2. Phenprocoumon. A 70-year-old woman stabilised on phenprocoumon developed a marked increase in prothrombin time from a range of 140 to 180 seconds up to 304 seconds, but no bleeding, within 4 days of starting to take clarithromycin 500 mg daily. The phenprocoumon was stopped and phytomenadione given. When the antibacterial was withdrawn she was restabilised on the original dosage of phenprocoumon. ¹⁷ For discussion of a cohort study in patients stabilised on phenprocoumon or acenocoumarol, which showed an increased risk of over-anticoagulation with clarithromycin, see Acenocoumarol, above.

3. Warfarin. In 1992 the CSM in the UK notified prescribers in a case of a woman taking warfarin for mitral valve disease who suffered a fatal cerebrovascular bleed 3 days after starting to take clarithromycin. ¹⁸ Her INR was above 10. A further patient stabilised on warfarin had a suprachoroidal haemorrhage 7 days after starting clarithromycin 250 mg twice daily, with permanent vision loss. Her INR was 8.2. She had a normal INR (2.3) three days prior to starting clarithromycin, and also 3 days after starting the course (2.9). ¹⁹

Other patients taking warfarin have been found to have INRs of 5.6 five days after starting clarithromycin, ²⁰ of 90.3 five days after completing a 10-day course of clarithromycin, ²⁰ of 17 five days after finishing a 14-day course of clarithromycin, ²¹ and of 7.3 within 12 days of starting clarithromycin. ²² None of these patients had bleeding complications. In a brief report in 2004, the Adverse Drug Reactions Advisory Committee of Australia state that they had received 6 reports of interactions between clarithromycin and warfarin (median INR of 7.6), two of which were symptomatic. ¹³

(c) Dirithromycin

In a study in 15 healthy subjects the pharmacokinetics and pharmacodynamics of a single 0.5-mg/kg dose of warfarin were not altered when it was given on day 10 of a 14-day course of dirithromycin 500 mg daily. ²³

(d) Erythromycin

Erythromycin caused a minor inhibition of warfarin metabolism in three pharmacokinetic studies, and there are at least 11 published cases of interactions with coumarins, and 19 cases mentioned in a report from the Adverse Drug Reactions Advisory Committee of Australia. These are discussed below.

1. Acenocoumarol. Haematuria occurred in a patient stabilised on acenocoumarol on the last day of a 14-day course of erythromycin. ²⁴ Another patient stabilised on acenocoumarol with an INR in the range of 3 to 4.5 was found to have an INR of 15 a week after starting to take erythromycin ethylsuccinate 1.5 g daily but no bleeding was seen. ²⁵ Conversely, in one cohort study in patients taking acenocoumarol or phenprocoumon, no cases of over-anticoagulation (INR greater than 6) occurred in patients treated with erythromycin (78 patients received this antibacterial). ¹⁶ Note that this study did show an increase for clarithromycin, see above.

2. Warfarin. A study in 12 healthy subjects found that the clearance of a single 1-mg/kg dose of warfarin was reduced by an average of 14% (range 0 to about 30%) when taken on day 5 of an 8-day course of erythromycin 250 mg every 6 hours. This change was greatest in those subjects with relatively low warfarin clearance rates. ²⁶ In another similar study, warfarin 0.5 mg/kg, given on day 10 of a 14-day course of erythromycin 250 mg four times daily increased the AUC of S-warfarin by 11.2% and of R-war-
farin by 11.9%. The INR increased by 10.2%. Similar effects were seen in another study in 8 patients stabilised on warfarin and who did not have infections. In these patients, erythromycin 333 mg three times daily for 7 days caused a mean 9.9% increase in the prothrombin time ratio, which was maximal by day 2 to 5. There was also a mean 9.4% increase in total plasma warfarin level, which was similar for the S- and R-enantiomers, and was maximal by day 7. No patient had a prothrombin time ratio above the therapeutic range and none required a reduction in warfarin dose. In contrast to the modest effects in the above studies, various case reports have demonstrated a marked increase in INR. For example, an elderly woman taking warfarin developed haematuria and bruising within a week of starting to take erythromycin stearate 500 mg four times daily for a chest infection. Her prothrombin time had risen to 64 seconds (prothrombin time ratio about 5.5). Within the previous month she had started taking digoxin and quinidine, and had her warfarin dose increased because of a decrease in prothrombin time. At least 8 other cases of bleeding and/or an increase in prothrombin time or INR have been described in patients taking warfarin with erythromycin (as the base, ethylsuccinate, stearate, or lactobionate). In addition, in a brief report in 2004, the Adverse Drug Reactions Advisory Committee of Australia stated that they had received 19 reports of interactions between erythromycin and warfarin (median INR of 9.7), only 4 of which were symptomatic.13 There is also a case report of sulfonamide-induced bullous haemorrhagic eruption in a patient taking warfarin, ‘co-trimoxazole’, (p.376) and erythromycin, in which the authors considered an interaction between warfarin and erythromycin may have contributed to the haemorrhagic component.20

