and mycophenolate. However, the effects of reduced mycophenolic acid levels could be significant in terms of acute graft rejection. Also the increases in the levels of the acyl glucuronide metabolite could put the patient at greater risk of adverse effects, although this was not seen in these studies. Mycophenolate should be monitored closely during concurrent use with rifampicin and the dose adjusted as required, both on starting or stopping rifampicin.

Mycophenolate + Sevelamer

Sevelamer moderately reduces mycophenolate levels.
Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 3 adult and 6 paediatric kidney transplant patients taking mycophenolate and ciclosporin were given sevelamer, either as a single 1.6-g dose (adults), or 1.2-g dose (children), or for 4 days (same dose given three times daily). The average age of the children was 12 years. The single dose of sevelamer reduced the AUC of mycophenolate by 25%, and multiple-dosing with sevelamer reduced the AUC of mycophenolate by 30%. The interaction was thought to be due to sevelamer reducing the absorption of mycophenolate.1

The clinical significance of this interaction is unclear although the manufacturers note that graft rejection has not been reported.2 However, it would seem prudent to monitor mycophenolate levels in any patient given sevelamer.3

Higher levels of mycophenolic acid have been seen in kidney transplant patients taking mycophenolate with sirolimus compared with similar patients taking mycophenolate with ciclosporin.

Clinical evidence and mechanism

A study in 12 kidney transplant patients taking mycophenolate 1 g twice daily at the same time as sirolimus (dose adjusted to attain therapeutic trough blood levels of 10 to 15 nanograms/mL), for 30 days found that the AUC0-9 of the active metabolite of mycophenolate, mycophenolic acid, was 1.5-fold higher in the sirolimus-treated group when compared to a similar group of 19 patients taking ciclosporin instead of sirolimus.1 A study in 13 kidney transplant patients taking mycophenolate 1 g twice daily with sirolimus (trough blood levels of 10 to 20 nanograms/mL), found that the mycophenolic acid trough levels and AUC were significantly higher in patients taking sirolimus, compared with a similar group of 17 patients given ciclosporin, although peak mycophenolic acid levels were similar. Mycophenolate dose reductions were required in 2 patients in the first month, another 3 patients in the second month and 6 patients in the third month (total of 11 patients), compared with the ciclosporin group where 5 patients needed mycophenolate dose reductions. A higher incidence of leucopenia at months 1 and 2 after transplantation was reported in patients taking sirolimus, rather than ciclosporin, with mycophenolate.2

Another study in 11 kidney transplant patients taking low-dose mycophenolate 500 mg twice daily with low-dose sirolimus (mean dose of between 3.6 to 4.5 mg daily adjusted to achieve a trough blood level of 5 to 10 nanograms/mL) found that the sirolimus-based regimen had a 4.4-fold higher dose-adjusted mycophenolic acid trough level than those found in another similar group of 10 patients taking a ciclosporin-based regimen.3

Yet another study in 15 kidney transplant patients taking mycophenolate with sirolimus looked at the effects of sirolimus on mycophenolate dose regimens of 500 mg, 750 mg, and 1 g twice daily and compared them with the effects of ciclosporin on mycophenolate 1 g twice daily in 12 similar patients. They found that mycophenolate 750 mg twice daily with sirolimus produced a comparable AUC0-12 and trough mycophenolic acid levels to mycophenolate 1 g twice daily with ciclosporin.

Importance and management

Ciclosporin is known to inhibit the metabolism of mycophenolate, producing lower levels of mycophenolic acid, see ‘Mycophenolate + Ciclosporin or Tacrolimus’, p.1067. Whether sirolimus specifically raises mycophenolic acid levels compared with ciclosporin taken on its own is unclear, however raised mycophenolic acid levels have been associated with increased risk of adverse effects.1,4,5 The authors of one of the studies suggested that the mycophenolate dose should be reduced from 1 g to 750 mg twice daily in patients taking sirolimus, as this produced comparable mycophenolic acid levels values with the recommended dose of mycophenolate 1 g twice daily with ciclosporin. However, until further information is available, patients taking mycophenolate and changed from ciclosporin to sirolimus should be closely monitored for signs of adverse effects, and the dose of mycophenolate reduced accordingly.

Mycophenolate + Sirolimus

St John’s wort does not appear to alter the pharmacokinetics of mycophenolate.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 8 stable kidney transplant patients taking mycophenolate and tacrolimus were given 600 mg of St John’s wort extract (Jasmin 300) daily for 14 days. The study intended to make dose adjustments to keep the trough mycophenolic acid levels within the desired range, but dosage adjustment was not found to be necessary in any of the 8 patients.1

Voriconazole had no effect on the pharmacokinetics of a single 1-g dose of mycophenolate.1

Sirolimus + ACE inhibitors

Oedema of the tongue, face, lips, neck and chest has been reported in patients taking sirolimus with enalapril or ramipril.

Clinical evidence

A study in 52 kidney transplant patients taking sirolimus 2 to 5 mg daily with ramipril 2.5 to 5 mg daily found that 5 of these patients developed non-life-threatening oedema within one month of starting ramipril. All of these patients had taken ramipril before their transplant without any adverse effects or signs of angioedema. The tongue oedema resolved within 2 weeks of stopping ramipril. The authors noted that at that time all 5 patients were taking sirolimus 5 mg daily and ramipril 5 mg daily, with their sirolimus levels in the higher end of the range between 16 to 20 nanograms/mL. Three months after their transplant, when sirolimus had been stabilised at a lower dose of 2 to 4 mg daily, resulting in blood levels of 8 to 12 nanograms/mL, ramipril was restarted at 2.5 mg daily with no adverse effects.1

A kidney transplant patient taking sirolimus 9 mg daily developed non-pitting oedema of the eyelid, cheek and lips when he started to take ramipril (dose not specified).2 Another kidney transplant patient who had taken enalapril 2.5 mg daily for two months developed erythematous skin lesions with non-pitting oedema of the neck, face and chest 9 days after she was switched from tacrolimus to sirolimus 2 mg daily. Symptoms resolved in both patients when the ACE inhibitor was stopped and corticosteroid therapy was increased.2
Mechanism, importance and management

ACE inhibitors alone can cause angioedema but in the study above, all 5 patients had previously taken an ACE inhibitor without any allergic reaction or adverse effects.1 Although not life-threatening, these reports of oedema suggest that caution should be used when either starting an ACE inhibitor in a patient already taking sirolimus or when starting sirolimus in a patient taking an ACE inhibitor. The effect may be dose-related, with higher doses of both drugs potentially posing a greater risk.2

---

### Sirolimus or Tacrolimus + Amiodarone

There is an isolated case report of increased sirolimus and tacrolimus levels associated with the concurrent use of amiodarone in a paediatric patient.

Clinical evidence, mechanism, importance and management

A 2-year-old heart transplant patient given tacrolimus 0.02 mg/kg daily was given amiodarone to control ventricular arrhythmias. Her tacrolimus trough levels were reported as within target range of 8 to 10 micrograms/L on both day 1 and day 3 after starting the amiodarone. She was then switched from tacrolimus to sirolimus 0.06 mg/kg daily, increased to 0.12 mg/kg after 2 days, with tacrolimus continued until therapeutic sirolimus levels were achieved. The sirolimus levels and tacrolimus levels 9 days after starting amiodarone were found to be 53 micrograms/L and 10 micrograms/L, respectively. Subsequent sirolimus doses were put on hold and tacrolimus was stopped. The sirolimus levels were raised for a further 14 days. Sirolimus was restarted at a lower dose (0.03 mg/kg daily) but the levels remained above 10 micrograms/L and the sirolimus dose was reduced further to 0.02 mg/kg daily.1 The elevated levels of both drugs were attributed to an interaction with amiodarone, which can inhibit the cytochrome P450 isozyme CYP3A4, and affect P-glycoprotein, which have effects on sirolimus and tacrolimus metabolism and clearance.5

The authors of this report advise that, because of the long half-life of sirolimus, and the difficulty in reducing elevated levels quickly, prescribers should consider reducing the sirolimus and tacrolimus doses before starting amiodarone1 rather than waiting for the interaction to occur. They also advise more frequent monitoring of sirolimus and tacrolimus levels if amiodarone is also given. This appears to be the only published report of this interaction at present.

---

### Sirolimus + Azoles

Sirolimus levels are markedly raised by ketoconazole, and itraconazole, posaconazole and voriconazole appear to interact similarly. Clotrimazole is also predicted to interact with sirolimus. A case report suggests that fluconazole also raises sirolimus levels. In theory it is possible that miconazole oral gel may also interact with sirolimus.

Clinical evidence

(a) Fluconazole

A patient taking sirolimus after a kidney transplant was given fluconazole 200 mg daily for oesophageal candidiasis. Because an interaction was anticipated, the sirolimus dosage was reduced from 4 to 3 mg daily. After 4 days the sirolimus level had risen from about 10 micrograms/L to 22.8 micrograms/L. The dose of sirolimus was then reduced to 2 mg daily, but by the seventh day of fluconazole treatment the sirolimus level had reached 35 micrograms/L, after which they began to fall. The patient then had a hyperkalaemic arrest and died.1 The sirolimus levels of another kidney transplant patient were raised almost fivefold about 3 weeks after she started to take fluconazole.2

---

(b) Itraconazole

A heart transplant patient needed only half of his normal sirolimus dose to maintain about the same trough levels when he took itraconazole 400 mg daily for a year.2 A kidney transplant patient taking sirolimus 5 mg daily was given an initial dose of itraconazole 600 mg daily on post-transplant day 10 followed by 400 mg daily. The sirolimus trough level was subtherapeutic at 6.8 nanograms/mL one day after starting itraconazole so the sirolimus dose was increased to 10 mg daily. The sirolimus level then increased rapidly and reached a level of 82.5 nanograms/mL 6 days after itraconazole was started.3 A haematopoietic stem cell transplant patient taking itraconazole 200 mg twice daily was changed from tacrolimus to sirolimus 7 mg daily. The sirolimus dose was reduced to 5 mg daily 6 days later because the sirolimus level was 17.5 nanograms/mL (therapeutic range 5 to 15 nanograms/mL). The sirolimus level was found to be 35.6 nanograms/mL two days later and sirolimus was stopped until the level had fallen back to the normal range. It was subsequently restarted and the dose adjusted between 0.5 mg and 2 mg daily according to levels.4

(c) Ketoconazole

A clinical study in 23 healthy subjects found that while taking ketoconazole 200 mg daily for 10 days, the maximum serum levels and AUC of a single 5-mg dose of sirolimus were increased 4.3-fold and 10.9-fold, respectively.5 In a study in 6 kidney transplant patients, ciclosporin was increased rapidly and reached a level of 82.5 nanograms/mL 6 days after itraconazole was started.3 A haematopoietic stem cell transplant patient taking itraconazole 200 mg twice daily was changed from tacrolimus to sirolimus 7 mg daily. The sirolimus dose was reduced to 5 mg daily 6 days later because the sirolimus level was 17.5 nanograms/mL (therapeutic range 5 to 15 nanograms/mL). The sirolimus level was found to be 35.6 nanograms/mL two days later and sirolimus was stopped until the level had fallen back to the normal range. It was subsequently restarted and the dose adjusted between 0.5 mg and 2 mg daily according to levels.4

(d) Voriconazole

Voriconazole 400 mg twice daily for one day, then 200 mg twice daily for 8 days markedly raised the maximum serum levels and AUC of a single 2-mg dose of sirolimus by about 7-fold and 11-fold, respectively.5 In a retrospective study of allogeneic haematopoietic stem cell transplant patients, 11 patients were found to have received both sirolimus and voriconazole for a median of 33 days (range, 3 to 100 days). Three patients had increased trough sirolimus levels of between 10 and 19 nanograms/mL and serious toxicity occurred in 2 of them. The other eight patients had their sirolimus dose reduced by 90% when voriconazole was started, in anticipation of the interaction. Trough sirolimus levels were similar to those before voriconazole administration and no significant toxicity from either drug was found.5 A patient taking sirolimus, who had markedly raised sirolimus levels with itraconazole, was given voriconazole, and the sirolimus dose was decreased to 0.5 mg daily in anticipation of a similar interaction. The sirolimus trough level was 6.4 nanograms/mL, about the patients’ usual range, two days after starting voriconazole.4

A case report describes a patient with a heart transplant who was given two doses of voriconazole 400 mg then 200 mg twice daily for 16 days. When sirolimus was started a dose of 1 mg gave a sirolimus trough level of 12.8 nanograms/mL, but after the voriconazole was stopped a dose of 5 mg only gave trough sirolimus levels of 7.4 nanograms/mL. Voriconazole has been seen to markedly raise sirolimus levels in a number of other patients.2

Mechanism

Ketoconazole, itraconazole, posaconazole and voriconazole are potent inhibitors of the cytochrome P450 isozyme CYP3A4, the isoenzyme that is at least partly responsible for the metabolism of sirolimus.10 Therefore these azoles probably cause raised sirolimus levels by inhibiting its metabolism. Fluconazole and miconazole also inhibit CYP3A4, but are less potent than ketoconazole. Hence sirolimus levels rise when fluconazole is given, but the rise is not as great as that seen with ketoconazole. Sirolimus is also a substrate for P-glycoprotein and, as azole antifungals may inhibit intestinal P-glycoprotein, this may also contribute to the interaction by increasing the oral bioavailability of sirolimus.3

Importance and management

The concurrent use of sirolimus is contraindicated by the manufacturers of voriconazole.2,11 The rises in sirolimus levels caused by voriconazole are probably too large to be easily accommodated by reducing the dosage of the sirolimus. One study found that an initial empiric reduction in
sirolimus dose by 90% at the start of treatment with voriconazole was adequate. However, more study is required to confirm the safety of such regimens.8

The manufacturers of sirolimus say that concurrent use of strong inhibitors of CYP3A4, including ketoconazole, voriconazole and itraconazole is not recommended,10,12 but note that any patient given these drugs should have their trough sirolimus levels closely monitored both during use and after they are stopped. Clotrimazol16,12 and posaconazole13 are predicted to interact similarly. Fluconazole, although a weaker inhibitor of CYP3A4 than ketoconazole, voriconazole or itraconazole, has been reported to interact in two cases. Sirolimus plasma levels should be monitored during treatment with and following the withdrawal of any of these antifungals.

There appear to be no reports of an interaction between miconazole and sirolimus. However, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of sirolimus if both drugs are given.14 An interaction with intravaginal miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%).15

Sirolimus + Calcium-channel blockers

Diltiazem and verapamil raise sirolimus levels, and dosage adjustments may be necessary. Nicardipine is predicted to interact similarly. Nifedipine appears not to interact with sirolimus.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 18 healthy subjects found that a single 120-mg oral dose of diltiazem increased the AUC and the maximum serum levels of a single 10-mg oral dose of sirolimus by 60% and 43%, respectively. The pharmacokinetics of diltiazem and its metabolites were unchanged. The likely reason for this interaction is that diltiazem inhibits the cytochrome P450 isozyme CYP3A4 in the intestinal wall and liver, which is the primary route of sirolimus metabolism. Diltiazem may also inhibit P-glycoprotein activity, which leads to increased sirolimus absorption.1 This was a single-dose study, but the evidence suggests that this interaction will also occur with multiple doses of both drugs, for which reason the manufacturers recommend whole blood monitoring and a possible sirolimus dosage reduction based on sirolimus levels if diltiazem is used concurrently.2,3

In 26 healthy subjects the concurrent use of sirolimus oral solution 2 g daily and verapamil 180 mg every 12 hours resulted in an increase in the sirolimus maximum levels and AUC, of 2.3-fold and 2.2-fold, respectively, and an increase in the maximum levels and AUC of 3-verapamil of 1.5-fold.2,3 The manufacturer notes that other calcium-channel blockers that inhibit CYP3A4 might interact similarly, and they specifically name nicardipine.2,3

Nifedipine [which does not inhibit CYP3A4] is said not to interact,2,3 and a study comparing 16 patients taking nifedipine and sirolimus with 10 patients taking sirolimus alone found no significant differences in sirolimus pharmacokinetics between the two groups.3

Sirolimus + Ciclosporin

Ciclosporin raises sirolimus serum levels, and this can be reduced by giving the drugs at least 4 hours apart. Concurrent use for longer than 3 to 4 months possibly increases renal toxicity, and should be used with caution only when the benefits outweigh the risks. Sirolimus has been reported to increase ciclosporin levels.15

Clinical evidence

(a) Effects on ciclosporin

A randomised study found that when sirolimus was added to ciclosporin/corticosteroid regimen in kidney transplant patients, the steady-state ciclosporin levels remained unchanged. Blood pressure, glomerular filtration rate, creatinine levels, triglyceride levels and liver enzymes (ALT, AST) were unchanged.1 A 2-week pharmacokinetic study in 40 kidney transplant patients found that sirolimus 0.5 to 6.5 mg/m2 given twice daily did not affect the pharmacokinetics of ciclosporin 75 to 400 mg twice daily. The patients were also taking prednisone.2 Two related studies in kidney transplant patients confirmed the absence of an effect of sirolimus on ciclosporin pharmacokinetics.3 Similarly, in another study in healthy subjects, single doses of sirolimus did not affect the pharmacokinetics of a single dose of ciclosporin (microemulsion formulation, Neoral) when given either at the same time or 4 hours apart.4

However, another study in kidney transplant patients taking ciclosporin (Neoral) and sirolimus (taken 4 hours after ciclosporin) over a 6 month period found that the oral clearance of ciclosporin was decreased, and lower doses of ciclosporin were needed to maintain therapeutic levels.5 A kidney transplant patient taking ciclosporin 400 mg daily with prednisone started taking sirolimus 2 mg daily. Within 2 weeks, she was readmitted to hospital with signs of ciclosporin toxicity, including raised creatinine, urea, and high blood pressure, and her ciclosporin level was found to have increased to 536 nanograms/mL. The ciclosporin dose was reduced to 300 mg daily, sirolimus continued, and her ciclosporin level reduced to 276 nanograms/mL. The sirolimus levels remained at 5.2 to 10.6 nanograms/mL, within the therapeutic range.6

(b) Effects on sirolimus

In a single-dose study in healthy subjects, ciclosporin (microemulsion formulation, Neoral) given 4 hours before sirolimus increased the maximum serum levels of sirolimus 1.4-fold and increased its AUC 1.8-fold. When the drugs were given at the same time, the effect was even greater, with a 2.2-fold increase in maximum sirolimus level and 3.3-fold increase in the AUC.4 This study confirmed the findings of a previous multiple-dose study in kidney transplant recipients,7 and similar results have been seen in other studies.8 Ciclosporin 300 mg taken at the same time, 2 hours after, or 4 hours after sirolimus 5 mg increased the AUC of sirolimus by 183%, 141%, and 80%, respectively, but when sirolimus was taken 2 hours before ciclosporin, there was no increase in the AUC or peak levels of sirolimus.9 The US manufacturer of sirolimus also presents data showing that ciclosporin oral solution (Sandimmune) given at the same time as sirolimus, increased sirolimus trough levels by 67% to 86% in 150 patients with psoriasis.5

Mechanism

It appears that ciclosporin inhibits the metabolism of sirolimus by the cytochrome P450 isozyme CYP3A4 in the gut and liver leading to increased sirolimus levels.4,5 P-glycoprotein inhibition may also contribute to the interaction.
Importance and management

An established interaction. The manufacturers recommend that sirolimus should be given 4 hours after microemulsion ciclosporin, and consistently, either with or without food. Despite this, it may still be necessary to reduce the sirolimus dose. Renal function should be closely monitored, and if serum creatinine levels increase, discontinuation of sirolimus or ciclosporin should be considered. If ciclosporin is withdrawn, the sirolimus dosage will need to be raised fourfold to take into account the absence of the interaction (twofold increase needed) and the need for increased immunosuppression (twofold increase needed). A target trough sirolimus level of 12 to 20 nanograms/mL (chromatographic assay) is recommended when ciclosporin has been withdrawn.

Until further clinical data are available, the manufacturer does not recommend usage of ciclosporin in high-risk patients (e.g. those with renal impairment, markers of rejection of multi-organ transplants) as insufficient numbers of this type of patient were studied. However, the US manufacturers state that it may be used in combination with ciclosporin in high-risk patients for up to 1 year. The concurrent use of both drugs increases the risk of developing calcineurin inhibitor-induced haemolytic uraemic syndrome/thrombotic thrombocytopenic purpura/thrombotic microangiopathy. An increased risk of hepatic artery thrombosis, leading to graft loss and/or death in most cases, has also been seen in clinical studies in de novo liver transplant patients taking sirolimus with ciclosporin, and the manufacturers do not recommend using sirolimus in liver or lung transplant patients as safety and effectiveness have not been proven.

Sirolimus + Corticosteroids

Intravenous methylprednisolone had no effect on trough sirolimus levels. Sirolimus slightly increased prednisolone levels (derived from prednisone), but this is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Methylprednisolone

When 14 patients taking sirolimus (and also taking either azathioprine or mycophenolate) were given methylprednisolone as a daily intravenous bolus for 1 to 5 days (total dose of between 500 mg and 3 g) the sirolimus trough concentrations were not significantly altered. No additional precautions seem necessary on concurrent use.

(b) Prednisolone or Prednisone

In a study in kidney transplant patients taking ciclosporin and prednisone 5 to 20 mg daily, only minor to moderate changes occurred in the pharmacokinetics of prednisolone when sirolimus 6 to 13 mg/m² daily was given for 2 weeks. The maximum plasma prednisolone levels were raised by 14%, and the AUC was raised by 18%. The clinical relevance of these findings is uncertain, but they are likely to be minor.

Sirolimus + CYP3A4 inducers

Drugs that induce the cytochrome P450 isoenzyme CYP3A4 are predicted to lower sirolimus levels. Close monitoring is recommended.

Clinical evidence, mechanism, importance and management

Sirolimus is extensively metabolised by cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and by the drug transporter protein P-glycoprotein: drugs that induce their activity are predicted to lower sirolimus levels.

‘Rifampicin’, (p.1074), and ‘phenytoin’, (p.1074), are known potent enzyme inducers, and have been seen to lower sirolimus levels, and the manufacturers predict that carbamazepine, phenobarbital (and thus, primidone), and St John’s wort will interact similarly. These predictions are as yet unconfirmed, but it would certainly be prudent to monitor sirolimus levels closely if any of these drugs are used concurrently. In the case of St John’s wort, it may be best to avoid the combination all together (see ‘drug-herb interactions’, (p.10)). What should be remembered is that the extent of the inducing effects of these drugs is not identical, so that very marked effects like those observed with rifampicin may not occur; nevertheless the interaction may still be clinically important.

Sirolimus + CYP3A4 inhibitors

Drugs that inhibit the cytochrome P450 isoenzyme CYP3A4 are predicted to raise sirolimus levels. Monitoring is recommended.

Clinical evidence, mechanism, importance and management

Sirolimus is extensively metabolised by cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and by the drug transporter protein, P-glycoprotein: drugs that inhibit their activity may raise sirolimus levels.

‘Ketoconazole and voriconazole’, (p.1071), ‘dietizam and verapamil’, (p.1072), ‘erythromycin’, (below) and ‘nelfinavir’, (p.1074) have been shown to raise sirolimus levels, and the manufacturers name a number of others that also inhibit CYP3A4, which they predict will interact similarly. They list bromocriptine (although there appear to be no reported interactions with bromocriptine due to CYP3A4 inhibition), cinetidine, and danazol. These predictions are as yet unconfirmed, but it would certainly be prudent to monitor sirolimus levels closely if these drugs are used concurrently. What should be remembered is that the extent of the inhibitory effects of these drugs is not identical, so that very marked effects like those observed with ketoconazole may not occur, nevertheless the interaction may still be clinically important. Grapefruit juice also inhibits CYP3A4 (potentially raising sirolimus levels), and in this case the manufacturers recommend that concurrent use should be avoided.

Sirolimus + Macrolides

Two patients had large elevations in their sirolimus levels when they were given erythromycin. Other macrolides are expected to interact similarly.
**Clinical evidence, mechanism, importance and management**

A case report describes 2 patients taking sirolimus who were also given erythromycin 1 3 times daily for suspected Legionella pneumonia. Despite reductions in the sirolimus dosage, the sirolimus levels of both patients rose fivefold.1

In 24 healthy subjects the concurrent use of erythromycin 800 mg three times daily with sirolimus oral solution 2 mg daily resulted in a significant increase in the peak blood levels and AUc of sirolimus, by 4.2- and 4.4-fold, respectively. The peak plasma levels and AUc of erythromycin were also increased, by 1.6- and 1.7-fold, respectively.2,3

Erythromycin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is the main enzyme responsible for the metabolism of sirolimus. Therefore erythromycin probably inhibited the metabolism of sirolimus, causing the levels to rise.

The manufacturers predict that other inhibitors of CYP3A4 (they name clarithromycin and telithromycin) will interact similarly, and should be avoided.2,3 The manufacturers of telithromycin specifically advise that if concurrent use is needed, sirolimus levels should be closely monitored and the dose altered as required, both when starting treatment and also when telithromycin is stopped.4

The manufacturers of sirolimus also name troleandomycin as a moderate inhibitor of CYP3A4, which may possibly interact.2,3 However, troleandomycin tends to be a more potent inhibitor of CYP3A4 than clarithromycin, so it would seem prudent to at least monitor concurrent use closely, or even consider avoiding the combination, as recommended with clarithromycin.

---

**Sirolimus + Miscellaneous**

The manufacturers of sirolimus note that cisapride and metoclopramide may increase sirolimus levels, although there do not appear to be any published reports of this interaction.1,2 No significant pharmacokinetic interaction has been found with acilcirov, digoxin, glibenclamide or co-trimoxazole.1,3,4 There is an isolated case report of atorvastatin increasing sirolimus trough serum levels twofold in one patient, and a reduction in the sirolimus dose was required.5

---

**Sirolimus + Phenytoin**

Two case reports describe increased sirolimus dose requirements in the presence of phenytoin.

Clinical evidence, mechanism, importance and management

An 11-year-old girl with a kidney transplant taking phenytoin started taking sirolimus 30 micrograms/kg twice daily following an episode of acute rejection. The dose of sirolimus was increased tenfold over the next few weeks in an attempt to achieve the target trough level of 10 to 20 nanograms/mL and two further episodes of acute rejection occurred. About one month after the sirolimus had been started, tacrolimus was added, and her phenytoin was stopped. Over the next few weeks her sirolimus level rose to about 40 nanograms/mL. The patient subsequently recovered.6

A 62-year-old woman started taking phenytoin 100 mg twice daily because she developed a seizure disorder following a liver transplant. At this time she was taking ciclosporin, but it was decided to start sirolimus because of neurological complications. The initial sirolimus dose of 5 mg daily produced subtherapeutic sirolimus levels. She was subsequently stabilised taking sirolimus 15 mg daily, with trough levels of less than 5 nanograms/mL. Phenytoin was stopped, and about 5 days later her trough sirolimus level was found to be around 15 to 20 nanograms/mL.

After a further 5 days, the sirolimus dose was reduced to 10 mg daily. The authors of this report suggest that the initial high sirolimus dose was necessary as phenytoin, a potent inducer of the cytochrome P450 isoenzyme CYP3A4, increased the metabolism of sirolimus, which is mainly metabolised by this isoenzyme. When the phenytoin was withdrawn, sirolimus metabolism returned to normal, resulting in high sirolimus levels.2

These appear to be the only reports of this interaction, but they are consistent with the way both drugs are known to interact. It would therefore seem prudent to monitor sirolimus levels in any patient in whom phenytoin is started or withdrawn, and to adjust the dose as necessary.

---

**Sirolimus + Protease inhibitors**

Nelfinavir increased the levels of sirolimus in one patient. Other protease inhibitors are predicted to also raise sirolimus levels.

Clinical evidence, mechanism, importance and management

An HIV-positive, liver transplant patient taking sirolimus 5 mg daily was given nelfinavir 250 mg twice daily (one-fifth of normal dose), lamivudine and zidovudine. Three weeks later, because of a reduced full blood count, her sirolimus blood levels were checked, and found to be 24.7 nanograms/mL. Her sirolimus dose was reduced to 3 mg daily and then 2 mg daily and her levels rechecked 5 days later. The trough sirolimus level was found to be 4.6 nanograms/mL, which was almost fivefold higher than the trough levels of 3 control patients taking sirolimus 5 to 7 mg daily but not taking nelfinavir. The peak level and AUc were also much higher in the patient taking nelfinavir.1

The manufacturers point out that sirolimus is extensively metabolised by cytochrome P450 isoenzyme CYP3A4 and cleared by P-glycoprotein, so drugs such as the protease inhibitors, which inhibit their activity may raise sirolimus levels.2,3 Close monitoring with dose adjustments are recommended during the concurrent use of sirolimus and nelfinavir, or any other protease inhibitor.

---

**Sirolimus + Rifamycins**

Rifampicin (rifampin) significantly decreases sirolimus levels. Rifabutin and rifampentine are predicted to interact similarly, although to a lesser extent.

Clinical evidence, mechanism, importance and management

A clinical study in 14 healthy subjects found that rifampicin (rifampin) 600 mg daily for 6 days increased the clearance of a single 10-mg oral dose of sirolimus 5.5-fold, and reduced the AUc and maximum serum levels of sirolimus by 52% and 71%, respectively. Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme by which sirolimus is metabolised.1,2 Therefore concurrent use increases sirolimus metabolism and reduces its levels. The manufacturers say that concurrent use is not recommended.1 Rifabutin [a weak CYP3A4 inhibitor] and rifapentine [a moderate CYP3A4 inhibitor] are predicted to also

**Tacrolimus + ACE inhibitors and Angiotensin II receptor antagonists**

Candesartan and losartan do not appear to affect the pharmacokinetics of tacrolimus, although concurrent use may increase the risk of developing hyperkalaemia.

**Clinical evidence, mechanism, importance and management**

A study in 12 kidney transplant patients taking tacrolimus twice daily for 12 days with candesartan cilexetil (2 mg daily for 3 days, then 4 mg daily for 3 days, and then 16 mg daily for 3 days) found that the pharmacokinetics of tacrolimus were unchanged. Renal function remained stable and unchanged, and no adverse effects were reported. Another study in a group of 21 kidney transplant patients taking tacrolimus found no significant change in the serum creatinine or the levels of tacrolimus when they also took candesartan cilexetil 4 to 12 mg daily for one year. Serum potassium levels were reported to have increased by an average of 0.34 mmol/L, although it is unclear from the study if this was specifically in the tacrolimus group or also included another group taking candesartan and ciclosporin. A study in kidney transplant patients taking tacrolimus and given losartan 50 mg daily for 12 weeks (some receiving 100 mg daily from week 8) for hypertension found no significant changes in the tacrolimus levels. Transient hyperkalaemia occurred in 4 of the 67 patients.

Tacrolimus may cause nephrotoxicity and hyperkalaemia, and thus both renal function and potassium levels should be monitored when ACE inhibitors or angiotensin II receptor antagonists are also given.

**Tacrolimus + Antacids**

There is some evidence to suggest that some antacids may possibly reduce the blood levels of tacrolimus, but the clinical importance of this awaits confirmation.

**Clinical evidence, mechanism, importance and management**

A very brief report states that widely variable trough plasma tacrolimus levels have been seen in patients taking sodium bicarbonate close to the time when the tacrolimus was given, and that the use of sodium bicarbonate results in lower blood levels of tacrolimus. No details were given. It was suggested that their administration should be separated by at least 2 hours, or the sodium bicarbonate replaced by sodium citrate and citric acid, to ensure stable trough tacrolimus levels are achieved.

A crossover study in healthy subjects found that a single dose of aluminium/magnesium hydroxide increased the mean AUC of tacrolimus by 21% and decreased the mean peak level of tacrolimus by 10%.

In *vitro* studies also found that aluminium hydroxide gel and magnesium oxide can cause a significant reduction in tacrolimus concentrations due to pH-mediated degradation and as a result it was suggested that the administration of antacids and tacrolimus should be separated.

However, a study in 18 renal transplant patients found that the concurrent use of *Maalox* (aluminium/magnesium hydroxide) or sodium bicarbonate did not reduce tacrolimus blood levels and no patients required a tacrolimus dose increase.

More study is needed to confirm and assess the extent and clinical importance of these interactions, but good monitoring would be appropriate if tacrolimus is given with any antacids, being alert for the need to separate the dosages by at least 2 hours.

---

**Tacrolimus + Azoles**

When tacrolimus is given orally, its serum levels are considerably increased by oral fluconazole, and tacrolimus dose reductions may be needed. Itraconazole, ketoconazole, posaconazole, voriconazole, and oral clotrimazole, also raise tacrolimus levels. There is some evidence that the levels of intravenous tacrolimus are minimally affected by fluconazole and ketocnazole. In theory it is possible that miconazole oral gel may also interact with tacrolimus.

**Clinical evidence**

(a) **Clotrimazole**

A study in 35 kidney transplant patients taking tacrolimus 150 micrograms/kg twice daily and clotrimazole 10 mg three times daily (17 patients) or nystatin (control group, 18 patients) found that clotrimazole significantly increased tacrolimus trough blood levels from 15 to 20 nanograms/mL up to 53 nanograms/mL at day 5. Tacrolimus levels were not affected by nystatin and by day 7 patients in the clotrimazole group were found to require significantly lower tacrolimus dosages than those in the nystatin group. In a liver transplant patient the trough plasma levels of tacrolimus 6 mg daily rose from 3.5 to 5.6 nanograms/mL within a day of clotrimazole 10 mg four times daily being started, and reached more than 9 nanograms/mL within 8 days. Later studies and rechallenge confirmed that the clotrimazole was responsible for the rise in tacrolimus levels. The tacrolimus AUC was nearly doubled.

(b) **Fluconazole**

Twenty organ transplant patients (11 livers, 6 kidneys, 2 hearts and one bone marrow) taking tacrolimus were also given fluconazole 100 or 200 mg daily for various fungal infections. On day 1 the median plasma trough levels of those given fluconazole 100 mg rose 1.4-fold, and in those taking 200 mg it rose 3.1-fold. The dosage of tacrolimus was reduced to accommodate this rise: the median dosage reduction was 56% (range 0 to 88%). The highest tacrolimus level was seen within 3 days. A pharmacokinetic study in one patient found that when fluconazole 100 mg daily was stopped, the tacrolimus AUC fell by about 60%.

Other studies in adult and paediatric patients and individual case reports have confirmed that tacrolimus levels are increased by oral fluconazole, increasing the risk of nephrotoxicity. In a retrospective study, patients given fluconazole required a 40% reduction in tacrolimus dose to achieve similar trough levels. A bone-marrow transplant patient taking tacrolimus and given fluconazole for oral candidiasis experienced headache and was found to have glycosuria, increased serum creatinine and Pelger-Huet anomaly of granulocytes, which disappeared after tacrolimus was discontinued. The effects were thought to be due to tacrolimus toxicity due to an interaction with fluconazole. However, one study found that if intravenous tacrolimus is given with intravenous fluconazole 400 mg, the steady-state levels of tacrolimus are only slightly increased (by about 16%), which was considered to be clinically unimportant.

(c) **Itraconazole**

A study in 40 lung transplant patients taking tacrolimus with prophylactic itraconazole 200 mg twice daily for 6 months found that when itraconazole was stopped the mean tacrolimus dose to maintain therapeutic levels increased by 76% (to 5.74 mg daily). The adverse effects and rejection rate were not affected by itraconazole. Similar findings are reported in another study in heart and lung transplant patients. Trough blood levels of tacrolimus in a heart-lung transplant patient increased threefold from 16 to 57 nanograms/mL and serum creatinine levels also rose after she was given itraconazole 200 mg daily. A kidney transplant recipient taking tacrolimus 6 mg daily was given itraconazole 100 mg twice daily for a
urinary candida infection. Within a day, the tacrolimus trough levels increased from 12.6 to 21 nanograms/mL and the tacrolimus dose was progressively reduced to 3 mg daily. Four days after the itraconazole was discontinued tacrolimus had to be progressively increased back to its initial dose.14 The interaction has been reported in three other renal transplant recipients.15,17

(d) Ketoconazole

In a kidney transplant patient taking tacrolimus and prednisone, the addition of ketoconazole 200 mg daily resulted in an increase in tacrolimus blood levels from 11.1 to 27.9 nanograms/mL, despite a 45% decrease in the dose of tacrolimus. Eventually the dose of tacrolimus had to be reduced by 80% to keep the levels within the therapeutic range. Tacrolimus levels decreased to 5.8 nanograms/mL within a week of discontinuing ketoconazole and so the dose was raised.18 A pharmacokinetic study in 6 healthy subjects found that ketoconazole 200 mg orally at bedtime for 12 days increased the bioavailability of a single 100 microgram/kg dose of oral tacrolimus from 14% to 30%.19 The manufacturer notes that the clearance of intravenous tacrolimus was not significantly changed by ketoconazole, although it was highly variable between patients.20

(e) Posaconazole

The peak blood level and AUC of a single 50 microgram/kg dose of tacrolimus was reported to be increased by 121% and 358%, respectively, by the addition of posaconazole.21

(f) Voriconazole

A small study comparing the tacrolimus levels of two patients, one taking voriconazole 200 mg twice daily, the other placebo, found that the tacrolimus levels were nearly tenfold higher in the patient taking voriconazole.22 This was originally designed as a larger study, but the study was stopped after the finding in these initial two subjects.23 Another study in 14 healthy subjects found that voriconazole 400 mg twice daily on day one, then 200 mg twice daily for 6 days increased the AUC and maximum plasma levels of a single 100 microgram/kg dose of tacrolimus by 3.2-fold and 2.3-fold, respectively.24 A liver transplant patient taking tacrolimus was hospitalised with multiple complaints, and was found to have a high tacrolimus level. Tacrolimus was withheld and later restarted at 3 mg daily and then gradually reduced to 1.5 mg daily. When voriconazole 400 mg twice daily was started, the tacrolimus dose was reduced by one-third to 0.5 mg daily, but eventually needed to be reduced to 0.15 mg daily (90% overall dose reduction) as a result of rising tacrolimus levels.25 A kidney transplant patient taking tacrolimus 2 mg daily had an increase in tacrolimus blood concentrations in a patient taking cyclosporine or tacrolimus in bone marrow transplant patients.26

Mechanism

Fluconazole, itraconazole, ketoconazole, posaconazole and voriconazole inhibit the metabolism of the tacrolimus by the gut wall and/or by the cytochrome P450 isoenzyme CYP3A4, and/or inhibit the activity of P-glycoprotein so that more tacrolimus is absorbed.10,14,19,22 Therefore, intravenous tacrolimus is little affected.10

Importance and management

The interaction between tacrolimus and fluconazole is established, clinically important and can develop rapidly (within 3 days). The authors of the report and study it would be prudent to monitor tacrolimus levels, and adjust the dose as necessary. The manufacturers of posaconazole recommend that the tacrolimus dose is reduced by about two-thirds in patients given posaconazole.21 Tacrolimus levels should be closely monitored and further dose adjustments made if needed. The manufacturers of voriconazole advise reducing the tacrolimus dose to one-third when starting voriconazole, closely monitoring tacrolimus levels throughout, and increasing the tacrolimus dose in response to levels obtained when voriconazole is stopped.27,28 However, greater reductions in tacrolimus dose may be needed in some patients,22,23 and raised tacrolimus levels requiring a total 90% tacrolimus dose reduction were reported in one patient.24

In vitro studies with human liver microsomes have shown that miconazole also inhibits liver and small intestine microsomes that metabolise tacrolimus and it seems possible that it may interact like fluconazole but this needs confirmation. There appear to be no clinical reports of an interaction between miconazole and tacrolimus. However, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of tacrolimus if both drugs are given concurrently.30 An interaction with intravenous miconazole could be very normal because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.31 No interaction would be expected if miconazole is applied to the skin.
Nifedipine causes a moderate rise in tacrolimus blood levels and also appears to be kidney protective. Case reports suggest that diltiazem and felodipine also elevate tacrolimus levels; nicardipine, nilvadipine and verapamil are predicted to interact similarly.

**Clinical evidence**

(a) **Diltiazem**

The trough blood levels of tacrolimus 8 mg twice daily increased from 12.9 to 55 nanograms/mL in a liver transplant patient within 3 days of him starting diltiazem (initially 5 to 10 mg/hour intravenously for one day, then 30 mg orally every 8 hours). The patient became delirious, confused and agitated. Both drugs were stopped, and over the next 3 days his mental state improved and his tacrolimus levels fell to 6.7 nanograms/mL. Tacrolimus was then restarted, gradually increasing to a dose of 5 mg twice daily, which produced levels of 9 to 10 nanograms/mL.1

A study in 2 liver and 2 kidney transplant patients found that diltiazem increased the AUC of tacrolimus. In the kidney transplant patients the increase appeared to be dose related; a 20-mg dose of diltiazem caused a 26% and 67% rise, while a 180-mg dose caused a 48% and 177% rise in each patient, respectively. The liver transplant patients did not have any alteration in the AUC of tacrolimus until they were given higher doses of diltiazem; one patient had an 18% rise following a 120-mg dose, the other a 22% rise following a 180-mg dose.2

A study in 7 liver transplant patients given tacrolimus 100 micrograms/kg twice daily found that modified-release diltiazem 90 mg daily did not significantly alter the absorption or metabolism of tacrolimus when compared to 7 similar patients not given diltiazem.3 The authors of the other study2 suggest that this lack of effect may have been because only 90 mg of diltiazem was used.

(b) **Felodipine**

A 13-year-old boy taking tacrolimus 4 mg twice daily was given felodipine 2.5 mg daily 15 days after receiving a kidney transplant. Two weeks later his tacrolimus level was reported as greater than 30 nanograms/mL (previous levels ranged from 10.6 to 20 nanograms/mL), and despite a reduction in the dose of tacrolimus to 3 mg twice daily a subsequent tacrolimus level was 53.9 nanograms/mL. He was eventually stabilised at the original tacrolimus levels with tacrolimus 500 micrograms twice daily. When the felodipine was stopped several months later, his tacrolimus dose needed to be raised to maintain therapeutic levels.4

(c) **Nifedipine**

A 1-year retrospective study of two groups of liver transplant patients found that in the 22 patients taking nifedipine 30 or 60 mg daily there was a 55% increase in the tacrolimus blood levels after 1 month. By 6 months the tacrolimus dosage had been reduced by a total of 25.5% in the nifedipine group and by 12 months by 31.4% when compared with the group not taking nifedipine. The nifedipine group also had improved renal function (lowered serum creatinine).5

**Mechanism**

Uncertain, but it seems likely that some calcium-channel blockers inhibit the cytochrome P450 isoenzyme CYP3A4 and/or P-glycoprotein, thereby reducing the metabolism of tacrolimus leading to increased blood levels.1,5 This is consistent with the findings of an *in vitro* study using human liver microsomes.6

**Importance and management**

In the case of nifedipine, this seems to be an established and clinically important interaction. However, the increase seems slow, and it seems likely that any decrease in the dose requirements of tacrolimus will be detected by routine monitoring. Although the information about diltiazem is less conclusive it would seem wise to follow the same precautions, as the effect of diltiazem on tacrolimus seems to vary greatly between the few patients studied. The manufacturers of felodipine advise monitoring tacrolimus levels if felodipine is given.5,6 Direct information about other calcium-channel blockers appears to be lacking, but the US and UK manufacturers of tacrolimus6,9 predict that *nicardipine* and *verapamil* may raise tacrolimus levels by inhibiting CYP3A4 (see Mechanism), and the UK manufacturers additionally suggest that *nilvadipine* may interact similarly.10
doubtful if a clinically relevant interaction will occur with topical chlo-
ramphencol because the dosage and the systemic absorption is small, but
this needs confirmation.

**Tacrolimus + Ciclosporin**

The manufacturers say that tacrolimus and ciclosporin should
not be used concurrently because of the increased risk of nephro-
toxicity.

**Clinical evidence, mechanism, importance and management**

One study found, that in patients with normal bilirubin levels, the half-life
of ciclosporin was prolonged from a range of 6 to 15 hours up to 26
to 74 hours, and the ciclosporin serum levels, measured by a fluorescent po-
larisation immunoassay, were raised by tacrolimus.1 On the other hand an-
other study found no changes in the pharmacokinetics of ciclosporin, as
measured by HPLC, in patients given tacrolimus, but creatinine levels
were almost doubled (suggesting kidney damage),2 which confirmed a
previous report suggesting that severe renal impairment may develop
when both drugs are given.3 Tacrolimus levels may also be raised by
ciclosporin.4 The manufacturers of tacrolimus say that it should not be giv-
en with ciclosporin because of the risk of additive/synergistic nephrotox-
icity, and, if ciclosporin is being replaced by tacrolimus, 12 to 24 hours
should elapse between stopping one drug and starting the other. If
ciclosporin levels are raised, the introduction of tacrolimus should be fur-
ther delayed.4,5

**Tacrolimus + Corticosteroids**

The effects of methylprednisolone on tacrolimus pharmacokinet-
tics are uncertain. Prednisone appears to reduce the levels of tac-
rolimus.