(e) Midecamycin diacetate

The pharmacokinetics of a single 8-mg oral dose of acenocoumarol were not significantly changed when it was taken on day 4 of a 9-day course of midecamycin diacetate 800 mg twice daily.37

(f) Roxithromycin

Roxithromycin did not alter the pharmacokinetics or effect of warfarin in one study. However, there are at least 2 published cases of interactions with coumarins, and one report reviewing 16 cases. These are discussed below.

1. **Aclacinomycins.** A 79-year-old man stabilised on aclacinomycins developed an abdominal wall haematoma 2 days after starting to take roxithromycin 150 mg twice daily for a lung infection.38 Six days later, on admission to hospital, his INR was found to be 5.9. Conversely, in one cohort study in patients taking acenocoumarol or phenprocoumon, no cases of over-anticoagulation (INR greater than 6) occurred in patients treated with roxithromycin (only 14 patients received this antibacterial).10 Note that this study did show an increase for clarithromycin, see above.

2. **Phenprocoumon.** A 75-year-old man taking phenprocoumon developed a marked increase in prothrombin time but no bleeding when he was given roxithromycin 300 mg daily for 5 days. The phenprocoumon was stopped and phytonadione given. When the antibacterial was withdrawn he was restabilised on the original dosage of phenprocoumon.11 For mention of a cohort study in patients stabilised on phenprocoumon or acenocoumarol showing no increased risk of overanticoagulation with roxithromycin, see Aclacinomycins, above.

3. **Warfarin.** In a study in which warfarin was given at a daily dose sufficient to maintain the thrombotest percentages at 10 to 20%, there was no difference in warfarin dose or AUC between 10 subjects given roxithromycin 150 mg twice daily for 2 weeks and 11 subjects given placebo. The dose of warfarin and the AUC of warfarin increased by about 10% in both the roxithromycin group and the placebo group, which was taken as indicating that steady state had not been achieved. Serum roxithromycin levels were unchanged by warfarin.39 In contrast, during the 1992 to 1995 period The Centre for Adverse Reactions Monitoring of New Zealand received 7 reports of a possible interaction with roxithromycin resulting in increased warfarin effects, and, during the same period, the Adverse Drug Reactions Advisory Committee of Australia received 9 similar reports. Review of the 16 cases showed that 7 patients had clinical symptoms of over-anticoagulation, and the other 9 were asymptomatic and detected by routine testing.40 In a 2004 update from ADRC, it was noted that they now had on record 56 cases of an interaction between roxithromycin and warfarin, with 27 cases being symptomatic. The median INR was 8.8, and the median time to onset was 6 days. One fatality occurred in a 79-year-old woman who started taking warfarin and roxithromycin at the same time. By day 8, she had an INR of 11.6, and subsequently died from widespread bleeding.13

(g) Telithromycin

In a placebo-controlled, crossover study in healthy subjects, telithromycin 800 mg once daily for 7 days did not alter the pharmacodynamics of a single-dose of warfarin 25 mg given on day 4. There was a small 20% increase in the AUC of R-warfarin, and a 5% increase in the AUC of S-warfarin, effects which the manufacturer does not consider to be clinically relevant.42 Conversely, a 73-year-old man taking warfarin for a metallic valve replacement started taking telithromycin 800 mg daily for 5 days for a cough. On the last day of treatment he developed haemoptysis and was found to have an INR of 11. His INR 10 days before telithromycin was started was 3.1. The telithromycin was stopped and he was subsequently restabilised on warfarin.43 Moreover, Health Canada reported that from May 2003 to September 2004 they had received 7 reports of suspected coagulation disorder interactions with telithromycin, 6 with warfarin and one with an unspecified oral anticoagulant. The INR was increased in 6 of the reports and decreased in the seventh.45