**Clinical evidence, mechanism, importance and management**

A review of early studies of tacrolimus stated that serum levels were said
to have been increased on 10 occasions, decreased on 5 occasions, and
unaltered on 2 occasions by methylprednisolone.1 In a randomised study conducted over 3 months, 31 patients receiving
tacrolimus, mycophenolate and daciuzimab were compared with 34 pa-
tients receiving tacrolimus, mycophenolate and prednisone. Higher tac-
rolimus doses were required to maintain therapeutic tacrolimus levels in
the prednisone group. This reached a maximum after one month, when a
30% larger tacrolimus dose was necessary.2 A further study found that pa-
tients taking higher doses of prednisone (more than 0.25 mg/kg daily)
also needed larger doses of tacrolimus to maintain therapeutic trough
blood levels. The authors considered that this was possibly due to induc-
tion of the cytochrome P450 isoenzyme CYP3A4 by prednisone and rec-
ommended that tacrolimus levels be closely monitored and adjusted
according to any changes in corticosteroid dose.3

O, Todo S, Fung JJ, Starzl TE. Pharmacokinetics of FK 506: preclinical and clinical studies.

**Tacrolimus + Danazol**

An isolated report describes an increase in tacrolimus levels in a
patient given danazol.

**Clinical evidence, mechanism, importance and management**

The trough serum levels of tacrolimus 10 mg daily rose from 0.7 to
2.7 nanograms/mL in a kidney transplant patient within 4 days of danazol
400 mg to 1.2 g daily being started. Despite a reduction in the danazol dosage
to 600 mg and then 400 mg daily, her tacrolimus and creatinine serum
levels remained high for one month until the danazol was withdrawn. The
reason is not known, but the authors suggest that danazol possibly inhibits
the metabolism (demethylation and hydroxylation) of tacrolimus by the
liver so that it is cleared from the body more slowly.1 Tacrolimus is me-
tabolised by the cytochrome P450 isoenzyme CYP3A4, and danazol has
been shown to inhibit this pathway (consider ‘Statins + Danazol’, p.1099).
Therefore although this is an isolated case it seems possible that it will be
of general significance. Monitor the effects of concurrent use in any pa-
tient, reducing the tacrolimus dosage as necessary.

**Tacrolimus + Echinocandins**

Caspofungin moderately decreases tacrolimus levels. Anidulafun-
gin and micafungin do not appear to affect tacrolimus pharma-
cokinetics, and tacrolimus does not affect the pharmacokinetics of
anidulafungin, caspofungin, or micafungin.

**Clinical evidence, mechanism, importance and management**

(a) Anidulafungin

Thirty-five healthy subjects were given a single 5-mg oral dose of tac-
rolimus 3 days before and on day 10 of a course of intravenous anidu-
lafungin (200 mg loading dose and then 100 mg daily). Anidulafungin did
not have any significant effects on the pharmacokinetics of tacrolimus and
no serious adverse effects were reported. The pharmacokinetics of anidu-
lafungin were not affected by tacrolimus.3 No additional monitoring
would seem to be required with this combination; however, bear in mind
that the study above was a single-dose study in healthy subjects. More
study is required in patients taking long-term tacrolimus.

(b) Caspofungin

The preliminary results of one study suggest that caspofungin reduces the
AUC of tacrolimus by 20% in healthy subjects,2 and reduces the trough
tacrolimus levels by 26%.3 Tacrolimus did not alter the pharmacokinetics
of caspofungin.2 The manufacturers of caspofungin advise that tacrolimus
levels should be monitored if caspofungin is given, and tacrolimus doses
adjusted as appropriate.3,4 Note that this change is relatively modest.

(c) Micafungin

Twenty-six healthy subjects were given single 5-mg doses of tacrolimus
alone, after intravenous micafungin 100 mg, and one day after intravenous
micafungin 100 mg daily for 5 days. The pharmacokinetics of tacrolimus
were not affected by micafungin, and single-dose tacrolimus had no ef-
ffects on the pharmacokinetics of micafungin.5 No additional monitoring
would seem to be required with this combination.

Tacrolimus + Grapefruit and other fruit juices

Grapefruit juice can markedly increase the serum levels of tacrolimus. Pomelo may interact similarly.

Clinical evidence and mechanism

(a) Grapefruit juice

Eight liver transplant patients were given 12 oz (about 360 mL) of grapefruit juice twice daily, which they drank within 45 minutes of taking their dose of tacrolimus. After one week it was found that their 12-hour trough, and 1-hour and 4-hour tacrolimus levels were raised by 300%, 195%, and 400%, respectively. Two patients had headaches, one had diarrhea and one had an increased creatinine level, that reversed, but none of the 12-developed rejection or irreversible toxicity. Two of the patients continued to drink the grapefruit juice and it was possible to halve their tacrolimus dosage. Similarly, 6 kidney transplant patients had their dose of tacrolimus reduced by an average of 40% after drinking 100 mL of grapefruit juice daily for 5 days. A liver transplant patient was advised to drink grapefruit juice in an effort to increase her tacrolimus trough blood levels, which were subtherapeutic (below 5 nanograms/mL) despite a dose of tacrolimus 10 mg daily. She drank 250 mL of grapefruit juice four times daily for 3 days during which time the tacrolimus level did not increase. However, one week after she stopped the grapefruit juice the tacrolimus level was found to have increased to 37 nanograms/mL.

(b) Pomelo

A case report describes a kidney transplant patient taking tacrolimus whose tacrolimus level rose from a range of 8 to 10 nanograms/mL up to 25.2 nanograms/mL after he ate about 100 g of pomelo (Citrus grandis, a fruit related to grapefruit). The same authors subsequently found that pomelo juice extract inhibited the cytochrome P450 isoenzyme CYP3A4 in vitro but had no effect on P-glycoprotein.

Importance and management

The reason for the rise in tacrolimus levels is not known, but it seems likely that it is due to inhibition of the metabolism of tacrolimus by some component of grapefruit juice and pomelo fruit. In practical terms the authors of the first report suggest that this interaction means that the dosage of tacrolimus can possibly be reduced (to save money) although there is a clear need to monitor the effects closely not only because of the inter-individual factors affecting tacrolimus dosing but also because of the difficulties of standardising grapefruit juice. However, the manufacturers of tacrolimus suggest that the combination should be avoided. Patients should be informed of the potential risk of this interaction.

Tacrolimus + Macrolides

Patients have had marked increases in serum tacrolimus levels accompanied by evidence of renal toxicity when they were given erythromycin. The same interaction has been seen in patients given clarithromycin, and is predicted with josamycin and troleandomycin. Although azithromycin would not be expected to interact, an isolated case reports an increase in tacrolimus levels on concurrent use.

Clinical evidence

(a) Azithromycin

One report briefly describes a patient taking tacrolimus following a bone marrow transplant who took a 10-day course of azithromycin (dose not stated) without any significant alteration in his serum creatinine or trough tacrolimus levels. However, a isolated case report describes an increase in tacrolimus levels from a range of 15.8 to 17.5 nanograms/mL to greater than 30 nanograms/mL in a patient who had been receiving intravenous tacrolimus 20 micrograms/kg daily 3 days after azithromycin 500 mg daily was started.

(b) Clarithromycin

A woman with a kidney transplant taking tacrolimus, prednisone and azathioprine was given clarithromycin 500 mg twice daily for 4 days, then 250 mg daily to treat a severe Mycoplasma pneumoniae infection. Despite a 64% reduction in the dosage of the tacrolimus, the trough tacrolimus concentrations rose sharply, from 2.8 to 36.1 nanograms/mL by day 6 and creatinine levels increased from 309 to 442 micromol/L. The tacrolimus dosage was further reduced and then stopped, and not restarted until the clarithromycin treatment was completed. In another 2 kidney transplant patients, tacrolimus levels increased by 146% and 131%, respectively, following 9 doses of clarithromycin 250 mg. Creatinine levels increased by 91% and 30%, respectively. Similarly the tacrolimus levels of a bone marrow transplant patient rose from below 1.1 to 10.1 nanograms/mL after he took clarithromycin 500 mg twice daily for about 4 days. A similar increase in tacrolimus levels has been reported in a heart transplant patient, despite an initial reduction in tacrolimus dose in anticipation of the interaction, and in another kidney transplant patient.

(c) Erythromycin

A liver transplant patient taking tacrolimus 6 mg twice daily for one year had a marked rise in serum tacrolimus levels from about 1.4 to 6.5 nanomol/L when intravenous ampicillin/sulbactam 3 g every 6 hours and oral erythromycin 250 mg every 6 hours were given for 4 days to treat pneumonia. Renal toxicity, demonstrated by increased blood urea and creatinine levels also occurred. The erythromycin was stopped, and the next day the tacrolimus was also stopped. Over the next week the plasma levels of the tacrolimus, blood urea nitrogen and creatinine fell. A kidney transplant patient had an increase in his plasma tacrolimus levels from 1.3 to 8.5 nanograms/mL 4 days after starting erythromycin 400 mg four times daily. His serum creatinine levels almost doubled. A man with a kidney transplant had a sixfold rise in tacrolimus blood levels when he took erythromycin. Another similar case has been described. Two children aged 3 and 7 years also had rises in tacrolimus blood levels, which were accompanied by renal toxicity when erythromycin was added.

Mechanism

The macrolides inhibit tacrolimus metabolism by the cytochrome P450 isoenzyme CYP3A. Azithromycin is less likely to interact with tacrolimus because it does not inhibit CYP3A.

Importance and management

Direct information seems to be limited to these case reports. However, it would be prudent to closely monitor the effects of adding clarithromycin or erythromycin in any patient, being alert for the need to reduce the tacrolimus dosage to avoid nephrotoxicity. The manufacturers predict that josamycin and troleandomycin will interact similarly and so the same precautions would also be appropriate. The manufacturers of telithromycin also recommend close monitoring of tacrolimus levels and reducing the tacrolimus dose as required. Most other macrolides would also be expected to interact although they do not all behave identically. The significance of the single case report of azithromycin increasing tacrolimus levels is unclear as azithromycin does not affect CYP3A, and therefore has been predicted not to interact, as suggested by the other case.

Mechanism

Metronidazole is a weak inhibitor of cytochrome P450 isoenzyme CYP3A4 and it has also been suggested that metronidazole is also an inhibitor or substrate for P-glycoprotein. As tacrolimus is metabolised by CYP3A4 and is also a substrate for P-glycoprotein, one or both of these mechanisms may be involved in this interaction.

Importance and management

These two cases appear to be the only reports of a possible interaction between tacrolimus and metronidazole. There is insufficient evidence to advocate monitoring in every patient given the combination, but it would be prudent to at least bear this interaction in mind if using metronidazole in patients taking tacrolimus.

Tacrolimus + Miscellaneous

Tacrolimus is metabolised by CYP3A4, the induction and inhibition of which may affect the serum levels of tacrolimus. The manufacturers also issue cautions about the concurrent use of tacrolimus and anticoagulants, antidiabetics, nephrotoxic and neurotoxic drugs.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers

*In vitro* studies with *rat* and human liver microsomes have found that tacrolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4. This means that drugs that induce CYP3A4 may potentially reduce the serum levels of tacrolimus.

Rifampicin (rifampin) and possibly phenytoin, known potent enzyme inducers, have been shown to lower tacrolimus levels (see ‘Tacrolimus + Rifaxmycin’, p.1083, and ‘Tacrolimus + Phenytoin’, p.1081), and the manufacturers suggest that carbamazepine, isoniazid and phenobarbital will interact similarly. However, note that there is little to suggest that isoniazid has a clinically significant effect on this isoenzyme.

These predictions are as yet unconfirmed, but it would certainly be prudent to monitor tacrolimus levels closely if any of these drugs (with the possible exception of isoniazid) are used concurrently. The manufacturers also note that in animal studies, tacrolimus has been shown to decrease the clearance and increase the half-life of pentobarbital, and a report also describes the use of a phenobarbital infusion to treat a tacrolimus overdose.

(b) CYP3A4 inhibitors

*In vitro* studies with *rat* and human liver microsomes have found that tacrolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4. This means that drugs that inhibit CYP3A4 may potentially increase the serum levels of tacrolimus. Most of the known inhibitors of CYP3A4 (such as the ‘azole’, p.1075), ‘protease inhibitors’, p.1082 and ‘macrolides’, p.1079) have clearly been shown to interact with tacrolimus. The manufacturers of tacrolimus suggest that other enzyme-inhibiting drugs may also inhibit tacrolimus metabolism and therefore suggest that its levels are monitored if they are given. They name bromocriptine, cimetidine, dapsone, ergotamine, lidocaine, midazolam, quinidine and tamoxifen. These predictions are as yet unconfirmed, and note that, with exception of cimetidine, these drugs are not commonly associated with clinically significant interactions by this mechanism.

(c) Neurotoxicity or nephrotoxicity

Other predicted interactions of tacrolimus include additive neuro- or nephrotoxicity with aliclrod, aminoglycosides, co-trimoxazole, ganciclovir, gysr inhibitors, NSAIDs (see ‘NSAIDS’, p.1081) or vancomycin (nephrotoxicity has been seen with amphotericin B and tacrolimus).

(d) Protein-binding interactions

Because tacrolimus is extensively bound to plasma proteins, the UK manufacturers mention the possibility of protein-binding interactions with oral
anticoagulants or antidiabetics,3 (but this has largely been discredited as a mechanism, see ‘Protein-binding interactions’, (p.3)).

### Tacrolimus + NNRTIs

Efavirenz appears to decrease the metabolism of tacrolimus.

**Clinical evidence, mechanism, importance and management**

An HIV-positive liver transplant patient who had taken efavirenz, lamivudine and zidovudine pre-transplantation and then again post-transplantation with concurrent tacrolimus and corticosteroids, had therapeutic tacrolimus levels for 6 days despite tacrolimus and the antiretrovirals being stopped because of zidovudine-induced rhabdomyolysis.1 Efavirenz is a known inducer of the cytochrome P450 isoenzyme CYP3A4 by which tacrolimus is metabolised. It seems likely that the effect of efavirenz was sufficient to dramatically reduce tacrolimus clearance. Although this is only an isolated case it is in line with the way both drugs are known to interact. It would seem prudent to closely monitor tacrolimus levels in any patient given efavirenz.

### Tacrolimus + NSAIDs

Two liver transplant patients taking tacrolimus developed acute renal failure after also taking ibuprofen.

**Clinical evidence, mechanism, importance and management**

Two patients with liver transplants taking tacrolimus developed acute but reversible renal failure, one after taking four Motrin (ibuprofen) tablets (strength not stated) and the other after three 400-mg tablets of ibuprofen taken over 24 hours. Both had stable renal function before taking the ibuprofen.1 NSAIDs are known to inhibit prostaglandin synthesis and as a result may decrease renal blood flow, which in certain circumstances can lead to renal failure. Renal impairment is more likely to occur in the presence of renal vasoconstrictors. Tacrolimus is known to cause renal vasoconstriction and thus the combined effects of ibuprofen and tacrolimus may have led to acute renal failure. Both patients also had a degree of liver impairment, which the authors suggest may have potentiated the toxicity of tacrolimus with ibuprofen.

The authors of the report say that if renal toxicity develops, tacrolimus should be withdrawn. They used intravenous prostaglandin-E1 effectively in one patient. They also suggest that NSAIDs should not be given to patients taking tacrolimus, especially if it is being used as rescue therapy for abnormal graft function.1 There seems to be nothing documented about adverse interactions with other NSAIDs but if the suggested mechanism is true, they may possibly behave like ibuprofen. The UK manufacturers of tacrolimus suggest that all NSAIDs may have additive nephrotoxic effects with tacrolimus.2

### Tacrolimus + Orlistat

Orlistat does not appear to significantly affect the pharmacokinetics of tacrolimus, although small dosage adjustments may be needed in some patients.

**Clinical evidence, mechanism, importance and management**

A study in 12 liver transplant patients taking tacrolimus with orlistat 120 mg three times daily for 6 months found that concurrent use was well tolerated. However, 4 patients required a reduction and 2 required an increase in their tacrolimus dose, although these adjustments were only minor dose changes. No diarrhoea was reported by the patients in this study, concurrent use was well tolerated and no episodes of rejection occurred. The authors concluded that orlistat could be safely used in patients taking tacrolimus provided that tacrolimus levels are carefully monitored.1

### Tacrolimus + Phenytoin

An isolated report describes an increase in serum phenytoin levels attributed to the use of tacrolimus. Phenytoin decreased tacrolimus levels in one case, and has been used to reduce tacrolimus levels after an overdose.

**Clinical evidence**

(a) Phenytoin levels

A kidney transplant patient taking phenytoin 500 and 600 mg on alternate days (and also taking azathioprine, bumetanide, digoxin, diltiazem, heparin, insulin and prednisone) had his immunosuppressant treatment changed from ciclosporin, to tacrolimus 14 to 16 mg daily. About 7 weeks later he presented to hospital because of a fainting episode and his phenytoin levels were found to have risen from 18.4 to 36.2 micrograms/mL. The phenytoin was temporarily stopped until his serum levels had fallen, and he was then discharged on a reduced phenytoin dosage of 400 and 500 mg on alternate days with no further problems.1 The presumption is that the fainting episode was due to the raised serum phenytoin levels.

(b) Tacrolimus levels

In one kidney transplant patient taking phenytoin, tacrolimus 250 micrograms/kg daily was needed to give a blood level of 9 nanograms/mL. Three months later phenytoin was gradually stopped, with gradual tapering of the tacrolimus dose. The patient was eventually stabilised with a tacrolimus dose of 160 micrograms/kg daily giving a blood level of 11 nanograms/mL.2 Another report describes the use of an intravenous phenytoin infusion to treat acute tacrolimus overdoses in 2 patients, with the aim of enhancing tacrolimus metabolism.3

**Mechanism**

Tacrolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4, and phenytoin is a known inducer of this system. Phenytoin is therefore predicted to decrease tacrolimus levels. In the first case, it was suggested that tacrolimus might have inhibited the metabolism of phenytoin, although other factors may have had some part to play in the raised phenytoin levels.1

**Importance and management**

No interaction is established, but based on the known metabolism of these drugs it would be prudent to monitor tacrolimus levels in a patient given phenytoin. Similarly, based on the single case of phenytoin toxicity, it may also be advisable to monitor phenytoin levels.

Tacrolimus + Protease inhibitors

Protease inhibitors including lopinavir, nelfinavir, ritonavir and saquinavir significantly inhibit the metabolism of tacrolimus and increase its blood levels.

Clinical evidence

A retrospective study in 10 HIV-positive kidney transplant patients found that all of the patients taking a protease inhibitor (not specified) required a tacrolimus dose reduction, and 3 of them needed to be changed from a protease inhibitor to an alternative antiretroviral.1

(a) Lopinavir

A liver transplant patient taking tacrolimus 5 mg twice daily to give a tacrolimus trough blood level of 10.6 nanograms/mL had a large increase in tacrolimus levels to 5 nanograms/mL when lopinavir/ritonavir was started, despite a tacrolimus dose reduction to 6 mg daily. Tacrolimus neutrotoxicity developed, but no nephrotoxicity was seen. The patient was eventually stabilised taking tacrolimus 500 micrograms weekly while taking lopinavir/ritonavir. Other patients have developed raised tacrolimus levels and been eventually reconstituted on tacrolimus dosages of 500 micrograms to 1 mg weekly, while taking lopinavir/ritonavir: tacrolimus levels have continued to increase despite tacrolimus doses being withheld.2,3

(b) Nelfinavir

An HIV-positive patient, with hepatitis C following a liver transplant was given stavudine, lamivudine, and nelfinavir 500 mg three times daily. Tacrolimus 6 mg daily was started postoperatively but high blood levels were observed and the dose was reduced over the next 3 months to a maintenance dose of 500 micrograms weekly, which achieved levels of between 7 and 25.9 nanograms/mL.4 A patient had a tacrolimus level of 10.9 nanograms/mL while taking tacrolimus 4 mg twice daily without antiretrovirals. When he was given a combination of didanosine, nelfinavir and stavudine, he had a tacrolimus level of 23.7 nanograms/mL, despite a dose reduction to tacrolimus 500 micrograms daily.5 A brief report describes petit mal seizures brought on by high tacrolimus levels, which were thought to be as a result of an interaction with nelfinavir. The patient was stabilised on once weekly tacrolimus.6 In a study HIV-positive patients who underwent liver transplantation were given tacrolimus and a HAART regimen, which included a protease inhibitor. Tacrolimus dosing was reduced in all patients on HAART to between 1 and 3 mg daily. A patient developed acute organ rejection due to low tacrolimus levels when nelfinavir was stopped without an increase in the tacrolimus dose.7

(c) Ritonavir

A case report describes an HIV-positive, kidney transplant patient who developed an increase in tacrolimus levels requiring a large dose reduction to tacrolimus 500 micrograms weekly when ritonavir and saquinavir were also given.8 A patient had a tacrolimus level of 10.9 nanograms/mL while taking tacrolimus 4 mg twice daily without antiretrovirals. When he was given a combination of didanosine, nelfinavir and stavudine, he had a tacrolimus level of 23.7 nanograms/mL, despite a reduction in the dose of tacrolimus to 500 micrograms daily. When nelfinavir was replaced by ritonavir and saquinavir, tacrolimus 1 mg twice daily resulted in tacrolimus levels in excess of 120 nanograms/mL with severe, prolonged toxicity.5 In a study HIV-positive patients who underwent liver transplantation were given tacrolimus with a HAART regimen, which included a protease inhibitor. Tacrolimus dosing was reduced in all patients on HAART to between 1 to 3 mg daily. One patient taking ritonavir had a tacrolimus level of 50 nanograms/mL despite the initial dose of tacrolimus being reduced to 3 mg daily. Another patient developed tacrolimus toxicity due to ritonavir and her tacrolimus dose needed to be reduced to 250 micrograms every 4 days to keep the tacrolimus levels within range.7

Mechanism

All protease inhibitors are, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which tacrolimus is metabolised. It therefore seems likely that the protease inhibitors reduced tacrolimus metabolism resulting in the extremely high levels seen. The protease inhibitors also inhibit P-glycoprotein, of which tacrolimus is a substrate. See also ‘Antiretrovirals’, (p.772). It has been suggested that this could lead to increased levels of unmetabolised tacrolimus in the bile which may be reabsorbed through the enterohepatic circulation system, thus further increasing tacrolimus levels.2

Importance and management

An established and clinically important interaction. It is advised that when protease inhibitors are given to patients taking tacrolimus, a significant reduction in the dose of tacrolimus is required, with close and frequent monitoring of tacrolimus blood levels. One centre said that they routinely decreased the tacrolimus dose to 1 mg to 3 mg daily in patients requiring a protease inhibitor-based HAART regimen, although some patients still developed toxicity despite this initial reduction.7

Tacrolimus + Proton pump inhibitors

Lansoprazole may increase tacrolimus levels in patients with low levels of the cytochrome P450 isoenzyme CYP3A4. Pantoprazole and omeprazole are predicted to interact similarly. Rabeprazole appears not to interact with tacrolimus.

Clinical evidence

A 57-year-old woman taking tacrolimus following a kidney transplant started taking lansoprazole 30 mg daily 19 days after her transplant because of a peptic ulcer. After 3 days her tacrolimus trough level rose from a range of 16.3 to 17.6 nanograms/mL up to 26.7 nanograms/mL. The tacrolimus dose was reduced, and levels of 12 to 15.4 nanograms/mL were achieved. When lansoprazole was replaced by famotidine the tacrolimus levels reduced to 8 nanograms/mL. The patient was later switched from famotidine to rabeprazole 10 mg daily without any further alteration in tacrolimus levels.1,2

Another report describes a patient who had no significant alteration in tacrolimus levels when rabeprazole 10 mg daily was started and stopped.2 A study in 6 transplant patients taking tacrolimus found that pantopra-zole 40 mg once daily for 5 days did not significantly affect the trough levels of tacrolimus.3

A study in 51 kidney transplant patients taking tacrolimus and omeprazole 20 mg daily found no significant interaction.4 A retrospective study in 38 kidney transplant patients found that when patients switched from cimetidine 400 mg daily to omeprazole 20 mg daily resulted in a 15% decrease in the dose/weight normalised tacrolimus trough levels.3

Mechanism

Two of the patients reported above had decreased activity of the cytochrome P450 isoenzyme CYP3A4, by which lansoprazole is mainly metabolised. When levels of this enzyme are low, CYP3A4 (which normally only metabolises a fraction of lansoprazole) becomes more important in...
the metabolism of lansoprazole, and interactions with drugs that affect CYP3A4 become more likely. Tacrolimus is metabolised by CYP3A4, and therefore competition with lansoprazole for metabolisation may have served to raised tacrolimus levels in these patients. Pantoprazole may interact similarly in poor metabolisers. The decreased tacrolimus levels in one study with omeprazole may have been more so with stopping the ce-metidine (a known enzyme inhibitor) than an effect of omeprazole. Rabe- prazole is metabolised non-enzymatically and therefore does not seem to interact.1,2

Importance and management

The incidence of the interaction between tacrolimus and lansoprazole is unknown. It would seem to most frequently occur in those with decreased CYP2C19 activity, and therefore it is not easy to predict which patients would be affected. The manufacturers of tacrolimus say that this interaction may also occur with omeprazole, which is metabolised in the same way as lansoprazole. It would seem prudent to monitor tacrolimus levels if either of these proton pump inhibitors is started or stopped. Although no interaction was noted in the study with pantoprazole, the authors do note that it may interact like lansoprazole in patients with CYP2C19 deficiency. Rabeprazole may be a suitable alternative proton pump inhibitor as limited evidence suggests that it does not interact, and nor would it be expected to do so.

| Tacrolimus + Quinolones |

Levofloxacin modestly increased the bioavailability of tacrolimus in one study. In vitro, enoxacin had no effect on tacrolimus metab- olism.

Clinical evidence, mechanism, importance and management

A study in 5 kidney transplant patients found that levofloxacin 500 mg twice daily for 5 days increased the AUC0-12 of tacrolimus by about 27%.1 On the basis of the study above and of some quite unexpected rises in drug levels and subsequent nephrotoxicity in a handful of patients taking the similarly metabolised immunosuppressant, cyclosporin, with a qui- nolone antibiotic (see ‘Ciclosporin + Antibacterials; Quinolones’, p.1018), one review suggested that close monitoring would be appropriate if tacrolimus is given with any quinolone. However, in vitro studies have suggested that enoxacin does not affect the metabolism of tacrolimus, and ciprofloxacin does not affect the immunosuppressant activity of tacrolimus. Further study is needed.

| Tacrolimus + Quinupristin/Dalfopristin |

Tacrolimus levels have been reported to increase by 15% during the concurrent use of quinupristin/dalfopristin. The manufacturer- es state that quinupristin/dalfopristin has been shown in vitro to inhibit the cytochrome P450 isoenzyme CYP3A4, the main isoen- zyme involved in the metabolism of tacrolimus. Tacrolimus levels should therefore be closely monitored during concurrent use.1

| Tacrolimus + Rifamycins |

A number of liver transplant patients have needed markedly increased tacrolimus dosages when rifampicin (rifampin) was added. A pharmacokinetic study has shown that rifampin increases the clearance and decreases the bioavailability of in- travenous and oral tacrolimus. Rifabutin is unlikely to interact to the same extent, but given the magnitude of the interaction with rifampin, caution is still warranted.

Clinical evidence

The trough tacrolimus blood levels of a 10-year-old boy with a liver trans- plant fell from 10 nanograms/mL to unmeasurable levels within 2 days of rifampicin (rifampin) 150 mg twice daily being started. His tacrolimus dosage was therefore doubled from 4 to 8 mg twice daily. When the rifampin was later stopped, the tacrolimus dosage had to be reduced to 3 mg twice daily to keep the blood levels in the region of 10 nanograms/mL.1

An extremely marked reduction in tacrolimus trough levels occurred in a 10-month-old child with a liver transplant when rifampin was given with tacrolimus. Tacrolimus levels fell to about one-tenth of baseline lev- els.2 This case has also been reported elsewhere.3 In another case, this time in an adult, a tenfold increase was needed in the tacrolimus dosage to keep trough blood levels within the target range when rifampin was started. However, despite levels within the acceptable range, a biopsy showed sus- pected tacrolimus nephrotoxicity, which was considered to be possibly due to the cumulative tacrolimus dose, or to high levels of tacrolimus me- tabolites (which were not measured).4 Another patient with a kidney trans- plant had a decrease in tacrolimus levels from 9.2 to 1.4 nanograms/mL 2 days after starting rifampicin. Rifampin was stopped and replaced by pyrazinamide, with a gradual return to the baseline tacrolimus level.1 A study in 6 healthy subjects supports the findings of these case reports. In the study, rifampin 600 mg daily significantly increased the clearance and decreased the bioavailability of both oral and intravenous tacrolimus.5

Mechanism

This interaction is thought to occur because rifampicin, a known enzyme inducer, increases the metabolism of the tacrolimus by the cytochrome P450 3A4 isoenzyme CY3A4 in the liver and small bowel, and by inducing P-glycoprotein, so that the tacrolimus is cleared more rapidly.

Importance and management

These reports are consistent with the way rifampicin interacts with many other drugs and therefore this interaction would seem to be of general clinical importance. It would be prudent to be alert for the need to raise the dosage of tacrolimus if rifampicin is added in any patient.

Direct information about rifabutin seems to be lacking, but any interaction with tacrolimus is likely to be much less marked than with rifampicin because its enzyme-inducing effects are considerably less. Nevertheless until the situation is clear it would be prudent to closely monitor concurrent use with any rifamycin, being alert for the need to raise the tacrolimus dosage.

Clinical evidence, mechanism, importance and management

A kidney transplant patient had a progressive reduction in tacrolimus levels requiring an increase in his tacrolimus dose after he started to take sevelamer 800 mg three times daily. A small pharmacokinetic study in the same patient found that the peak level was increased from 9.9 to 13.1 nanograms/mL and the AUC0-7 was increased 2.4-fold, 3 days after sevelamer was stopped.1 Sevelamer can affect the absorption of drugs and the reduction in tacrolimus levels may be due to binding with sevelamer in the gut preventing its absorption.

This appears to be the only case report of an interaction between these two drugs, but sevelamer has been seen to have similar effects on a number of other drugs. It is recommended that any drug for which a reduction in the bioavailability may be clinically significant should be taken at least one hour before or three hours after sevelamer.2 Tacrolimus levels should be closely monitored and the dose adjusted as needed if concurrent use is required.

### Tacrolimus + Sildenafil

Sildenafil does not appear to affect the pharmacokinetics of tacrolimus. The levels of sildenafil were higher in patients taking tacrolimus than in healthy subjects, but it is not clear whether this was due to tacrolimus alone. A marked blood pressure drop occurred when both drugs were given in one study.

### Clinical evidence, mechanism, importance and management

In 10 men with erectile dysfunction, taking tacrolimus after a kidney transplant, a single 50-mg dose of sildenafil did not affect the pharmacokinetics of tacrolimus. When the pharmacokinetics of sildenafil were compared with those quoted by the manufacturer it was found that the maximum plasma concentration and AUC of tacrolimus were increased by 55% and 90%, respectively in patients taking tacrolimus. The AUC of the sildenafil metabolite was also raised. There are several possible reasons for these differences. The pharmacokinetics quoted by the manufacturers are from healthy subjects, not patients, and the patients in the study were taking a multitude of other drugs, some of which could have affected sildenafil. Apart from the pharmacokinetic effects, it was noted that the mean blood pressure dropped by 27/20 mmHg after sildenafil was given, which could be of significance in patients with cardiovascular disease.3 A subsequent study by the same authors, in 9 men with erectile dysfunction taking tacrolimus after a kidney transplant, found that sildenafil 25 mg daily for 3 days had no significant effects on the pharmacokinetics of tacrolimus.4 Another study in 4 patients taking tacrolimus found that sildenafil 50 or 100 mg produced no change in tacrolimus levels.5

It would appear that sildenafil does not affect tacrolimus levels, however, given the reduction in blood pressure seen in one study,3 it may be prudent to initially prescribe sildenafil at the 25 mg dose, as the authors of this study advise, and increase it as required and tolerated.

### Tacrolimus + Sirolimus

Sirolimus may reduce tacrolimus blood levels. There is some evidence to suggest that tacrolimus may increase the clearance of sirolimus.

### Clinical evidence, mechanism, importance and management

A study in 18 liver transplant and 7 kidney-pancreas transplant patients taking tacrolimus and sirolimus found no difference in the pharmacokinetics of either drug and no nephrotoxicity when the drugs were taken either simultaneously or 4 hours apart.1 A single-dose study in 28 healthy subjects found no pharmacokinetic interaction between sirolimus and tacrolimus when they were given either at the same time or 4 hours apart.2 However subsequent studies have found decreases in tacrolimus levels due to the concurrent use of sirolimus. A study in 7 children with kidney transplants taking tacrolimus and prednisone found that the addition of sirolimus to treat chronic allograft nephropathy resulted in a decrease in dose-normalised tacrolimus trough blood levels from 0.14 kg/L to 0.1 kg/L on day 3 and 0.08 kg/L on day 28. All patients required a tacrolimus dose increase, with a mean increase of about 70% (range 21.9 to 245.4%) in order to keep the tacrolimus blood levels above 3 nanograms/mL. This was thought to be due to a reduction in the bioavailability of tacrolimus rather than increased excretion.3 Another study in 28 kidney transplant patients taking tacrolimus and given sirolimus 0.5, 1, or 2 mg daily also found an initial reduction in the tacrolimus level with time. The tacrolimus levels recovered, but a trend towards reduced tacrolimus levels was seen with continued dosing. Tacrolimus did not appear to alter sirolimus levels, when compared with previous data in studies with sirolimus alone.4

A study in 16 adult kidney transplant patients taking tacrolimus and fixed-dose sirolimus 500 micrograms or 2 mg daily found a significant, dose-dependent increase in the AUC of tacrolimus of 16% and 31%, respectively, and an increase in the peak levels of tacrolimus of 19% and 33%, respectively, when sirolimus was stopped.5

A study in paediatric kidney transplant patients found the clearance of sirolimus in patients was increased in those taking tacrolimus, when compared with those not taking a calcineurin inhibitor.6 A retrospective study in adult kidney transplant patients taking tacrolimus and sirolimus found that concurrent use may be associated with extensive tubular cell injury and a unique form of cast nephropathy.7

The manufacturers of sirolimus note that clinical studies in de novo liver transplant patients have found an increased risk of hepatic artery thrombosis when tacrolimus is also given: concurrent use is not recommended in this patient group.8 Patients taking sirolimus with tacrolimus should have their tacrolimus and probably sirolimus levels closely monitored and the dose adjusted if needed.

### Tacrolimus + SSRIs and related antidepressants

Marked increases in tacrolimus levels and toxicity were observed when three patients were also given nefazodone. In theory, fluvoxamine may increase tacrolimus levels. Paroxetine and sertraline may not interact, but the situation is not clear.

### Clinical evidence

A kidney transplant patient taking tacrolimus 5 mg daily developed delirium and renal failure 4 weeks after starting to take nefazodone 150 mg daily. The tacrolimus levels had been 9.4 nanograms/mL some 3 months earlier when he was taking a dose of 6 mg daily, but in the presence of nefazodone the tacrolimus level increased to 46.4 nanograms/mL with a tacrolimus dose of 5 mg daily. His serum creatinine had doubled. The tacrolimus level fell to 29.6 nanograms/mL within 2 days of the dose being reduced to 3 mg daily. Nefazodone was then replaced by paroxetine 20 mg daily. After 3 days the tacrolimus dose was increased to 5 mg daily and satisfactory levels of 12.4 nanograms/mL were observed.1
A kidney transplant patient taking prednisone, azathioprine and tacrolimus 5 mg daily for 2 years experienced headache, confusion and ‘grey areas’ in her vision within one week of starting nefazodone 50 mg twice daily in place of sertraline, for depression. Her serum creatinine had risen from 132 to 195 micromol/L and her trough tacrolimus level was greater than 30 nanograms/mL. Nefazodone was replaced by sertraline, and tacrolimus was withheld for 4 days. Signs of tacrolimus-induced neurotoxicity disappeared within 36 hours and serum creatinine and tacrolimus levels returned to pretreatment levels within 2 weeks.2

Another patient developed raised liver enzymes and raised tacrolimus levels after taking nefazodone and tacrolimus for 2 weeks. When nefazodone was stopped his liver enzymes normalised over the next 5 days, and his tacrolimus levels fell from 23 to 9.5 nanograms/mL over 10 days.3

**Mechanism**

Tacrolimus is metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited by nefazodone, concurrent use therefore results in increased levels of tacrolimus. Paroxetine and sertraline do not have significant effects on CYP3A4 and are therefore not expected to interact with tacrolimus.

**Importance and management**

Information appears to be limited but what is known indicates that tacrolimus levels or at least signs of toxicity should be well monitored if nefazodone is also given. In view of the narrow therapeutic index of tacrolimus, it may be advisable to avoid concurrent nefazodone.

**Fluvoxamine** is an inhibitor of CYP3A4 and so theoretically could affect the metabolism of tacrolimus. Close monitoring of tacrolimus levels is therefore advised. Paroxetine and sertraline and possibly other SSRIs may be suitable alternative antidepressants, but the evidence is slim, so additional monitoring may still be warranted.1 Further study on the use of antidepressants with tacrolimus is needed.

### Tacrolimus + St John’s wort (Hypericum perforatum)

**St John’s wort decreases tacrolimus levels.**

**Clinical evidence**

In a clinical study, 10 healthy subjects were given a single 100-microgram/kg dose of tacrolimus alone, or after they took St John’s wort 300 mg three times daily for 14 days. On average St John’s wort decreased the maximum blood level of tacrolimus by 65% and its AUC by 32%. However, the decrease in AUC ranged from 15% to 64%, with one patient having a 31% increase in AUC.1 Similar results have been found in a study in 10 kidney transplant patients given St John’s wort (*Jarsin300*) 600 mg daily for 2 weeks. In order to achieve target levels, the tacrolimus dose was increased in all patients, from a median of 4.5 mg daily to 8 mg daily. Two weeks after stopping St John’s wort, tacrolimus doses were reduced to a median of 6.5 mg daily, and then to the original dose of 4.5 mg daily after about 4 weeks.2

A case report describes a 65-year-old patient taking tacrolimus following a kidney transplant. The patient started to take St John’s wort (*Neuropant*) 600 mg daily, and after one month the tacrolimus trough blood levels had dropped from a range of 6 to 10 nanograms/mL down to 1.6 nanograms/mL, with an unexpected improvement in creatinine levels. When the St John’s wort was stopped, tacrolimus levels and creatinine returned to the previous range. Subsequently a lower target range of tacrolimus was set.3

**Mechanism**

St John’s wort induces the cytochrome P450 isoenzyme CYP3A4 and affects the transporter protein P-glycoprotein. CYP3A4 and P-glycoprotein are involved in the metabolism and clearance of tacrolimus, so an increase in their effects would be expected to result in a decrease in tacrolimus levels.1,3

**Importance and management**

Although the evidence currently seems limited to these reports the interaction between tacrolimus and St John’s wort has been predicted from the pharmacokineti cs of these two drugs. Given the unpredictability of the interaction (and the variability in content of St John’s wort products) it would seem prudent to avoid St John’s wort in transplant patients, and possibly other types of patient taking tacrolimus. If St John’s wort is started or stopped, monitor tacrolimus levels and adjust the dose accordingly.

**An isolated report suggests that theophylline may increase tacrolimus blood levels.**

**Clinical evidence**

A kidney transplant patient taking tacrolimus 7 mg daily was given theophylline 600 mg daily to treat post-transplant erythrocytosis. After 1 month serum creatinine increased from 110 to 145 micromol/L and the tacrolimus trough blood level increased to 16 nanograms/mL, from a range of 5 to 15 nanograms/mL. The theophylline dosage was reduced to 300 mg daily on 4 days of each week and one month later the serum creatinine was 175 micromol/L and the trough tacrolimus level was 48.5 nanograms/mL. Theophylline was discontinued and the renal function and trough tacrolimus levels rapidly returned to normal. The pharmacokinetics of tacrolimus were later assessed in the same patient. Theophylline 125 mg daily for 4 days was associated with an almost five-fold increase in the AUC of tacrolimus and an increase in the peak tacrolimus blood levels from 19.3 to 37.4 nanograms/mL, without significant alterations in renal function on this occasion.1

**Mechanism**

Unclear. An *in vitro* study found that tacrolimus and theophylline each exhibited a negligible effect on the metabolism of the other drug.2 However, the authors of the case report suggest that theophylline levels in their patient could have been sufficient to inhibit the cytochrome P450 isoenzyme-mediated metabolism of tacrolimus.1

**Importance and management**

Direct information seems to be limited to this single case report. The authors conclude that low-dose theophylline may be given to transplant patients with erythrocytosis provided that tacrolimus levels are closely monitored.1 However, this interaction is unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring in every patient, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Lipid regulating drugs

This section is concerned with the drugs that are used for dyslipidaemias (i.e. disturbed levels of lipids in the blood). In the very broadest of terms (and ideally) they lower the blood levels of cholesterol and low-density lipoprotein (LDL), and raise those of high-density lipoprotein (HDL). Such drugs include the statins (more properly known as HMG-CoA (hydroxymethylglutaryl-coenzyme A) reductase inhibitors), fibrates, ezetimibe, bile-acid binding resins (e.g. colestipol, colestyramine) and nicotinic acid (niacin) and related drugs. These are listed in ‘Table 30.1’, (below). Where lipid regulating drugs affect other drugs the interactions are covered elsewhere.

1. Muscle toxicity. Statins are generally well-tolerated, but have two major but relatively uncommon adverse effects. They raise liver enzymes and can cause skeletal muscle disorders (e.g. myalgia, myopathy and rhabdomyolysis). Rhabdomyolysis is a syndrome resulting from skeletal muscle injury, which results in the release of the enzyme creatine kinase (among other things) into the circulation. Creatine kinase (CK) is also known as creatine phosphokinase (CPK). Both terms are used throughout the text, the choice being dependent on the term used in the source quoted. Rhabdomyolysis can range from asymptomatic elevations in creatine kinase to acute renal failure, and in its severest form may be life-threatening. As well as elevated creatine kinase levels, signs and symptoms of rhabdomyolysis include muscle pain and weakness, reddish-brown urine (myoglobinuria).1

Just how statins cause muscle disorders is as yet unclear, although it is thought to be connected to elevated statin levels.2 Any pharmacokinetic interaction that results in a marked rise in statin levels is therefore to be regarded seriously.

One of the ways statin levels can become elevated is if the interacting drug inhibits the metabolism of the statin, with the result that it is cleared from the body more slowly and it begins to accumulate (see pharmacokinetics below). The overall risk of myopathy with the statins is quite cleared from the body more slowly and it begins to accumulate (see pharmacokinetics below). The overall risk of myopathy with the statins is quite

2. Pharmacokinetics. Lovastatin and simvastatin are extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 so that drugs that can inhibit this enzyme can cause marked rises in blood statin levels. Atorvastatin is also metabolised by CYP3A4, but to a lesser extent than lovastatin or simvastatin. Some of the statins are not metabolised by this enzyme so they interact differently. Fluvastatin is metabolised primarily by CYP2C9 (with a minor contribution from CYP3A4), 10% of rosuvastatin is metabolised, and the isoenzymes involved appear to be CYP2C9 and CYP2C19, while the cytochrome P450 system does not appear to be involved in the metabolism of pravastatin.6

The statins are also P-glycoprotein substrates, and may therefore interact due to competition for this carrier, generally resulting in altered oral bioavailability.6 However, in vitro study has suggested that, due to the low affinity of atorvastatin and simvastatin for P-glycoprotein this is unlikely to be a clinically significant cause of statin drug interactions.7 Some metabolites of atorvastatin, lovastatin and simvastatin have been shown to inhibit P-glycoprotein, while fluvasstatin and pravastatin seem to have little effect.8 There appears to be no data on the effect of rosuvastatin on P-glycoprotein.9

(b) Bile-acid binding resins

Bile-acid binding resins lower cholesterol by binding with bile acids in the gastrointestinal tract to form an insoluble complex that is excreted in the faeces. This predisposes them to interactions by binding with other drugs in the same way as they do with bile acids, which prevents absorption or local action of the affected drug. These binding interactions are not covered here, but are covered under the affected drugs. A new bile-acid bind-
(c) Ezetimibe

Ezetimibe is a cholesterol absorption inhibitor, and, as the name suggests, it and the major metabolite, ezetimibe glucuronide, impair the intestinal absorption of cholesterol, both from the diet and biliary cholesterol. The absorption of other fats is not affected. Ezetimibe has not been found to have significant effects on cytochrome P450, suggesting it is unlikely to interact by this mechanism.