(h) Unspecified macrolides

The INR increased by an estimated 0.319 in 35 patients taking warfarin when prescribed an oral macrolide (not named) in a prospective study of the effect of antibacterials on anticoagulation.46

**Mechanism**

Erythromycin is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4. However, this isoenzyme has only a minor role in the metabolism of warfarin’, (p.358), specifically the less active R-isomer of warfarin. Consequently, only minor increases in the levels of warfarin have been seen in pharmacokinetic studies, which would generally not be expected to be clinically relevant. However, it is possible that even these small changes might be important in a very few patients, particularly those with a low prothrombin complex activity. Other macrolides (azithromycin, clarithromycin, dirithromycin, roxithromycin) have less effect on CYP3A4 than erythromycin, and consequently would be expected to have even less effect on the pharmacokinetics of warfarin or acenocoumarol, which is borne out in the few studies available. Nevertheless, cases of interactions have been reported for nearly all these macrolides. Moreover, one cohort study found that clarithromycin increased the risk of an interaction and erythromycin did not. It is possible that there is some other, as yet unidentified, mechanism involved. Alternatively, it is equally possible that the relatively few cases just represent idiosyncratic effects attributable to other factors, and not to any interaction (see also ‘Coumarins + Antibacterials’, p.365).

**Importance and management**

The minor pharmacokinetic interaction with erythromycin and warfarin is established, but would not generally be expected to be clinically relevant. This is borne out by the relatively few published reports of an interaction (11 published case reports worldwide and 19 cases reported to the Adverse Drug Reactions Advisory Committee of Australia). Other macrolides would be even less likely to inhibit the metabolism of warfarin or acenocoumarol than erythromycin, and this is borne out by studies with dirithromycin, midecamycin and roxithromycin. Nevertheless, cases of important interactions have been reported for most of the other macrolides (azithromycin, clarithromycin, roxithromycin, and telithromycin). Moreover, one cohort study found an increased risk of over-anticoagulation with clarithromycin but not with erythromycin. Taken together, the available evidence suggests that because very occasionally and unpredictably the effects of warfarin and acenocoumarol or phenprocoumon appear to mask each other by macrolides, it would be prudent to increase monitoring in all patients when they are first given any macrolide antibacterial. There is some evidence that this may be particularly important in those who clear warfarin and other anticoagulants slowly and who therefore only need low doses. The elderly in particular would seem to fall into this higher risk category. With azithromycin, bear in mind that, because of azithromycin’s long half-life, the interaction may possibly not become apparent until a couple of days after a short course (i.e. 5 days) of azithromycin has been stopped.

One early study found that metronidazole increased the half-life of a single dose of warfarin by one-third and increased its effects, and another cohort study showed that the combination caused a marked increase in INR, without bleeding. Case reports support these findings. There is a single case of a markedly increased INR and bleeding in a man taking phenprocoumon was given nimorazole.

**Clinical evidence**

(a) **Metronidazole**

Metronidazole 250 mg three times daily for a week increased the half-life of a single 1.5-mg/kg dose of warfarin by about one-third (from 35 to 48 hours) in 8 healthy subjects, and increased the prothrombin time from a mean of 100 to 142 seconds. When the warfarin enantiomers were given separately, the anticoagulant effects of $S$-warfarin were virtually doubled and the half-life increased by 60%, but the response to $R$-warfarin was only affected in one subject. In a retrospective cohort study, 32 patients taking warfarin had an INR reading before and during concurrent metronidazole use. In these patients, the mean INR increased from 2.2 to a maximum of 4.3 by day 8 of concurrent use. Fourteen of the 32 had an INR above 4, but no bleeding events were recorded.

Bleeding has been seen in 2 patients taking warfarin and metronidazole. One of them had severe pain in one leg, ecchymoses, and haemorrhage of both legs, and an increase in her prothrombin time from 17 to 19 seconds within 17 days of starting the metronidazole. A further report describes 3 elderly patients taking warfarin, who developed raised INRs after being given intravenous metronidazole. In the first patient the INR on admission was 4.6, and so warfarin was stopped. The next day metronidazole was given for about 24 hours, and on day 4 the INR had reached 10.3. In the second patient the INR on admission was 4.9 and so the warfarin was stopped. Later that day metronidazole was started, and the INR was reduced to 1.7 with fresh frozen plasma. Nevertheless by day 5 the INR had reached 6 (metronidazole had been stopped on day 2). In the third patient the INR on admission was 4 and so the warfarin was stopped. Later that day metronidazole was given, and the INR was reduced to 2.1 with fresh frozen plasma. Nevertheless by day 5 (while still receiving metronidazole) the INR had reached 10.