(d) Fibrates

Fibrates are protein-bound drugs that are metabolised via the cytochrome P450 isoenzyme CYP3A4. They are not generally recognised as inhibitors of this enzyme. Although protein binding contributes to their interactions, this mechanism alone does not usually lead to serious interactions. This leaves their mechanism of interaction largely unexplained, although it has been suggested that they may act as inhibitors of glucuronidation. As with the statins (see above), fibrates are also recognised as causing myopathies, and the risk of this appears to be greatly increased when they are given with statins, see ‘Statins + Fibrates’, p.1100.

(e) Nicotinic acid

Nicotinic acid has little effect on the cytochrome P450 isoenzyme system and is therefore unlikely to result in significant pharmacokinetic interactions. It also appears to increase the risk of myopathies when given with statins, see ‘Statins + Nicotinic acid (Niacin)’, p.1106. Also note that although no interaction has been generally shown with acipimox the manufacturers recommend caution with drugs that interact with nicotinic acid. This is because nicotinic acid is an analog of acipimox, and so may share its interactions.

**Ezetimibe + Cyclosporin**

The levels of ezetimibe and possibly cyclosporin may be elevated by their concurrent use, and so the combination should be used with caution.

**Clinical evidence, mechanism, importance and management**

A randomised, crossover study in 12 healthy subjects found that ezetimibe 20 mg daily for 8 days increased the AUC of a single 100-mg dose of cyclosporin by 15%. The authors noted that it would be difficult to determine the outcome of long-term concurrent use, but the modest effect seen suggested that caution was necessary if the combination was given. However, an efficacy study noted that in 16 renal transplant patients the addition of ezetimibe 10 mg daily had no effect on ciclosporin levels. A case report describes a heart transplant patient taking ciclosporin 100 mg twice daily with atorvastatin 40 mg daily. As his LDL-cholesterol was inadequately lowered by the atorvastatin, and greater doses had not been tolerated due to elevated creatine kinase levels, ezetimibe 10 mg daily was added. His LDL-cholesterol then decreased from 126 mg/dL to 51 mg/dL (target less than 100 mg/dL), and so his dose of ezetimibe was decreased to 5 mg daily. The authors of this case report note that only about 50% of heart transplant patients taking ciclosporin were slightly but not significantly altered by the colestyramine,1 There would seem to be no good reason for avoiding concurrent use.

**Ezetimibe + Rifampicin (Rifampin)**

Single-dose rifampicin increases ezetimibe levels without altering its effects on sterols, whereas multiple doses of rifampicin decrease ezetimibe levels and almost totally abolish its effects.

**Clinical evidence**

In a single-dose study investigating the disposition of ezetimibe 8 healthy subjects were given ezetimibe 20 mg with rifampicin 600 mg. Rifampicin increased the ezetimibe maximum serum levels by about 2.5-fold, without affecting the AUC. The maximum serum levels of ezetimibe glucuronide (the major active metabolite of ezetimibe) were similarly increased, and its AUC was also increased, by about twofold. The sterol-lowering effects of ezetimibe were also more rapid in the presence of rifampicin, but the overall effect was unchanged, possibly because ezetimibe and its glucuronide were excreted more rapidly. In another study by the same researchers ezetimibe 20 mg was given 12 hours after the last dose of an 8-day course of rifampicin 600 mg daily. This time both the AUC and maximum serum levels of ezetimibe and its glucuronide were decreased (AUC decreased by more than 50%) and the effect of ezetimibe on sterols was almost completely abolished.

**Mechanism**

The raised ezetimibe levels seen in the single-dose study are thought to occur because rifampicin enhances the absorption of ezetimibe, probably by inhibiting intestinal P-glycoprotein, and another transporter protein, MRP2. However, inhibition of MRP2 appears to reduce enterohepatic circulation, which is needed for the long duration of ezetimibe effects, and therefore shortens the sterol-lowering effects of ezetimibe. It seems likely that the balance of these factors is altered when rifampicin is given in multiple doses, which leads to a reduction in the effects of ezetimibe. Other factors are possibly also involved.

**Importance and management**

Information about the interaction between ezetimibe and rifampicin appears to be limited to these studies, which were primarily designed to investigate ezetimibe disposition. However, it seems likely that the effects of ezetimibe will be reduced in patients who are also given multiple doses.
Fibrates + Bile-acid binding resins

Colestyramine does not alter the pharmacokinetics of clofibrate when both drugs are given at the same time. Similarly, colestevelam does not alter the pharmacokinetics of clofibrate or fenofibrate, and colesevelam does not alter the pharmacokinetics of fenofibrate. Colestipol can reduce the absorption of gemfibrozil if given at the same time, but not if administration is separated by 2 hours. A similar interaction occurs between bezafibrate and colestipyramine.

Clinical evidence, mechanism, importance and management

(a) Bezafibrate

The manufacturers of bezafibrate recommend that there should be a 2-hour interval between administration of [drugs such as colestyramine] and bezafibrate, as the absorption of bezafibrate may otherwise be impaired.1

(b) Clofibrate

Over a 6-day period no clinically relevant changes in the pharmacokinetics of clofibrate occurred in 24 healthy subjects, who were given daily doses of colestipol 10 g at the same time as clofibrate 500 mg.2 Colesyramine 4 g four times daily had no effect on the fasting plasma levels, urinary and faecal excretion, or the half-life of clofibrate in 6 patients taking 1 g of clofibrate twice daily. In this study, the morning and evening doses of colesyramine were taken at the same time as the clofibrate.3

(c) Fenofibrate

Over a 6-day period no clinically relevant changes in the pharmacokinetics of fenofibrate occurred in 18 healthy subjects, who were given daily doses of colestipol 10 g at the same time as fenofibrate 200 mg in the morning, and colesyramine 5 g at the same time as fenofibrate 100 mg in the evening.4 In a randomised, crossover study 27 healthy subjects took fenofibrate 160 mg with colesyramine 3.75 g, four hours before colesyramine, or alone. Colesyramine caused some slight changes in the pharmacokinetics of fenofibrate when both drugs were given simultaneously but this was not considered to be clinically significant.5

(d) Gemfibrozil

A study in 10 patients with raised serum cholesterol and triglyceride levels found that if gemfibrozil 600 mg was given alone, 2 hours before or 2 hours after colesyramine 5 g, the serum gemfibrozil concentration curves were similar. However, when both drugs were given at the same time, the AUC of gemfibrozil was reduced by about a third.6 Another study found that combined use of gemfibrozil and colesyramine (doses not separated) enhanced the LDL-lowering effects of both drugs, but tended to mitigate the HDL-raising effects of the gemfibrozil.7 Combined use is effective, but information is very limited about the clinical importance of the reduction in gemfibrozil bioavailability. However, the interaction can be avoided by separating the administration of the two drugs by at least 2 hours.7

Fibrates + Colchicine

Case reports suggest that the current use of fibrates and colchicine can result in rhabdomyolysis or neuromyopathy.

Clinical evidence

A 40-year-old man with chronic hepatitis and nephritic syndrome, who had been taking colchicine 500 micrograms three times daily uneventfully for 2 to 3 years, started taking gemfibrozil 600 mg twice daily. About one month later he presented with muscle pain and dark brown urine, and had a creatinine kinase of 3 559 units/L, and he was diagnosed as having rhabdomyolysis. Both drugs were stopped, and he recovered over the following 9 days.1 Another case report describes neuromyopathy (creatine kinase level 15 084 units/L), in a patient who had been taking bezafibrate 400 mg daily with colchicine 3 mg daily for 14 days.2 This patient was known to have renal impairment.

Mechanism

Colchicine alone can, rarely, cause myopathy. However, it is more common in those given colchicine long term (as in the case with gemfibrozil), in high dose, or in the presence of renal impairment (as in the case with bezafibrate).3 As the fibrates can also, rarely, cause myopathy, an additive or synergistic effect seems possible.

Importance and management

Although information seems limited to these two cases, the effects seen are known to be associated with both colchicine and the fibrates, so an interaction, all be it rare, seems to be established. It would be prudent to suspect this interaction in any patient presenting with muscle pain or a raised creatinine kinase level. The section on ‘muscle toxicity’, (p.1086), discusses risk factors for myopathy and it would seem prudent to be aware of these, as both patients in the cases above had other risk factors for rhabdomyolysis.

Fibrates + Diuretics

Treatment with clofibrate in patients with nephrotic syndrome receiving furosemide has sometimes led to marked diuresis and severe and disabling adverse muscular effects. An isolated report describes rhabdomyolysis in a patient taking bezafibrate and furosemide.

Clinical evidence

(a) Bezafibrate

An isolated report attributed a case of acute renal failure and rhabdomyolysis to treatment with bezafibrate 400 mg daily and furosemide 25 mg on alternate days.1

(b) Clofibrate

Three patients with hyperlipoproteinaemia secondary to nephrotic syndrome, taking furosemide 80 to 500 mg daily, developed severe muscle pain, low lumbar backache, stiffness, and general malaise with pronounced diuresis within 3 days of starting to take clofibrate 1 to 2 g daily. Similarly, a patient taking bendrofluamide 10 mg daily developed adverse muscle effects within 3 days of starting clofibrate. Of these 4 patients, 3 had documented raised serum transaminases or creatine phosphokinase.

Two other patients had raised levels of serum transaminases or creatine phosphokinase while taking clofibrate with furosemide.

A further study in 4 of the 6 patients discussed above and 4 healthy controls, free serum clofibrate was markedly higher in the patients, and this correlated with low serum albumin. Urinary clofibrate excretion was markedly delayed.2
Mechanism
Not understood. The marked diuresis may have been due to competition and displacement of the furosemide by the clofibrate from its plasma protein binding sites. Clofibrate occasionally causes a muscle toxicity, which could have been exacerbated by the urinary loss of Na⁺ and K⁺ and the increase in the half-life of clofibrate. The reason for the bezafibrate/furosemide-induced rhabdomyolysis is unknown.

Importance and management
The clinical documentation seems to be limited to these reports. It appears to be a combination of a drug–drug interaction (clofibrate with furosemide or bezafibrate with gemfibrozil) and renal failure. The authors of a single report suggest that serum proteins and renal function should be checked before giving clofibrate to any patient. If serum albumin is low, the total daily dosage of clofibrate should not exceed 500 mg for each 1 g per 100 mL of the albumin concentration. However, note that this guidance is old.

Fibrates + Ezetimibe
Ezetimibe does not alter fenofibrate or gemfibrozil pharmacokinetics. Fenofibrate and gemfibrozil may modestly increase ezetimibe levels, although this is unlikely to be clinically relevant. The manufacturers currently advise caution if ezetimibe is given with a fibrate, because of the theoretical increased risk of gallstone formation.

Clinical evidence
(a) Fenofibrate
In a randomised, crossover study 18 healthy subjects were given ezetimibe 10 mg daily with fenofibrate 145 mg daily for 10 days, or either drug alone. Ezetimibe did not affect the AUC of fenofibrate, and although fenofibrate increased the total AUC of ezetimibe and ezetimibe-glucuronide by 1.5-fold this was not considered to be clinically significant.

(b) Gemfibrozil
In a randomised, placebo-controlled study, 32 otherwise healthy patients with hypercholesterolaemia were given fenofibrate 200 mg daily, ezetimibe 10 mg daily, both drugs in combination, or placebo daily for 14 days. The combination was well-tolerated, and resulted in an increased reduction in LDL-cholesterol than that achieved by either active drug alone. Concurrent use did not affect the pharmacokinetics of either drug. A further efficacy and safety study in 172 patients taking ezetimibe 10 mg daily with fenofibrate 160 mg daily, found that there was a trend towards increased treatment-related adverse effects, when compared with patients taking either drug alone. However, the incidence of musculoskeletal disorders was similar.

Mechanism, importance and management
Despite these seemingly favourable results, the UK manufacturers of ezetimibe state that the safety of combined use with fibrates is not yet established. This is because both fibrates and ezetimibe increase cholesterol excretion into the bile, which could promote the production of gallstones. They say that if gallstones or gall bladder disease is suspected then the combination should be discontinued.

Fibrates + Nifedipine
It has been suggested that three cases of rhabdomyolysis occurred because of an interaction between bezafibrate and nifedipine, but it seems more likely that the dose of bezafibrate was too high.

Clinical evidence, mechanism, importance and management
Rhabdomyolysis developed in 4 of 5 patients undergoing CAPD, who were given bezafibrate 200 to 400 mg daily for raised cholesterol and triglyceride levels. Of these, 3 patients were also taking nifedipine, and one of these 3 was also taking lovastatin. Raised creatinine kinase levels developed within 8 to 16 days of concurrent use, and resolved within 48 hours of stopping the bezafibrate. The authors suggest that nifedipine may have competed with bezafibrate for metabolism by the cytochrome P450 isoenzyme CYP3A4. They therefore say that patients with renal failure needing a fibrate should avoid taking CYP3A4 substrates. However, as the recommended dose for bezafibrate in CAPD patients is 200 mg every 72 hours it appears likely that the high dose, and not an interaction, was responsible for the rhabdomyolysis. No precautions therefore seem necessary.

Fibrates + Rifampicin (Rifampin)
Preliminary evidence suggests that rifampicin can reduce the plasma levels of the active metabolite of clofibrate, but rifampicin apparently has no effect on gemfibrozil pharmacokinetics.

Clinical evidence, mechanism, importance and management
(a) Clofibrate
A 35% reduction in the steady-state plasma levels of the active metabolite of clofibrate, chlorophenoxyisobutyric acid (CIPB), was seen in 5 healthy subjects after they took rifampicin 600 mg daily for 7 days. This appears to occur because the metabolism of CIPB by the liver and/or the kidneys is increased. On the basis of this study it would now be prudent to monitor serum lipid levels of patients taking clofibrate if rifampicin is added, and to increase the clofibrate dosage if necessary. More study is needed to establish this interaction.

(b) Gemfibrozil
Rifampicin 600 mg daily for 6 days did not significantly affect the pharmacokinetics of gemfibrozil 600 mg in a study in 10 healthy subjects. No special precautions seem necessary.

Fibrates; Ciprofibrate + Ibuprofen
An isolated report describes a patient taking ciprofibrate who developed acute renal failure and rhabdomyolysis after taking ibuprofen.

Clinical evidence, mechanism, importance and management
A 29-year-old man with type M hyperlipidaemia had been taking ciprofibrate 100 mg daily for 6 months began to take ibuprofen 200 mg and then 400 mg daily for a painful heel. The pain became general, his urine turned ‘muddy’, he complained of having a ‘stiff body’, and he rap-
Oral contraceptives increase the clearance of clofibrate but the significance of this is unclear.

Clinical evidence, mechanism, importance and management
A comparative study in men, women, and women taking combined oral contraceptives found that the clearance of clofibrate was increased by 48% in those taking combined oral contraceptives, apparently due to an increase in clofibrate glucuronidation.1 Another study found that combined oral contraceptives increased the excretion of clofibric acid glucuronide (the pharmacologically active form of clofibrate) by 25%.2 None of these studies addressed the question of whether concurrent use significantly reduces clofibrate efficacy, but it would seem prudent to monitor for increases in blood lipid levels. It should be noted that combined oral contraceptives themselves can have various adverse effects on lipid levels, and these may impair the effects of treatment.

Plasma clofibrate levels can be approximately doubled by probenecid, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management
A pharmacokinetic study in 4 healthy subjects taking clofibrate 500 mg every 12 hours found that probenecid 500 mg every 6 hours for 7 days almost doubled the steady-state clofibrate levels, from 72 to 129 mg/L, and raised the free clofibrate levels from 2.5 to 9.1 mg/L. The suggested reason is that the probenecid reduces the renal and metabolic clearance of the clofibrate by inhibiting its conjugation with glucuronic acid.1 The clinical importance of this interaction is uncertain. It appears not to have been assessed.

Antacids can reduce the absorption of gemfibrozil.

Clinical evidence, mechanism, importance and management
A study in patients with kidney and liver disease found that the concurrent use of antacids (aluminium hydroxide, aluminium magnesium silica hydrate) reduced the maximum plasma gemfibrozil levels by about 50 to 70%, and the AUC by about 30 to 60%. The precise values are not given in the text. The reasons for these reductions are not known, but it was suggested that the gemfibrozil is adsorbed onto the antacids in the gut. The authors recommend that gemfibrozil is given 1 to 2 hours before antacids.1 More study is needed to confirm these findings.

Fibrates; Clofibrate + Hormonal contraceptives

Fibrates; Gemfibrozil + Antacids

Antacids can reduce the absorption of gemfibrozil.

Clinical evidence, mechanism, importance and management
A study in patients with kidney and liver disease found that the concurrent use of antacids (aluminium hydroxide, aluminium magnesium silica hydrate) reduced the maximum plasma gemfibrozil levels by about 50 to 70%, and the AUC by about 30 to 60%. The precise values are not given in the text. The reasons for these reductions are not known, but it was suggested that the gemfibrozil is adsorbed onto the antacids in the gut. The authors recommend that gemfibrozil is given 1 to 2 hours before antacids.1 More study is needed to confirm these findings.

Fibrates; Gemfibrozil + Psyllium

When 10 healthy subjects took gemfibrozil 600 mg with, or 2 hours after, 3 g of psyllium in 240 mL water, the AUC of gemfibrozil was reduced by about 10%.1 This change in bioavailability is almost certainly too small to be clinically significant.

Nicotinic acid (Niacin) + Aspirin

Aspirin reduces the flushing reaction that often occurs with nicotinic acid, but there is some evidence that it can also increase nicotinic acid plasma levels.

Clinical evidence, mechanism, importance and management
Nicotinic acid (70 to 100 micrograms/kg per minute as an infusion over 6 hours) was given to 6 healthy subjects. When the subjects were also given aspirin 1 g orally 2 hours after the infusion was started, the plasma nicotinic acid levels rose markedly, and its clearance was reduced by 30 to 54%.1 The probable reason is that the salicylate competes with the nicotinic acid for metabolism by glycine conjugation in the liver so that the clearance of nicotinic acid is reduced, resulting in a rise in its levels. The clinical importance of this effect when aspirin is given to reduce the annoying nicotinic acid flushing reaction2 is not known. However, as nicotinic acid is titrated upwards, according to efficacy and tolerability, any increase in its levels caused by aspirin is probably naturally accounted for.

Nicotinic acid (Niacin) + Nicotine

An isolated report describes an unpleasant flushing reaction that developed in a woman taking nicotinic acid when she started to use nicotine transdermal patches.

Clinical evidence, mechanism, importance and management
A case report describes a woman who had taken nicotinic acid 250 mg twice daily for 3 years without problems, as well as nifedipine, ranitidine, colisterylamine and fumarate. Following laryngectomy for cancer of the larynx, she restarted all of the drugs except the colisterylamine and began to use nicotine transdermal patches 21 mg daily to try to give up smoking. On several occasions, shortly after taking the nicotinic acid, she developed unpleasant flushing episodes lasting about 30 minutes. No further episodes developed when the nicotinic acid was stopped.1 The reasons are not understood, but flushing is a very common adverse effect of nicotinic acid, and it would seem that in this case the nicotine patch may have been responsible for its emergence. A comment on this report suggests that this reaction may possibly have an immunological basis.2 Either way, this reaction is more unpleasant than serious.

Statins + ACE inhibitors

In general the statins do not appear to interact with the ACE inhibitors. An isolated report describes severe hypokalaemia in a diabetic given lisinopril with lovastatin, and acute pancreatitis has been attributed to the use of lisinopril with atorvastatin.
Clinical evidence, mechanism, importance and management

Retrospective analysis of clinical study data found no evidence that the safety of lovastatin was altered by the use of unspecified ACE inhibitors in 142 patients. Another retrospective analysis of clinical study data found no evidence that the safety or efficacy of fluvastatin was altered by the use of unspecified ACE inhibitors. Likewise, the UK manufacturer of atorvastatin says that in clinical studies it was given with ACE inhibitors without evidence of significant adverse interactions. A study in healthy subjects found that simvastatin had no effect on the pharmacokinetics or ACE-inhibitory effects of ramipril or its metabolites. Similarly, no evidence of clinically important adverse interactions was found when moexipril was used with cholesterol-lowering drugs [not specifically named]. An isolated report describes a type I diabetic (receiving insulin) with hypertension and hyperlipidaemia who developed myositis and severe hyperkalaemia (serum potassium 8.4 mmol/L) when given lovastatin 20 to 40 mg daily with lisinopril 50 mg daily. His serum potassium returned to about 5.5 mmol/L after the lovastatin was stopped and the dosage of lisinopril lowered (to 20 mg daily). About 3 months later, the patient resumed taking the lovastatin, but after only 2 doses he again had severe myositis and hyperkalaemia, which resolved after the lovastatin was discontinued. The reason seemed to be a combination of the hyperkalaemic effects of the lisinopril, the release of intracellular potassium into the blood stream associated with the myositis caused by the lovastatin, and a predisposition to hyperkalaemia due to the diabetes and mild renal impairment. Another case report describes the development of acute pancreatitis in a patient who had been taking lisinopril 10 mg daily with atorvastatin 20 mg daily for 9 months. No other cause for the pancreatitis was identified, and both drugs alone have, rarely, been associated with the development of pancreatitis. These are unusual cases and, given the widespread use of these drugs in these classes they seem unlikely to be of general importance. No special precautions would seem to be necessary if ACE inhibitors are given with statins.

Statins + Angiotensin II receptor antagonists

There is some evidence of a high incidence of myopathy when amiodarone is given with high doses of simvastatin. Cases of myopathy and rhabdomyolysis have been reported in patients taking the combination.

Clinical evidence, mechanism, importance and management

The manufacturers of simvastatin note that in an ongoing unpublished clinical study, myopathy (clinically significant muscle pain with a creatinine kinase at least 10 times the upper limit of normal) has been reported in 6% of patients receiving simvastatin 80 mg daily with amiodarone. There is some evidence from reports to the US FDA that the concurrent use of simvastatin with amiodarone is associated with a higher incidence of muscle toxicity than pravastatin with amiodarone. They reported that the percentage of reports of muscle, liver, pancreas, and bone marrow toxicity associated with statins and involving concurrent amiodarone was 1% for simvastatin and 0.4% for pravastatin. A 63-year-old man developed diffuse muscle pain with generalised muscular weakness 4 weeks after starting to take simvastatin 40 mg daily, and about 2 weeks after starting to take amiodarone (1 g daily for 10 days, then 200 mg daily thereafter). There was a marked increase in creatinine kinase, which normalised after stopping both drugs. A 77-year-old man taking multiple medications including amiodarone 100 mg daily and simvastatin 20 mg daily, developed increasing lower-extremity pain and darkening of his urine 3 weeks after his simvastatin dose was increased to 40 mg daily. He was diagnosed with rhabdomyolysis secondary to simvastatin use, although a later comment suggested that amiodarone could have contributed. Two other cases of rhabdomyolysis in patients taking amiodarone with simvastatin (one involving clarithromycin), have also been reported. One of these patients had pneumonia, and the other diabetes, both of which have been suggested as risk factors for rhabdomyolysis.

Amiodarone is an inhibitor of various cytochrome P450 isoenzymes. Whether it inhibits the metabolism of simvastatin and other extensively-metabolised statins, and thereby increases the risk of muscle toxicity, is not known. Amiodarone alone may sometimes cause myopathy.

The interaction is not established. However, one manufacturer in the UK recommends that the dose of simvastatin should not exceed 20 mg daily in patients also taking amiodarone unless the clinical benefit is likely to outweigh the increased risk of myopathy and rhabdomyolysis. Another contraindicates the combination. The US manufacturer advises only using doses of simvastatin above 20 mg if the benefits outweigh the risks.

Until more is known, caution is certainly warranted. See also ‘muscle toxicity’, for further guidance on monitoring and risk factors for muscle toxicity. Lovastatin is metabolised in the same way as simvastatin, and shares many of its interactions: the manufacturers of lovastatin suggest a maximum dose of 40 mg daily in the presence of amiodarone.

Pravastatin appears less likely to interact.

Ibresartan and telmisartan appear not to alter the pharmacokinetics of simvastatin, fluvastatin does not alter the pharmacokinetics of losartan or its active metabolite, and olmesartan appears not to interact with pravastatin.

Clinical evidence, mechanism, importance and management

(a) Fluvastatin

In a crossover study 12 healthy subjects were given losartan 50 mg in the morning for 7 days, followed by fluvastatin 40 mg at bedtime for 7 days, and then both drugs together for another 7 days. It was found that the steady-state pharmacokinetics of losartan and its active metabolite, E-3174, were not significantly altered by fluvastatin. It was anticipated that fluvastatin might inhibit the conversion of losartan to E-3174 by inhibiting the cytochrome P450 isoenzyme CYP2C9 (compare ‘Angiotensin II receptor antagonists + Azoles’, p. 35). The findings of this study indicate that a clinically relevant pharmacokinetic interaction is unlikely, and no losartan dose adjustment is required on combined use.

(b) Pravastatin

The manufacturer of olmesartan states that it has no clinically relevant interaction with pravastatin in healthy subjects.

(c) Simvastatin

A study in 12 healthy subjects found that ibresartan 300 mg had no significant effect on the pharmacokinetics of a single 50-mg dose of simvastatin, or its metabolite simvastatin acid, and the combination was well-tolerated. No clinically relevant interaction was noted when telmisartan was given with simvastatin.

2. Olmece (Olmesartan medoxomil). Daiichi Sankyo UK Ltd. UK Summary of product characteristics, August 2006.

**Statins + Antacids**

An aluminium/magnesium hydroxide antacid (Maalox) causes a moderate reduction in the bioavailability of atorvastatin, pravastatin, and rosuvastatin, but the lipid-lowering efficacy of atorvastatin and pravastatin is not affected.

**Clinical evidence, mechanism, importance and management**

In a multiple-dose study, 18 patients were given atorvastatin 10 mg daily for 15 days with 30 mL of an aluminium/magnesium hydroxide antacid (Maalox TC) four times daily for a further 17 days. The maximum serum levels and AUC of atorvastatin were reduced by 34%, and the absorption rate was also reduced by the antacid. However, the LDL-cholesterol reduction remained the same.1 The concurrent use of the same antacid (Maalox TC) 15 mL four times daily, given one hour before pravastatin, reduced the bioavailability of a single 20-mg dose of pravastatin by 28%. This change was less than that seen with food, which did not alter pravastatin efficacy.2 There is therefore no need to avoid the concurrent use of aluminium/magnesium hydroxide antacids such as Maalox, nor does the dosage of atorvastatin or pravastatin need to be raised.

The US manufacturers of rosuvastatin quote a study in which an aluminium/magnesium hydroxide antacid reduced the levels of a 40-mg dose of rosuvastatin by 54%. No clinically significant interaction was seen when the doses were given 2 hours apart, and a 2-hour separation is therefore recommended on concurrent use.3

**Statins + Azoles**

Fluvastatin modestly increases the levels of fluvastatin and rosuvastatin, but not pravastatin. Mifazocin would be expected to interact similarly. Itraconazole causes a marked rise in the serum levels of atorvastatin, lovastatin, pravastatin and simvastatin, but no change in fluvastatin or rosuvastatin levels. Ketoconazole would be expected to interact similarly. Rhabdomyolysis has been reported in some cases. Due to the risk of myopathy, the manufacturers of voriconazole caution, and the manufacturers of posaconazole contraindicate, concurrent use with atorvastatin, lovastatin and simvastatin.

**Clinical evidence**

(c) Atorvastatin

A case report describes a 76-year-old man taking multiple medications, including pravastatin 80 mg daily with fluvastatin 150 mg daily, unevenly for about 18 months. Due to an inadequate response to the pravastatin he was changed to atorvastatin 40 mg daily. Within one week he developed dyspnoea, myopathy, rhabdomyolysis and renal failure. Although both drugs were stopped he later died of multi-organ failure. The authors considered an interaction between atorvastatin and fluvastatin as the most likely explanation for the rhabdomyolysis.1

Ten healthy subjects were given itraconazole 200 mg daily for 5 days with a single 40-mg dose of atorvastatin on day 4. The itraconazole increased the AUC of atorvastatin acid and atorvastatin lactone fourfold and threefold, respectively, and increased their half-lives threefold and twofold, respectively. The AUC values of active and total HMG-CoA reductase inhibitors were increased 1.6- and 1.7-fold, respectively.2 In a similar study, the same dose of itraconazole increased the AUC of atorvastatin by 2.5-fold and of atorvastatin lactone by about threefold. Another study has also shown that itraconazole raises atorvastatin levels.3

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 2 cases of rhabdomyolysis involving atorvastatin.4

(b) Fluvastatin

A randomised, double-blind study in 12 healthy subjects found that flucnocazole (400 mg on day 1 followed by 200 mg daily for 3 days) increased the AUC of a single 40-mg dose of fluvastatin by 84% and increased its maximum plasma level by 44%. The pharmacokinetics of the flucnocazole were unaffected.6 In a similar study, itraconazole 100 mg daily for 4 days did not significantly affect the pharmacokinetics of fluvastatin, apart from a small increase in its half-life.7

(c) Lovastatin

In a double-blind, crossover study in 12 healthy subjects itraconazole 200 mg daily or a placebo was given for 4 days with a single 40-mg oral dose of lovastatin on day 4. On average the peak plasma concentration and the 24-hour AUC of the lovastatin were increased more than 20-fold. The peak plasma concentration of the active metabolite of lovastatin,lovastatin acid, was increased 13-fold (range 10 to 23-fold) and its AUC was increased 20-fold. The creatine kinase activity of one subject increased 10-fold, but in the other 11 subjects it remained unchanged.8 Another study also found similar pharmacokinetic changes.7 Brief mention is also made of severe rhabdomyolysis in one patient given lovastatin and itraconazole.8

A 63-year-old woman who had been taking lovastatin 80 mg, nicotinic acid 3 g daily, timolol and aspirin for almost 10 years without problems, developed weakness and tenderness in her arms, back and legs within 2 weeks of starting to take itraconazole 100 mg twice daily. A few days later her urine became brown, and positive for haem. She was diagnosed as having acute rhabdomyolysis and hepatotoxicity. The lovastatin, nicotinic acid and itraconazole were stopped, and she was treated with ubeidecarenone. Over the next 18 days her elevated serum enzymes returned to normal, although her plasma cholesterol levels almost doubled. She was restarted on nicotinic acid 11 weeks later without problems.9

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 6 cases of rhabdomyolysis involving lovastatin.2

(d) Pravastatin

A randomised, double-blind study in 12 healthy subjects found that flucnocazole (400 mg on day 1 followed by 200 mg daily for 3 days) had no significant effect on the pharmacokinetics of a single 40-mg dose of pravastatin.8

The AUC of a single 40-mg dose of pravastatin was increased by 71% in 10 healthy subjects who took itraconazole 200 mg daily for 4 days, although this did not reach statistical significance.10 In a similar study, the same dosage of itraconazole caused a modest 51% increase in the AUC of pravastatin.3 In contrast, one study in 104 subjects found that itraconazole had no effect on pravastatin pharmacokinetics.4

(e) Rosuvastatin

Fluvastatin 200 mg once daily for 11 days increased the AUC and maximum plasma concentration of rosuvastatin (given on day 8) by 14% and 9%, respectively, in 14 healthy subjects. The proportion of circulating active HMG-CoA reductase inhibitors was not affected by flucnocazole.11 In similar studies by the same workers, itraconazole and ketoconazole also had no clinically significant effect on the levels of rosuvastatin.

(f) Simvastatin

An 83-year-old man who had been taking multiple medications including simvastatin 40 mg daily for 2 years was given flucnocazole 400 mg daily as part of a prophylactic regimen against chemotherapy-induced neutropenic sepsis. After one week he developed generalised muscle weakness and was found to have brown urine and an elevated serum creatine kinase. His medication was stopped, and he was treated with hydration and diuretics, after which his symptoms resolved.14

In a two-phase crossover study, 10 healthy subjects were given itraconazole 200 mg daily or a placebo for 4 days, with a single 40-mg dose of simvastatin on day 4. The peak serum levels of total simvastatin acid (simvastatin acid plus simvastatin lactone) were increased 17-fold and the AUC was increased 19-fold. The maximum serum levels and the AUC of total HMG-CoA reductase inhibitors increased about 3-fold and 5-fold, respectively.10
A 74-year-old who had been taking simvastatin 40 mg daily, lisinopril and aspirin for about a year without problems developed pain in his feet, and then in his arms and neck, within 3 weeks of starting itraconazole 200 mg daily. His urine turned brown, his muscles were tender, and abnormal serum creatine kinase and other enzyme levels were found. A diagnosis of rhabdomyolysis was made.11 A 70-year-old with a kidney transplant was taking concomitant diltiazem and one of these statins 200 mg daily. Despite the high dose of simvastatin, even in conjunction with ciclosporin (see also ‘Statins + Ciclosporin’, p.1097), he had experienced no problems. Within 2 weeks of starting itraconazole 100 mg twice daily he developed malaise and general muscle weakness with elevated creatine kinase levels, which was diagnosed as rhabdomyolysis. His serum simvastatin levels were found to be raised. A later subject also had an increase in simvastatin serum levels, from 0.5 to 6.5 nanogram/mL within a day of starting itraconazole 200 mg daily.12 Three further similar cases have also been reported with the combination of simvastatin, ciclosporin and itraconazole.17–19 Gemfibrozil was also taken in one of these cases.19 In addition, three similar cases have been reported in patients taking simvastatin, which developed between 10 days and 4 weeks after starting ketoconazole 200 or 400 mg daily.20-22 In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 4 cases of rhabdomyolysis involving simvastatin.23

**Mechanism**

Fluconazole and miconazole inhibit the cytochrome P450 isoenzymes CYP2C9 and CYP3A4, whereas itraconazole and ketoconazole are potent inhibitors of CYP3A4. Consequently their interaction profiles differ amongst the various statins depending on which isoenzymes are involved in the metabolism of the statins in question: this has been shown in several studies.26,27 From these studies it appears that the effect of itraconazole is greatest on lovastatin and simvastatin, with a marked effect on pravastatin or rosuvastatin, and no effect on fluvastatin. Flucnazoile has a marked effect on fluvastatin, but no effect on pravastatin. See ‘Lipid regulating drugs’, (p.1086) for further discussion on the metabolism of the statins.

**Importance and management**

An established interaction of clinical importance, which differs depending on the drug pair used. The differing risks and management of the various drug pairs are discussed below. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

1. **Lovastatin or simvastatin.** The very marked increases in levels of lovastatin and simvastatin that can occur considerably increase the risk of severe muscle damage and therefore the use of these statins with itraconazole or ketoconazole should be avoided. If a short course of an azole antifungal is considered essential, the manufacturers suggest temporary withdrawal of the statin.21–24 The manufacturers of voriconazole predict that it will interact with statins metabolised by the cytochrome P450 isoenzyme CYP3A4, resulting in elevated statin levels, and possibly rhabdomyolysis. They suggest that a dosage reduction of the statin should be considered during concurrent use.25 The manufacturer of posaconazole (also a CYP3A4 inhibitor) contraindicates its use with simvastatin or lovastatin.26

2. **Atorvastatin.** Although the increase in the levels of atorvastatin are not as great as those with lovastatin or simvastatin, they are still marked, and unless the benefits outweigh the risks the combination of an azole antifungal with atorvastatin should, where possible, be avoided. As a general rule, any patient given atorvastatin with an azole should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. Note that the manufacturer of posaconazole contraindicates its use with atorvastatin,26 and the manufacturers of voriconazole suggest considering a dosage reduction of the statin.26,27

3. **Fluvastatin.** The clinical relevance of the modest changes in fluvastatin levels with different azole antifungals is unclear. Note that in a review of the FDA spontaneous reports of statin-associated rhabdomyolysis for the period November 1997 to March 2000, azole antifungals were not identified as a potentially interacting drug in any of the reports for pravastatin.23

that concurrent use actually has additive lipid-lowering effects.2,3 In the studies in large numbers of hypercholesterolaemic patients have shown that concurrent use of bile-acid binding resins bind with statins in the gut and thereby reduce the amount of statin available for absorption.

**Importance and management**

Established interactions but of only relatively minor importance. Despite the reduction in the bioavailability of pravastatin caused by colestyramine or colestipol, the overall lipid-lowering effect is increased by concurrent use.5,7 The effects of the interaction can be minimised by separating their administration as described above. This can be easily achieved by taking the colestyramine or colestipol with meals, and the pravastatin at bedtime. Similarly, any interaction between fluvastatin and colesterylam can be minimised by taking fluvastatin at least 4 hours after colesterylam. There would appear to be no reason for avoiding concurrent use of atorvastatin and colestipol, nor lovastatin and colesterylam.

**Clinical evidence**

(a) **Atorvastatin**

A study in which atorvastatin and colestipol were given concurrently found that although the serum levels of atorvastatin were reduced by about 25%, the total reduction in the LDL-cholesterol levels was greater than when each drug was given alone.1

(b) **Fluvastatin**

Colestyramine 8 g given at the same time as fluvastatin 20 mg decreased the AUC and the maximum plasma levels of fluvastatin by 89 and 96%, respectively, in 19 healthy subjects. When the fluvastatin was given 2 hours after the colestyramine, the AUC and the maximum plasma levels of fluvastatin were reduced by just over 50%.2 In another study in 20 healthy subjects, the AUC and maximum plasma levels of fluvastatin were reduced by 51 and 82%, respectively, when fluvastatin was taken 4 hours after colestyramine 8 g and a meal.2

Despite these marked reductions in fluvastatin bioavailability, other studies in large numbers of hypercholesterolaemic patients have shown that concurrent use actually has additive lipid-lowering effects.2,3 In the first of these studies, fluvastatin was given 4 hours after colestyramine,2 but the other study did not indicate whether or not doses were separated.3

(c) **Lovastatin**

An open-label crossover study in 22 healthy subjects found that the pharmacokinetics of lovastatin 20 mg given with a meal were not significantly affected when colesuvelam 2.25 g was given at the same time.6

(d) **Pravastatin**

In a randomised study 33 patients with primary hypercholesterolaemia were given pravastatin 5, 10, or 20 mg twice daily before their morning and evening meals for 4 weeks and then for a further 4 weeks they also took colestyramine 24 g daily. The colestyramine was taken at least an hour after the pravastatin. Despite the fact that the colestyramine reduced the bioavailability of the pravastatin by 18 to 49%, the reduction in blood lipid levels was enhanced by concurrent use.7 A related study in 18 subjects found that colestyramine reduced the bioavailability of pravastatin by about 40% when given at the same time, but only small and clinically insignificant pharmacokinetic changes occurred when the pravastatin was given one hour before, or 4 hours after the colestyramine.7 Similarly, a multicentre study involving 311 patients found that the combined use of pravastatin 40 mg daily and colestyramine 12 g daily was highly effective in the treatment of hypercholesterolaemia. The colestyramine was taken at least one hour after the pravastatin.7

**Colestipol** reduced the bioavailability of pravastatin in 18 subjects by about 50%, but no reduction in bioavailability was seen when pravastatin was given 1 hour before colestipol and a meal.6

**Mechanism**

It seems probable that these bile-acid binding resins bind with statins in the gut and thereby reduce the amount of statin available for absorption.

**Statins + Calcium-channel blockers**

Marked rises in statin plasma levels have been seen when lovastatin or simvastatin were given with diltiazem, and when simvastatin was given with verapamil. Isolated cases of rhabdomyolysis have occurred as a result of these interactions. However, overall, it seems that problems with combinations of statins and calcium-channel blockers (particularly the dihydroxypridine-type) are rare.

**Clinical evidence**

(a) **Atorvastatin**

The manufacturers of amiodipine state that it does not affect the pharmacokinetics of atorvastatin.1 They also note that no clinically significant interactions were seen in clinical studies in which atorvastatin was used with antihypertensives, including unspecified calcium-channel blockers.1 However, they do warn that drugs that are metabolised by the cytochrome P450 isoenzyme CYP3A4 (e.g. calcium-channel blockers) do have the potential to interact.1

A 60-year-old man taking atorvastatin 20 mg daily, developed rhabdomyolysis 3 weeks after diltiazem (an inhibitor of CYP3A4) was started.8 Another similar case has also been reported.8

(b) **Fluvastatin**

A retrospective study of the effects of antihypertensives on the efficacy of fluvastatin found that the concurrent use of unspecified calcium-channel blockers did not significantly affect the safety or lipid-lowering effects of fluvastatin, although there was a trend towards enhanced lowering of triglycerides.4

(c) **Lovastatin**

A retrospective study of the effects of lovastatin and antihypertensive medication found that when calcium-channel blockers (diltiazem, nifedipine or verapamil) were used in combination with lovastatin there was an additional 3 to 5% lowering in the LDL-cholesterol, which was of marginal significance.5 Pharmacokinetic studies have shown that oral diltiazem increases the AUC and maximum serum levels of lovastatin by about fourfold.6,7 In another study, lovastatin 20 mg and isradipine 5 mg
was given to 12 healthy subjects either alone or together for 5 days. **Isradipine** reduced the AUC of lovastatin by 40%, in males but not females. **Pravastatin**

**A** A study in 10 healthy subjects found that sustained-release **diltiazem** 120 mg twice daily had no effect on the pharmacokinetics of a single 20-mg dose of pravastatin. Similarly, a study in 15 healthy subjects found that extended-release **verapamil** 480 mg daily for 3 days did not affect the pharmacokinetics of pravastatin 40 mg daily.

**E** **Simvastatin**

1. **Amlodipine**. In a study in 8 patients taking simvastatin 5 mg daily the addition of amlodipine 5 mg daily for 4 weeks increased the maximum levels and AUC of simvastatin by a modest 1.4- and 1.3-fold, respectively, without affecting the lipid profiles of the patients.

2. **Diltiazem**. A single 20-mg dose of simvastatin was given to 10 healthy subjects after they had taken sustained-release diltiazem 120 mg twice daily for 2 weeks. Diltiazem caused a about a fivefold increase in the simvastatin AUC, a fourfold increase in the maximum serum levels, and a 2.5-fold increase in the half-life. The clinical relevance of the diltiazem interaction was demonstrated in a 53-year-old man, who developed rhabdomyolysis 3 months after diltiazem 30 mg four times daily was added to established treatment with simvastatin 40 mg daily. Both drugs were discontinued and he recovered over the following 10 days. Other similar cases have also been reported.

An **in vitro** study using human liver microsomes also found that diltiazem moderately inhibits simvastatin metabolism.

3. **Lacidipine**. In a randomised, crossover study simvastatin 40 mg daily was given for 8 days, with or without lacidipine 4 mg daily. Lacidipine raised the AUC of simvastatin by 35%, which was considered to be modest and unlikely to be of clinical significance.

4. **Verapamil**. A study in which 12 subjects were given verapamil 80 mg three times daily, found a 4.6-fold increase in the AUC of simvastatin, a 2.6-fold increase in its maximum serum levels, and about a twofold increase in its half-life. Similarly, a study in 12 healthy subjects found that extended-release verapamil 480 mg daily for 3 days caused a fivefold increase in the maximum serum levels of simvastatin 40 mg, and about a fourfold increase in its AUC.

The clinical relevance of the verapamil interaction was demonstrated in a 63-year-old man, who developed rhabdomyolysis 3 months after verapamil 30 mg four times daily was added to established treatment with simvastatin 40 mg daily. Both drugs were discontinued and he recovered over the following 14 days.

An **in vitro** study using human liver microsomes also found that verapamil moderately inhibits simvastatin metabolism.

**Mechanism**

Diltiazem and verapamil inhibit the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of lovastatin, simvastatin and to an extent, atorvastatin. Therefore concurrent use of these drugs results in an increase in the levels of the statin. One study found that oral, but not intravenous diltiazem interacts, suggesting that it is CYP3A4 in the gut wall that is the site of the interaction. Isradipine and lovastatin are both metabolised by CYP3A4, and therefore the modest interaction may have occurred as a result of competition for metabolism. A similar mechanism probably accounts for the modest interaction between simvastatin and lacidipine or amlodipine. See ‘Lipid regulating drugs’, (p.1086), and ‘Calcium-channel blockers’, (p.860), for more information about the way these groups of drugs are metabolised.