(b) **Nimorazole**

A 66-year-old man who had been taking phenprocoumon for 15 years with an INR around 2.5 was diagnosed with carcinoma of the glottis. He received radiotherapy 6 times a week with nimorazole 2.5 g given 1.5 hours prior to the radiotherapy as a radiosensitiser. At the 16th dose, he had haemoptysis, on the 17th dose continuous haematuria, and then on the 22nd dose his INR was found to be 7.5. Fluconazole had been started 4 days previously. When the patient had recovered and restarted phenprocoumon, he was rechallenged with nimorazole prior to his last 5 days of radiotherapy, with an INR increase from 3.7 to 5.3.

**Mechanism**

In the early study, it was suggested that metronidazole probably inhibits the activity of the enzymes responsible for the metabolism (ring oxidation) of the more potent isomer $S$-warfarin, but not $R$-warfarin. Reduction of protein binding coupled with reduced metabolism was suggested by other authors. Nimorazole may act similarly, although there are other likely contributing factors in the case with this drug including coconitum ‘fluconazol’, (p.387), and reduced ‘vitamin-K intake’, (p.409). See also, ‘antibacterials’, (p.365).

**Importance and management**

The interaction between metronidazole and warfarin appears to be established and clinically important, although the documentation is limited. Monitor the INR when both drugs are used and adjust the warfarin dose accordingly. Nothing seems to be documented about other anticoagulants but it would be prudent to expect other coumarins to behave similarly. The single case with nimorazole suggests that caution may also be warranted with this drug.
Coumarins + Antibacterials; Penicillins

Isolated cases of increased prothrombin times and/or bleeding have been seen in patients given amoxicillin (with or without clavulanic acid) intravenous benzylpenicillin, pheneticillin or talampicillin. An increased risk of over-anticoagulation was seen with amoxicillin with or without clavulanic acid in cohort studies, but not flucloxacillin. There is also some evidence that phe-noxyethylpenicillin (penicillin V) does not interact.

In contrast, several cases of markedly reduced warfarin effects (warfarin resistance) have been seen with intravenous nafcillin, with a 75% reduction in warfarin half-life documented in one case. Similarly, other studies and cases suggest that dicloxacillin may cause a modest reduction in warfarin effects in many patients, and that some may experience greater reductions, with thrombosis being reported in one case.

Clinical evidence

(a) Amoxicillin ± clavulanic acid

An 81-year-old woman taking acenocoumarol 3 mg daily (INR 2.5 to 4) developed bruising and an increased INR of 7.1 within a week of starting amoxicillin 500 mg every 8 hours. Another patient stabilised on warfarin (INR 2 to 3) had a normal INR (2.55) 4 days after completion of a 7-day course of co-amoxiclav (amoxicillin with clavulanic acid), but about 2.5 weeks after the course a routine INR was 6.2. A further 3 days later it was 8.7 and microscopic haematuria was detected. In one case control study, use of co-amoxiclav was found to be associated with an increased risk of an INR of greater than 6 (odds ratio 4.1; range 0.9 to 19.2) in patients stabilised on either acenocoumarol or phenprocoumon. Amoxicillin alone was associated with a smaller increased risk (odds ratio 1.7; range 0.6 to 4.7). Conversely, in a population-based cohort study in similar patients conducted by the same research group, the risk of over-anticoagulation (INR greater than or equal to 6) was greater for amoxicillin alone than amoxicillin plus an enzyme inhibitor. The relative risk for amoxicillin alone was 10.5 (range 5.1 to 21.7) and for amoxicillin plus an enzyme inhibitor was 5.1 (range 1.9 to 13.9). The increased risk was observed in the early stages of concurrent use but was greater after 4 or more days of treatment.

In contrast to these reports of increased anticoagulation, a very brief report states that in an audit of an anticoagulant clinic, 5 patients who had taken amoxicillin had an unspecified decrease in prothrombin time.

(b) Ampicillin

A bulletin briefly mentions a case of an increased prothrombin time in a patient taking warfarin with ampicillin and flucloxacillin.