**Importance and management**

Information is limited, but what is known suggests that the concurrent use of these drugs is normally uneventful. Even with those pairs of drugs where the increases in plasma levels are quite large (such as when simvastatin was given with diltiazem or verapamil) problems seem to be very rare. Indeed an analysis of the 45 study and the Heart Protection Study (which used maximum simvastatin doses of 40 mg) found no evidence that the concurrent use of a calcium-channel blocker increases the risk of myopathy. Therefore concurrent use need not be avoided, but it has been suggested that treatment with a statin in a patient taking diltiazem (and probably verapamil) should be started with the lowest possible dose and titrated upwards, or, if diltiazem (or verapamil) is started, the dose of the statin should be considerably reduced. The manufacturers of lovastatin recommend restricting the dose to 40 mg daily if verapamil is given, and the manufacturers of simvastatin suggest restricting the dose to 20 mg daily. Note that one UK manufacturer recommends that the combination should be avoided, which seems somewhat over-cautious. In the UK it has been suggested that the dose of simvastatin should be restricted to 40 mg daily in the presence of diltiazem. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

**Statins + Carbamazepine**

**Carbamazepine dramatically reduces simvastatin levels.**

**Clinical evidence**

In a randomised, crossover study 12 healthy subjects were given car

**Carbamazepine** therefore increases simvastatin metabolism, leading to reduced levels. **Lovastatin**, and to a lesser extent, **atorvastatin** are also metabolised by CYP3A4.

**Importance and management**

Although this appears to be the only study, the effects of concurrent use are consistent with both the way carbamazepine interacts with many other CYP3A4 substrates and the way simvastatin interacts with other CYP3A4
Ciclosporin can cause marked rises in the plasma levels of atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin, and for some of the statins this has led to the development of serious myopathy (rhabdomyolysis) accompanied by renal failure. The plasma levels of ciclosporin appear not to be affected by fluvastatin, lovastatin, pravastatin, or rosuvastatin, but some moderate changes in ciclosporin levels have been seen when atorvastatin or simvastatin were given.

Clinical evidence

(a) Atorvastatin

1. Effect on ciclosporin. In a study of 10 patients taking ciclosporin following a kidney transplant, 4 showed increases in their trough ciclosporin levels of between 26 and 54% when atorvastatin 10 mg was added, necessitating a dosage reduction of ciclosporin. No changes were seen in 6 other patients, and the incidence of adverse effects was no greater than in a control transplant group not given atorvastatin.7,8 Similar results were seen in other studies, one using fluvastatin 20 mg twice daily, 9 and one in 17 renal transplant recipients taking extended-release fluvastatin.10 In an open-label study 10 stable heart transplant patients taking ciclosporin were randomised to receive fluvastatin 40 mg daily for 10 days. When compared with historical controls not taking ciclosporin, the maximum serum levels of ciclosporin generally decreased (by a mean of 13.5%). However, 4 patients needed a decrease in their ciclosporin dose and one patient needed an increase.2 A further analysis of this study has been reported elsewhere.10 A case of rhabdomyolysis was reported in a woman who took both drugs for 28 days after beginning therapy than on day 1 (suggesting accumulation) and were estimated to be 20-fold higher than values reported in healthy subjects not taking ciclosporin.17 A further study found that the AUC of lovastatin was five times greater in patients taking ciclosporin than in patients not taking ciclosporin, irrespective of whether the patients had received transplants or were receiving other immunosuppressants.18 There are at least 9 documented cases of rhabdomyolysis, often resulting in acute renal failure, in patients taking ciclosporin and lovastatin.19-23 In each of these cases the patient was taking lovastatin 40 to 80 mg daily. Several other studies suggest that this interaction may be dose-related. In one study, 15 patients taking ciclosporin were given lovastatin 20 mg daily without problem, but 4 of 5 other patients, who were given lovastatin 40 to 80 mg daily developed rhabdomyolysis, which was associated with renal failure in two of them.24 In a further study 24 patients were given lovastatin 10 or 20 mg daily in addition to ciclosporin. Of the 12 receiving the 20-mg dose, 7 developed either myalgia and muscle weakness or raised creatine phosphokinase levels, but only one patient from the 10-mg group did.25 A report describes a case of rhabdomyolysis when clopidogrel was added to treatment with ciclosporin and lovastatin.26 The incidence of myopathies with lovastatin is about 0.1 to 0.2%,1 but in the presence of ciclosporin the incidence is said to be as high as 30%.27

(b) Fluvastatin

1. Effect on ciclosporin. When fluvastatin 20 mg daily was given to 16 patients taking ciclosporin 21 to 103 months after renal transplantation, no significant changes were seen in their ciclosporin levels.12 Several studies have shown no rises in creatine phosphokinase levels,28,32,33 and no increase in adverse effects17,32,34 when pravastatin in doses of 10 to 40 mg daily was given with ciclosporin.

(c) Lovastatin

1. Effect on ciclosporin. Ciclosporin and creatine phosphokinase levels were not significantly changed in 6 renal transplant patients taking ciclosporin and lovastatin (10 mg for 8 weeks, then 20 mg for 12 weeks).13 Similar results were found in another study.16

2. Effect on lovastatin. The plasma levels of lovastatin 10 to 20 mg daily in 6 patients also taking ciclosporin were about the same as those seen in healthy subjects taking lovastatin 40 mg alone (i.e. the levels were increased by up to fourfold by ciclosporin).15 In another study in 21 renal transplant patients taking ciclosporin, the maximum serum levels and AUC of lovastatin 20 mg daily were 40 and 47% higher, respectively, 28 days after beginning therapy than on day 1 (suggesting accumulation) and were estimated to be 20-fold higher than values reported in healthy subjects not taking ciclosporin.17

(d) Pravastatin

1. Effect on ciclosporin. Several studies have shown no significant change in ciclosporin levels in patients also taking pravastatin.17,28

2. Effect on pravastatin. A study in 19 paediatric and adolescent cardiac transplant patients (mean age 12.1 years) found that triple immunosuppressant therapy (17 patients taking ciclosporin) raised the maximum levels and AUC of pravastatin 10 mg daily for 8 weeks by about eightfold and tenfold, respectively, when compared with control subjects not receiving immunosuppressants. There was extremely large intersubject variation in the pravastatin AUC and maximum levels.29 Similar results have been found in studies in adults.30,31 Although a study in patients taking ciclosporin found that the AUC of pravastatin 20 mg daily did not differ between day 1 and day 28 of therapy (suggesting no accumulation), the AUC values were estimated to be five to sevenfold higher than in patients not taking ciclosporin.17 In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 5 cases of rhabdomyolysis involving atorvastatin.9

(e) Rosuvastatin

In an open-label study 10 stable heart transplant patients taking ciclosporin were given rosuvastatin 10 mg daily for 10 days. When compared to healthy historical controls, the rosuvastatin maximum levels and AUCs were found to have been increased by 10.6-fold and 7.1-fold, respectively. Rosuvastatin had little effect on ciclosporin levels.35

(f) Simvastatin

1. Effect on ciclosporin. A study found that the ciclosporin levels of 12 renal transplant patients fell from 334 to 235 micrograms/L after simvastatin 5 to 15 mg daily was added.36 A retrospective study by the same authors confirmed these results in 12 patients.36 In contrast, a single-dose pharmacokinetic study suggested that simvastatin increases the maximum levels and AUC of ciclosporin by a modest 8% and 13%, respectively.37

2. Effect on simvastatin. A group of 20 heart transplant patients were given simvastatin 10 mg daily and ciclosporin over a period of 4 months. The plasma levels of simvastatin acid were at least 6 times higher in 7 patients taking ciclosporin than in 7 control patients not taking ciclosporin.38 Similarly, a study comparing 5 renal transplant patients taking ciclosporin and
simvastatin 20 mg daily with 5 renal transplant patients not given ciclosporin found that the AUC and maximum serum levels of simvastatin were 2.5-fold and 2.5-fold greater, respectively, in the patients taking ciclosporin. There are at least 5 documented cases of rhabdomyolysis, one of which was fatal, in patients given ciclosporin and simvastatin. Although this report describes a case of rhabdomyolysis when clopidogrel was added to treatment with ciclosporin and simvastatin. In a review of the FDA sponsored reports of statins-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 31 cases of rhabdomyolysis involving simvastatin. In the first study cited above, significant changes in ciclosporin levels and creatine kinase were seen, and the combination was well tolerated. Similar results were found in another study over 8 months.

**Mechanism**

The marked rises in statin levels and/or toxicity (rhabdomyolysis) probably occur because both the statin and ciclosporin compete for the same metabolising enzyme, the cytochrome P450 isoenzyme CYP3A4. The extent of the interaction seems to depend on the relative affinities of the different statins for this isoenzyme, and also on whether they can be metabolised by alternative pathways. F-glycoprotein and other transporter proteins may also have a part to play, especially in the raised ciclosporin levels seen with pravastatin. See ‘Lipid regulating drugs’, (p.1086) for more information about the metabolism of the statins.

In the cases where rhabdomyolysis developed when clopidogrel was added to treatment with ciclosporin and a statin it was thought that the addition of clopidogrel (which may also inhibit the cytochrome P450 enzyme system) may have destabilised the delicate metabolic equilibrium between the statins and ciclosporin precipitating the development of rhabdomyolysis.

**Importance and management**

The interacting effect of ciclosporin on the statins is well documented, well established and clinically important. Concurrent use need not be avoided (except in the case of rosuvastatin, where concurrent use is contraindicated in the UK) but it should be very well monitored, a precautionary recommendation being to start (or reduce) the statin to the lowest daily dose appropriate to the patient’s condition.

The manufacturers of simvastatin suggest that the dose should not exceed 10 mg daily, and the manufacturer of lovastatin suggests its dose should not exceed 20 mg daily.

The manufacturer of pravastatin suggests a starting dose of 20 mg. Note that, unlike the UK manufacturers, the US manufacturers do not contraindicate rosuvastatin. However, they do warn that the risk of myopathy is increased, and advise that this should be taken into consideration when deciding on a dose. Therefore, as with other statins, it would seem that the lowest daily dose of rosuvastatin should be used.

Any patient given ciclosporin with a statin should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, withdrawing the statin has been shown to resolve the symptoms.

Alterations in ciclosporin levels with the statins are generally small and seem likely to be identified by routine ciclosporin monitoring. However, note that the status of the statin, and possibly atorvastatin had some-
Statins + Colchicine

Three case reports describe myopathy or rhabdomyolysis in patients given colchicine with fluvastatin, pravastatin or simvastatin. It seems possible that this interaction could occur with colchicine and any statin.

Clinical evidence

(a) Fluvastatin

A 70-year-old man who had been taking fluvastatin 80 mg daily for 2 years started taking colchicine 1.5 mg daily for an attack of gouty arthritis. Within 3 days he felt nauseous and began to develop muscle pains and weakness. On admission to hospital he was found to have acute renal failure and a raised creatine kinase, and was diagnosed with rhabdomyolysis. Both drugs were stopped and he made a full recovery over 2 months. He was eventually restarted on fluvastatin without incident.1

(b) Pravastatin

A 65-year-old woman who had been taking pravastatin 20 mg daily for 6 years was given colchicine 1.5 mg daily for an episode of gout. Within 20 days she had developed muscle weakness in the legs and had a slightly raised creatine kinase. A diagnosis of myopathy was made and so both the colchicine and pravastatin were stopped. The weakness resolved over the following week. The colchicine was subsequently given alone, and myopathy did not occur.2

(c) Simvastatin

A patient with chronic renal failure who had been taking simvastatin for 2 years was given colchicine for gout. Within 2 weeks he developed muscle weakness, which was diagnosed as myopathy. Both drugs were stopped and the symptoms resolved.3

Mechanism

It has been suggested that the interaction between simvastatin occurs because both drugs are metabolised by the cytochrome P450 isoenzyme CYP3A4. However, as the interaction has subsequently been seen with fluvastatin and pravastatin this seems unlikely to be the full explanation. P-glycoprotein has also been implicated.2 Colchicine alone can, rarely, cause myopathy. However, it is more common in those given colchicine long term, in high dose, or in the presence of renal impairment.2 As the statins can also cause myopathy, an additive or synergistic effect seems possible.1

Importance and management

Although this interaction is rare it is serious. Given the evidence available it seems likely to occur with all statins, although this has not been clearly demonstrated. All patients taking statins should be warned about the symptoms of myopathy and told to report muscle pain or weakness. It would be prudent to reinforce this advice if they are given colchicine. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

Statins + Danazol

Severe rhabdomyolysis and myoglobinuria developed in a man taking lovastatin about two months after danazol was added. Another report describes a similar interaction with simvastatin.

Clinical evidence

(a) Lovastatin

A 72-year-old man taking atenolol, aspirin, dipyridamole and lovastatin 20 mg twice daily was admitted to hospital after complaining of myalgia over the last 12 days, and brown urine over the last 5 days. His condition was diagnosed as severe rhabdomyolysis and myoglobinuria. About 2 months previously he had started taking danazol 200 mg three times daily and prednisone, and one month previously he had received a 10-day course of doxycycline 100 mg twice daily. The aspirin and lovastatin were stopped (danazol was stopped 4 days before admission and the doxycycline was stopped 5 days before the onset of symptoms), and all the symptoms resolved. Laboratory tests were normal within 2 weeks.1

(b) Simvastatin

A 68-year-old man who had been taking simvastatin 40 mg daily long-term without problem developed rhabdomyolysis (progressive muscle pain and weakness, tea-coloured urine, renal impairment, and a raised creatine phosphokinase) within 3 weeks of starting to take danazol 200 mg three times daily. He was given haemodialysis and subsequently recovered.

Mechanism

It has been suggested that danazol (and the doxycycline) were possibly hepatotoxic, which led to decreased lovastatin metabolism, or that the danazol had a direct toxic effect on the muscles.1 Danazol inhibits the cytochrome P450 isoenzyme CYP3A4 by which simvastatin and lovastatin are metabolised, which would result in raised statin levels, and therefore myopathy and rhabdomyolysis.1,2 This seems a more likely explanation for the effects seen.

Importance and management

These appear to be the only reports of this apparent interaction, but the pharmacokinetic basis of the interaction seems to be established. The US manufacturers of lovastatin3 suggest that the dose should not exceed 20 mg daily in the presence of danazol. Similarly the manufacturers of simvastatin suggest that the dose should not exceed 10 mg daily in the presence of danazol.4,5 It would seem prudent to reinforce the symptoms of myopathy and tell patients to report any unexplained muscle pain, tenderness or weakness. The authors of the lovastatin report1 point out that, as in this case, severe lovastatin muscle toxicity may be very slow to develop. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

The statins that are not significantly metabolised by CYP3A4 (fluvastatin, pravastatin, rosuvastatin) are not expected to interact.

Statins + Diuretics

In clinical studies, the safety and efficacy of statins were not altered by concurrent use of diuretics.

Clinical evidence, mechanism, importance and management

Retrospective analysis of clinical study data1 found no evidence that the safety or efficacy of lovastatin was altered by the use of potassium-sparing diuretics (hydrochlorothiazide with triamterene or amiloride), or thiazide diuretics (mostly hydrochlorothiazide). Another retrospective study of 19 patients found that the addition of lovastatin to diuretic treat-
ment caused an initial 30% fall in total serum cholesterol levels for one month, followed by a rise of about 20%. In a further 13 patients, the addition of diuretic treatment to lovastatin caused a 20% fall in total serum cholesterol for one month and then a 20% rise back to baseline values. The diuretics used were furosemide (16 patients), triamterene/hydrochlorothiazide (7), hydrochlorothiazide (8), indapamide (1). The fall and subsequent rise in serum cholesterol levels occurred in all of the patients except just the one taking indapamide. 2 The reason for this initial fall in cholesterol, particularly when the diuretic was added to the statin, is unknown, and the findings of this study are difficult to interpret.

Retrospective analysis of clinical trial data found no evidence that the safety or efficacy of fluvastatin was altered by the use of unspecified diuretics. 3 Likewise, the manufacturer of atorvastatin 4 says that in clinical studies it was used commonly with unnamed diuretics without evidence of significant adverse interactions.

The bulk of the evidence suggests no special precautions are necessary if diuretics are given concurrently with statins.

**Ezetimibe**

Ezetimibe does not appear to have adverse pharmacokinetic interactions with atorvastatin, fluvastatin, lovastatin, rosuvastatin or simvastatin. However, some evidence suggests that concurrent use may increase the risk of myopathy.

**Clinical evidence**

(a) **Atorvastatin**

In a three-arm study patients were given atorvastatin 80 mg daily, atorvastatin 80 mg daily with ezetimibe 10 mg daily, or atorvastatin 40 mg daily with ezetimibe 10 mg daily. No difference in adverse events was noted between each of the 3 groups and there were no significant elevations in creatine kinase. No cases of myopathy or rhabdomyolysis occurred, and the combination was well-tolerated. 1

(b) **Fluvastatin**

In a randomised, crossover study 32 otherwise healthy subjects with hypercholesterolaemia were given either ezetimibe 10 mg daily, fluvastatin 20 mg daily or both drugs in combination for 14 days. The combination was well tolerated, no significant pharmacokinetic interaction occurred, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable. 2 A further similar case has also been reported. 3

**Fenofibrate**

The plasma levels of lovastatin, simvastatin, atorvastatin and pravastatin are increased by gemfibrozil, the levels of fluvastatin are increased by bezafibrate, and the levels of pravastatin are increased by fenofibrate. No pharmacokinetic interactions occur with the combinations of fluvastatin with gemfibrozil, lovastatin with bezafibrate, and pravastatin, rosuvastatin or simvastatin with fenofibrate. Both statins and fibrates are known to cause rhabdomyolysis, and their concurrent use increases the risk of this reaction.

5. Reyderman L, Kosoglou T, Cutler DL, Maxwell S, Statkovich P. The effect of fluvastatin on the pharmacokinetics of both drugs were not significantly changed, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable. 2

(a) **Lovastatin**

In a randomised, crossover study 18 healthy subjects were given either ezetimibe 10 mg daily, lovastatin 20 mg daily or both drugs in combination for 7 days. The combination was well tolerated, and no significant pharmacokinetic interaction was noted. 3

(b) **Rosuvastatin**

In a placebo-controlled study 12 otherwise healthy subjects with hypercholesterolaemia were given ezetimibe 10 mg daily with rosuvastatin 10 mg daily for 14 days. The combination was well tolerated (no significant changes in liver enzymes or creatinine phosphokinase were noted), the pharmacokinetics of both drugs were not significantly changed, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable. 4

(c) **Simvastatin**

In an 1993 placebo-controlled study 3 other otherwise healthy subjects with hypercholesterolaemia were given ezetimibe 10 mg daily with rosvastatin 10 mg daily for 14 days. The combination was well tolerated (no significant changes in liver enzymes or creatinine phosphokinase were noted), the pharmacokinetics of both drugs were not significantly changed, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable. 5

**Mechanism, importance and management**

The available evidence suggests that on the whole the concurrent use of a statin with ezetimibe does not result in a change in the pharmacokinetics of either drug. However, there is some evidence to suggest that concurrent use may increase the risk of myopathy. Therefore any patient taking a statin who is also given ezetimibe should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). See also ‘muscle toxicity’ (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Note that a combination preparation containing simvastatin and ezetimibe is widely available.

Clinical evidence

A. Bezafibrate
(a) Fluvastatin
In one study bezafibrate 200 mg three times daily increased the AUC and maximum levels of fluvastatin 20 mg daily by about 50 to 60%. Bezafibrate pharmacokinetics were not affected.5
(b) Lovastatin
In a study in 11 healthy subjects the pharmacokinetics of a single 40-mg dose of lovastatin were not altered by bezafibrate 400 mg daily for 3 days.2
B. Fenofibrate
(a) Pravastatin
A single-dose study in 23 healthy subjects found that the concurrent use of pravastatin 40 mg and fenofibrate 201 mg had no effect on the pharmacokinetics of either drug, but a moderate increase in the formation of a non-toxic pravastatin metabolite was seen. This was not thought to be clinically important.3 In a multiple-dose study pravastatin 40 mg daily was given to 23 healthy subjects with fenofibrate 160 mg daily. Fenofibrate increased the maximum levels and AUC of pravastatin by about 40% and 30%, respectively. Similar increases were seen for the main pravastatin metabolite. The combination was well tolerated, and the increases were considered to be modest.4 However, a case report describes a patient taking fenofibrate 300 mg daily, who developed rhabdomyolysis after starting pravastatin 10 mg daily.5
(b) Rosuvastatin
A 7-day course of fenofibrate 67 mg three times daily and rosuvastatin 10 mg daily resulted in only minor changes in fenofibric acid and rosuvastatin exposure in 14 healthy subjects, when compared with either drug given alone.6
(c) Simvastatin
In a randomised, crossover study 25 healthy subjects were given simvastatin 80 mg daily with fenofibrate 160 mg daily for 7 days. The pharmacokinetics of both drugs and their main metabolites (as assessed in 12 subjects) were unchanged by concurrent use. All 25 subjects were assessed for safety, and the combination was found to be well tolerated.7
C. Gemfibrozil
(a) Atorvastatin
A pharmacokinetic study in 10 healthy subjects found that gemfibrozil 600 mg twice daily increased the AUC of atorvastatin and its metabolites by 24% and 30 to 80%, respectively, which was considered a moderate increase.8 A 43-year-old woman with multiple medical problems was taking gemfibrozil 600 mg twice daily. After a recurrent attack of pancreatitis, atorvastatin 10 mg and glibenclamide (glyburide) 2.5 mg, both twice daily, were added to her treatment. About 3 weeks later she developed brown and turbid urine (suggesting urinary myoglobin), creatine kinase levels of 4633 units/L and had myalgia. She was diagnosed as having rhabdomyolysis. Her serum creatine kinase levels rapidly fell when the atorvastatin and gemfibrozil were withdrawn.9
In a case series of 10 patients taking a statin who presented for muscle biopsy, one patient taking gemfibrozil developed myopathy 3 months after his dose of atorvastatin was increased from 10 to 20 mg.10
(b) Fluvastatin
In a randomised, crossover study 15 patients were given fluvastatin 20 mg and gemfibrozil 600 mg twice daily. The pharmacokinetics of both gemfibrozil and fluvastatin were unchanged by concurrent use and no significant adverse effects were noted.11
(c) Lovastatin
In a pharmacokinetic study, 11 healthy subjects were given gemfibrozil 1.2 g daily for 3 days, with a single 40-mg dose of lovastatin on day 3. The AUC and maximum plasma level of lovastatin acid (a metabolite) were nearly threefold greater in the presence of gemfibrozil.2
By 1990 the FDA had documented 12 case reports of severe myopathy or rhabdomyolysis associated with the concurrent use of lovastatin and gemfibrozil. The mean serum creatine kinase levels of the patients reached 15 230 units/L. Four of those tested showed myoglobinuria and five had acute renal failure.13 Details of cases of rhabdomyolysis associated with the concurrent use of these drugs,14,15,17 have been given elsewhere. Other cases of rhabdomyolysis have been seen in patients taking lovastatin and gemfibrozil, with ciclosporin,19 or niacin.20 Aside from these cases, a review of combined statin/fibrate use identified a further 4 cases of rhabdomyolysis involving gemfibrozil and lovastatin, all involving lovastatin doses of 40 mg and above.21 However, in contrast, other reports22-25 describe apparently safe and effective concurrent use under very well controlled conditions, although elevated creatine phosphokinase levels, without rhabdomyolysis, were seen in up to 8% of cases.
(d) Pravastatin
In a study in 18 healthy subjects gemfibrozil 600 mg caused no clinically significant changes in the bioavailability of a single 20-mg dose of pravastatin.26 However, another study using pravastatin 40 mg found that the AUC and maximum levels of pravastatin were increased roughly threefold and twofold, respectively.27 A 12-week study with pravastatin 40 mg daily and gemfibrozil 600 mg twice daily found that marked abnormalities in creatine kinase concentrations (four times the pretreatment values) occurred in 1 of 71 patients taking pravastatin alone, 1 of 73 patients taking placebo, 2 of 72 patients taking gemfibrozil alone, and 4 of 75 patients taking gemfibrozil with pravastatin. The differences between treatments were not statistically significant. Two patients taking combination therapy had this withdrawn because of asymptomatic creatine kinase elevations. Severe myopathy or rhabdomyolysis was not seen in any patient, although 14 patients had musculoskeletal pain, but in most cases this was not considered to be related to treatment.28
(e) Rosuvastatin
In a randomised, crossover study 20 healthy subjects were given gemfibrozil 600 mg twice daily for 7 days, with a single 80-mg dose of rosuvastatin on day 4. The AUC of rosuvastatin was increased 1.88-fold (11 subjects assessed) and the maximum levels of rosuvastatin were increased 2.21-fold. Three subjects had asymptomatic increases in ALT levels (less than 2.5 times upper limit of normal).29
(f) Simvastatin
A 62-year-old man with diabetes taking simvastatin 20 mg daily and gemfibrozil 600 mg daily (as well as acenocoumarol, glibenclamide (glyburide) and diclofenac) was hospitalised because of melaena, generalised myalgia, malaise and brown urine. Laboratory tests confirmed the diagnosis of rhabdomyolysis. He recovered when the simvastatin and gemfibrozil were stopped.30 Another diabetic patient had been taking simvastatin and gemfibrozil 600 mg daily for 2½ years (as well as felodipine, indapamide, calcium carbonate, bumetanide, psyllium, acenocoumarol and insulin). She complained of tiredness, generalised myalgia and anuria 3 months after her dosage of simvastatin had been increased to 80 mg daily. Rhabdomyolysis with exaggerated renal impairment were diagnosed and confirmed. She recovered when the simvastatin and gemfibrozil were stopped.30 Three further cases of rhabdomyolysis have been reported in patients taking simvastatin, 3 weeks to 3 months after starting gemfibrozil.31-33 One of these cases was fatal.31 A pharmacokinetic study found that when gemfibrozil was given with simvastatin the AUC of simvastatin acid (an active metabolite of simvastatin) was increased nearly twofold and the peak concentration was doubled.34 In a case series of 10 patients taking a statin who presented for muscle biopsy, two patient taking gemfibrozil developed myopathy while also taking simvastatin.10
D. Unspecified Fibrates
In a review35 of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, fibrates (unspecified) were potentially implicated in 10 of 73 cases of rhabdomyolysis seen with atorvastatin, 4 of 10 with fluvastatin, 5 of 40 with simvastatin, 6 of 71 with pravastatin, and 33 of 215 with simvastatin.

Mechanism
Not understood. Myopathy can occur with statins and fibrates alone and their effects may therefore be additive or synergistic. There is also some evidence that the fibrates may inhibit the metabolism of the statins, but not because they inhibit the cytochrome P450 isozyme CYP3A4.2,24 More recent study has shown that gemfibrozil may inhibit the glucuronidation of some of the statin metabolites, and that gemfibrozil is an inhibitor of some of the CYP2C isoenzymes.36 Other evidence suggests that drug transporter proteins (such as OATP2) may also be involved.27,29
Importance and management

There are many studies showing efficacious use of many pairs of statins and fibrates, and the overall incidence of myopathy with a statin and a fibrate has been put at 0.12%. Nevertheless, the risks of these combinations are evident, at least for individual patients, and generally the combinations should only be used if the benefits of use outweigh the risks. The manufacturer of bezafibrate contraindicates the use of a statin if a number of conditions considered to be risk factors for myopathy (such as renal impairment and hyperthyroidism) are present. Monitoring of creatine kinase has been suggested in patients taking a statin with a fibrate, but this will not necessarily identify all cases of developing rhabdomyolysis. As a general rule, any patient given a statin and a fibrate should be told to report any symptoms of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

Individual combinations of statins and fibrates are associated with different levels of risk. The interactions of lovastatin and simvastatin with fibrates, particularly gemfibrozil, are established and clinically important. The FDA discourage the concurrent use ofLovastatin with gemfibrozil in any patient. The concern is that it should be clearly indicated in patients with compromised liver or renal function.12 The manufacturers of lovastatin and simvastatin recommend that combined use with fibrates should generally be avoided, but if the benefits are considered to outweigh the risks, a low dose of the statin should be used. In the presence of a fibrate, the maximum generally recommended dose for lovastatin is 20 mg and for simvastatin is 10 mg. Fenofibrate is excluded from this recommendation for simvastatin, and gemfibrozil is particularly cautioned.13-40 The UK manufacturer of rosuvastatin recommends starting with a 5 mg dose of rosuvastatin, and increasing the dose to 10 mg when any patient taking a fibrate. Further, the US manufacturer recommends a maximum dose of 10 mg of rosuvastatin in patients taking gemfibrozil.42

Statins + Fusidic acid

Rhabdomyolysis has been described in patients given atorvastatin or simvastatin with fusidic acid. Clinical evidence, mechanism, importance and management

A patient with a renal transplant and diabetes taking various drugs was given atorvastatin 10 mg daily for hyperlipidaemia. Six weeks later, before his next transplant, clindamycin and ciprofloxacin were discontinued and fusidic acid 1.5 g daily was started. At this time serum creatine kinase was 54 units/L. Two weeks later the patient was admitted with progressive muscle weakness and pain in both legs. His serum creatinine kinase was 3550 units/L. Both myoglobin levels were raised. Both myoglobin levels were raised. There was no clinical or laboratory evidence of rhabdomyolysis, which was initially mistaken for drug induced hepatitis, has also been reported.42,43

Large amounts of grapefruit juice markedly increase the plasma levels of lovastatin and simvastatin, but only modestly affect the plasma levels of atorvastatin. Pravastatin seems not to interact. The clinical significance of the possible effects of pomegranate juice on rosuvastatin, and orange juice on pravastatin are unclear.

Clinical evidence

(a) Atorvastatin

Twelve healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 5 days. On day 3 they were given a single 40-mg dose of atorvastatin with the grapefruit juice then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The AUC0-90 of atorvastatin acid and total HMG-CoA reductase inhibitors were increased 2.5-fold and 1.5-fold, respectively. Other studies, using 250 mL of single-strength grapefruit three times a day, have found broadly similar increases in atorvastatin levels.2,3

(b) Lovastatin

Ten healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 3 days. On day 3 they took lovastatin 80 mg with 200 mL of grapefruit juice, then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The mean peak levels of the lovastatin and its active metabolite, lovastatin acid, were increased 12-fold and 4-fold, respectively, and the mean AUCs were increased 15-fold and 5-fold, respectively.4 However, another study in which lovastatin 40 mg was given the evening after single-strength grapefruit juice was taken with breakfast found that the AUC and maximum serum levels of lovastatin were approximately doubled, and the AUC and maximum serum level of lovastatin acid were only increased 1.6-fold.5 It has been suggested that if the grapefruit juice had been given at the same time as the lovastatin in the latter study then much greater increases in the AUC and maximum serum levels would have been found.6

(c) Pravastatin

Grapefruit juice did not significantly affect the pharmacokinetics of a single 40-mg dose of pravastatin. In this study, 200-mL of double-strength grapefruit juice was given three times daily for 2 days, and then on the third day 200 mL was given with the pravastatin and again after 30 and 90 minutes.1 A further study using 10 mg of pravastatin similarly found that grapefruit juice did not significantly affect pravastatin pharmacokinetics.3

In a study in 14 healthy subjects a total of 800 mL of orange juice, was given over about 3 hours, starting 15 minutes before a 10-mg dose of pravastatin. Orange juice increased the AUC of pravastatin by a modest 1.5-fold, without affecting the maximum pravastatin levels.7

(d) Rosuvastatin

A case report describes a 48-year-old man taking ezetimibe 10 mg daily, and rosuvastatin 5 mg on alternate days, who developed rhabdomyolysis within 3 weeks of starting to drink 200 mL of pomegranate juice twice weekly. Although the patient had been stable taking ezetimibe with rosuvastatin for 15 months he had a history of myopathy with statins and had an elevated creatine kinase before statin treatment had started.8

(e) Simvastatin

Ten healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 2 days. On day 3 they took 60 mg of simvastatin with 200 mL of grapefruit juice, then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The mean peak serum levels of the simvastatin and simvastatin acid, were increased 9-fold and 7-fold, respectively, and the mean AUCs were increased 16-fold and 7-fold, respectively.9 In a further study by the same research group, when simvastatin was given 24 hours after the last dose of grapefruit juice (same dosage regimen as the previous study) the effect was only 10% of that observed during concurrent use, and had disappeared within 3 to 7 days.10 The manufacturer notes that the effect of 240 mL of standard grapefruit juice on simvastatin was minimal (13% increase in AUC of active plasma HMG-CoA reductase inhibitors). However, another study found as little as 200 mL of grapefruit juice taken daily for 3 days could increase the maximum levels of simvastatin and simvastatin acid by up to about fourfold.11 A case report describes rhabdomyolysis in a patient taking simvastatin 80 mg daily (dose increased 6 months prior to presentation), which occurred 4 days after she started to eat one fresh grapefruit a day.12

Mechanism

It seems almost certain that some components of the grapefruit juice (not yet positively identified but possibly naringenin), inhibit the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut wall, thereby reducing the metabolism of the statins as they are absorbed, and allowing more to pass into the body. See ‘Lipid regulating drugs’, (p.1086) for more information about the metabolism of the statins.

Importance and management

Information about the interaction of statins and grapefruit juice seems to be mainly limited to pharmacokinetic reports (i.e. few adverse case reports) but they are consistent with the way other CYP3A4 inhibitors interact with the statins.

Large increases in the serum levels of lovastatin and simvastatin are potentially hazardous because elevated statin levels carry the risk of toxicity (muscle damage and the possible development of rhabdomyolysis). As even small quantities of grapefruit juice taken in the morning can significantly affect simvastatin levels the UK manufacturers say that concurrent use should generally be avoided.13,14 In the US the manufacturers suggest that intake of grapefruit juice should be restricted to less than 1 quart (roughly 1 litre) daily.15,16 See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

The modest increase in atorvastatin levels when taken with high doses of grapefruit juice seems less likely to be clinically relevant, but the UK manufacturer suggests that large quantities should be avoided.17 In general, the occasional glass of grapefruit juice would not appear to be a problem. Pravastatin seems not to interact. Information about other statins appears to be lacking, but no interaction would be expected with fluvastatin or rosvastatin.

The interaction of pomegranate juice with rosuvastatin and ezetimibe seems to be limited to one case report, which is clouded by other possible contributory factors. Furthermore, although pomegranate juice has been shown to inhibit CYP3A4,4 rosuvastatin is not metabolised by this route. Although it is possible that other mechanisms may be responsible, no firm conclusions can be drawn from this case.

The interaction of pravastatin with orange juice would be expected to be of little clinical significance in most patients, but this needs confirmation.

Statins + H₂-receptor antagonists or Proton pump inhibitors

No clinically significant interaction appears to occur between cimetidine and atorvastatin, fluvastatin, or pravastatin, between ranitidine and fluvastatin, or between fluvastatin and omeprazole.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a crossover study, 12 healthy subjects were given atorvastatin for 15 days with and without cimetidine 300 mg four times daily. Cimetidine had no effect on the maximum serum levels or AUC of atorvastatin. Cimetidine had little effect on the lipid-lowering ability of atorvastatin, except that the reduction in triglycerides was slightly less, but this difference was considered to be of little clinical significance. There would appear to be no reason to avoid concurrent use. Esomeprazole has been implicated in a case of rhabdomyolysis involving atorvastatin and clarithromycin. See ‘Statins + Macrolides’, below.

(b) Fluvastatin

The manufacturers of fluvastatin say that its bioavailability is increased by cimetidine, omeprazole, and ranitidine (AUC increased by 24 to 33%), but they say that this is of no clinical relevance. No special precautions would seem to be necessary.

(c) Pravastatin

Cimetidine 300 mg four times daily for 3 days increased the bioavailability of a single 20-mg dose of pravastatin by 58%. The dose of pravastatin was given on day 3, one hour after the first dose of cimetidine. However, the manufacturers say that it is unlikely that the changes caused by cimetidine will affect the clinical efficacy of pravastatin.

3. Lescol (Fluvastatin sodium). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2006.

Statins + Imitinib

Imatinib raises simvastatin serum levels, increasing the risk of toxicity. It seems likely that lovastatin and possibly atorvastatin may also be similarly affected.

Clinical evidence, mechanism, importance and management

In a single-dose study, 20 patients with chronic myeloid leukaemia were given simvastatin 40 mg prior to and on the last day of a 7-day course of imatinib 400 mg daily. Imatinib increased the maximum serum levels of simvastatin twofold and the AUC threefold. The authors conclude that caution is warranted if simvastatin and imatinib are taken concurrently.

Imatinib inhibits the cytochrome P450 isozyme CYP3A4, by which simvastatin is metabolised. It therefore seems likely that lovastatin will be similarly affected, and atorvastatin may be affected to some extent (see ‘Lipid regulating drugs’, p.1086). These rises increase the risk of simvastatin toxicity (myopathy and rhabdomyolysis), for which reason a dosage reduction should be considered.

As a general rule, any patient given imatinib with atorvastatin, lovastatin or simvastatin should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Macrolides

Cases of acute rhabdomyolysis have been reported between lovastatin and azithromycin, clarithromycin, or erythromycin and between simvastatin and clarithromycin or roxithromycin. Macrolide antibacterials have also been potentially implicated in cases of rhabdomyolysis with atorvastatin and pravastatin. Pharmacokinetic studies suggest that the macrolides increase the levels of the statins metabolised by CYP3A4 (namely atorvastatin, lovastatin and simvastatin).

Clinical evidence

(a) Azithromycin

A 51-year-old man who had been taking lovastatin 40 mg daily for 5 years developed muscle aches and fever one day after finishing a 5-day course of azithromycin 250 mg daily. His creatine phosphokinase levels were elevated and he was diagnosed as having rhabdomyolysis. This patient was also taking diltiazem, doxazosin, glibenclamide (glyburide), ‘thyroid’, allopurinol, naproxen, prednisone, loratadine and inhaled beclometasone.

In a randomised study, two groups of 12 healthy subjects were given atorvastatin 10 mg daily for 8 days with azithromycin 500 mg daily or placebo for the final 3 days. When the azithromycin group were compared with the placebo group no change in atorvastatin pharmacokinetics were noted.

(b) Clarithromycin

A 76-year-old woman who had been taking lovastatin 40 mg daily for 5 years developed muscle pain and weakness 2 days after completing a 10-day course of clarithromycin 500 mg twice daily. Later, when hospitalised, she was found to have elevated creatine phosphokinase levels and was diagnosed as having acute rhabdomyolysis. In a similar case, a 64-year-old man with multiple pathologies, including renal impairment, developed rhabdomyolysis 3 weeks after clarithromycin was added to his treatment, which included simvastatin 80 mg daily. Other reports describe 7 further cases of rhabdomyolysis in patients taking simvastatin, atorvastatin, or lovastatin, which in some cases occurred within days of the clarithromycin being started. In five of these cases the patients were also taking amiodarone, ciclosporin, efavirenz/lopinavir/ritonavir, esomeprazole, gemfibrozil, which may also have had some part to play in the reaction.

A preliminary report of a pharmacokinetic study suggests that clarithromycin 500 mg twice daily for 7 days can increase the AUC and maximum levels of a single 40-mg dose of simvastatin eightfold. In a randomised study, two groups of 12 healthy subjects were given atorvastatin 10 mg daily for 8 days with clarithromycin 500 mg twice daily or placebo for the final 3 days. When the clarithromycin group were compared with the placebo group the atorvastatin AUC was 82% higher and the maximum serum levels 50% higher.

In a randomised study 3 groups of 15 healthy subjects were given atorvastatin 80 mg daily, pravastatin 40 mg daily or simvastatin 40 mg daily with clarithromycin 500 mg twice daily for 8 days. Clarithromycin increased the AUC of atorvastatin by fourfold, pravastatin by twofold and simvastatin by tenfold.

(c) Erythromycin

Twelve healthy subjects were given a single 10-mg dose of atorvastatin on day 7 of an 11-day course of erythromycin 500 mg four times daily. The maximum serum atorvastatin levels were raised by 38% and the AUC was raised by 33% by the erythromycin. Either lovastatin or pravastatin 40 mg daily was given to 12 healthy subjects for 14 days, with erythromycin 500 mg three times daily for the last 7 days. The erythromycin caused the maximum serum levels and AUC of lovastatin to rise more than fivefold. The pharmacokinetics of the pravastatin remained unchanged. Similarly, fluvastatin levels are not significantly altered by erythromycin.

A man taking lovastatin 20 mg three times daily, diltiazem, allopurinol and aspirin developed progressive weakness and diffuse myalgia after taking erythromycin 500 mg every 6 hours for 13 days. When admitted to hospital his creatine kinase level was high (35 200 units/L) and his urine was reddish-brown. The rhabdomyolysis was treated by stopping the lovastatin, and by giving furosemide with vigorous intravenous hydration.
A woman who had been taking lovastatin for 7 years developed multiple organ toxicity (rhabdomyolysis, acute renal failure, pancreatitis, lizado reticularis and raised aminotransferase levels) when erythromycin was added. Four other cases of rhabdomyolysis attributed to the combination of gemfibrozil 600 mg twice daily, simvastatin 80 mg daily and diltiazem, developed muscular weakness and myalgia 7 days after starting roxithromycin. All drugs were stopped, and initially she developed myoglobinuria and had a further elevation in her creatinine kinase level, but this normalised over the following 18 days. She was discharged after 6 weeks, by which time she had regained full strength. In a randomised, crossover study, 12 healthy subjects were given lovastatin 80 mg either alone or following 5 days of pre-treatment with roxithromycin 300 mg four times daily. Roxythromycin increased the maximum level and AUC of lovastatin acid by 38% and 42%, respectively, and decreased the maximum level and AUC of lovastatin lactone by a similar amount. 

Mechanism
Most macrolides inhibit the cytochrome P450 isoenzyme CYP3A4, by which lovastatin, simvastatin and, to some extent, atorvastatin are metabolised. Hence the concurrent use of a macrolide raises the levels of these statins, leading in some instances to toxicity (myopathy and rhabdomyolysis). No interaction would be expected with pravastatin because it is not metabolised by CYP3A4, although a moderate effect has been found with clarithromycin and no interaction would be expected with azithromycin as it does not appear to inhibit CYP3A4. See ‘Lipid regulating drugs’, (p.1086) for a more detailed discussion of statin metabolism.

Importance and management
Information about the interactions between statins and macrolide antibacterials seems to be limited to the reports cited here. In general it appears that the macrolides raise the levels of statins metabolised by CYP3A4 (i.e. atorvastatin, lovastatin and simvastatin), but not all patients are affected. One study found a large interpatient variation in results, which may account for this. It should be noted that the manufacturers of lovastatin and simvastatin specifically recommend that these drugs are not used with clarithromycin, erythromycin or telithromycin, and suggest that the statin be temporarily withdrawn if these antibiotics are required. The risk is smaller with atorvastatin, but as the cases illustrate adverse interactions are possible. The US manufacturers therefore recommend that concurrent use should only be undertaken if the benefits outweigh the risks. Pravastatin and fluvastatin are not metabolised by CYP3A4, and so would not be expected to interact with macrolides via this mechanism, but potential cases have been identified. This is worth noting when considering rosuvastatin, which is also said to have a low propensity for interactions with CYP3A4.

To be on the safe side, any patient taking any statin who is given a macrolide (except probably azithromycin) should be warned to be alert for any signs of myopathy (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.
A 44-year-old man who had uneventfully taken simvastatin 40 mg daily for 19 weeks developed ‘tea-coloured’ urine, initially misdiagnosed as a urinary tract infection, a month after starting to take nefazodone 100 mg twice daily. A month later he was also complaining of severe myalgias of the thighs and calves, and was found to have muscle weakness and tenderness. Laboratory tests confirmed a diagnosis of rhabdomyolysis and myositis. He was asymptomatic within 3 weeks of stopping both drugs, and remained problem-free 5 weeks after restarting simvastatin 40 mg daily. A further case of rhabdomyolysis has been reported in a 72-year-old man taking simvastatin. Symptoms developed 6 weeks after nefazodone was initiated (2 weeks after a dose increment). He recovered with rehydration after the nefazodone was stopped. Similarly, another case report describes rhabdomyolysis in a 56-year-old man taking simvastatin, which developed about 5 weeks after nefazodone was initiated (4 weeks after a dose increment). In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, nefazodone was potentially implicated in 2 cases of rhabdomyolysis involving simvastatin.

**Importance and management**

Information about interactions between nefazodone and the statins seems to be limited to these reports so that the risks associated with using nefazodone are uncertain. The manufacturers of lovastatin and simvastatin advise avoiding the combination. Some caution is probably prudent with atorvastatin as it is also metabolised by CYP3A4. Patients given atorvastatin with nefazodone should be told to report any signs of myopathy and to be limited to these reports so that the risks associated with using nefazodone are uncertain. The suggestion is that nefazodone (an inhibitor of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of simvastatin) caused a marked increase in the serum levels of the simvastatin with accompanying toxicity. The same mechanism might also account for the interaction with lovastatin, but the explanation for the case with pravastatin is less clear. See, ‘Lipid regulating drugs’, (p.1086) for a more detailed discussion of statin metabolism.

**Mechanism**

Uncertain. The suggestion is that nefazodone (an inhibitor of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of simvastatin) caused a marked increase in the serum levels of the simvastatin with accompanying toxicity. The same mechanism might also account for the interaction with lovastatin, but the explanation for the case with pravastatin is less clear. See, ‘Lipid regulating drugs’, (p.1086) for a more detailed discussion of statin metabolism.