(c) Benzylpenicillin

One patient stabilised on warfarin (prothrombin time 20 seconds) was found to have an increased prothrombin time of 32 seconds 8 days after starting intravenous benzylpenicillin 24 million units daily for subacute bacterial endocarditis. The benzylpenicillin was continued, and the warfarin dose reduced for 18 days. However, the prothrombin time dropped below the therapeutic range, and the warfarin dose was increased back to the original dose, still with continuation of the benzylpenicillin for a further 3 weeks.

(d) Flucloxacillin

In a controlled study in 7 patients stabilised on warfarin and without infections, dicloxacillin 500 mg four times daily for 7 days reduced the mean prothrombin time by 1.9 seconds. One patient had a 5.6 second reduction. This study was conducted because the authors had noted a case of a patient receiving warfarin who had a decrease in prothrombin time when dicloxacillin was started. Another patient stabilised on warfarin had a 17% fall in prothrombin times within 4 to 5 days of starting dicloxa-cillin 500 mg four times daily, with a documented 20 to 25% reduction in both S- and R-warfarin levels. In a retrospective review, 7 other patients similarly treated were also identified as having a 17% reduction in prothrombin times. In yet another case, a patient who had previously required warfarin 10 mg daily subsequently needed an increased dosage of 15 mg daily while taking dicloxacillin 4 g daily long-term. However, another case report suggested a greater effect of dicloxacillin—a patient taking 500 mg every 6 hours required an increase in warfarin dose from a range of 35 to 40 mg weekly up to 50 to 60 mg weekly, with INRs still being subtherapeutic (about 1.5). Moreover, when a woman taking warfarin was given dicloxacillin 500 mg four times daily she developed a heart valve thrombosis, suggesting inadequate anticoagulation. Her INR was 1.4, and an increased warfarin dose was required for 3 weeks after she stopped dicloxacillin.

(e) Flucloxacillin

In one cohort study in patients taking acenocoumarol or phenprocoumon, no cases of over-anticoagulation (INR greater than 6) occurred in patients taking flucloxacillin (25 patients received this antibacterial). Note that this study did show an increase for amoxicillin, see above. A bulletin briefly mentions a case of an increased prothrombin time in a patient taking warfarin with ampicillin and flucloxacillin.

(f) Nafcillin

The prothrombin time of a 29-year-old patient stabilised on warfarin fell from a range of 20 to 25 seconds down to 16 seconds 5 days after intravenous nafcillin 2 g every 4 hours was started for endocarditis. Over the next 2 weeks the prothrombin time ranged between 14 and 17 seconds despite an eventual doubling of the warfarin dose, and heparin was substitut-ed. In this patient the half-life of a single 30-mg dose of warfarin was 11 hours when nafcillin was taken, 17 hours 4 days after stopping nafcil-lin, and 44 hours eight months after the nafcillin was discontinued. At least 10 other cases of this warfarin resistance have been reported with high-dose nafcillin.

(g) Pheneticillin

In one cohort study in patients taking acenocoumarol or phenprocoumon, one case of over-anticoagulation (INR greater than 6) occurred in a group of 219 patients treated with pheneticillin, giving a calculated relative risk of 0.9.

(h) Phenoxymethylpenicillin (Penicillin V)

When 10 patients taking an unnamed anticoagulant were given intrave-nous phenoxymethylpenicillin calcium 300 000 units four times daily for 4 days, none had a change in their prothrombin-proconvertin value. For mention that, in another study no patients taking penicillins including phe-noxyethylpenicillin had an increase in INR see (j) below.

(i) Talampicillin

A bulletin briefly mentions a case of bleeding (haematuria, epistaxis) and an increase in the prothrombin ratio in a patient taking warfarin and talampicillin.

(j) Unspecified penicillins

In one analysis of patients taking warfarin with antibacterials, there was no association between use of penicillins (phenoxymethylpenicillin (penicillin V) and broad-spectrum penicillins) and an increase in INR. The estimated change in INR was 0.117 in 109 patients given the combi-nation.

Mechanism

Not understood. The interaction between nafcillin and warfarin is possibly due to increases in the metabolism of warfarin by the liver. Dicloxacillin also possibly reduces serum warfarin levels. Other penicillins (ampicillin, benzylpenicillin, carbenicillin, methicillin, ticarcillin) have caused increased bleeding times when given alone, principally due to platelet inhibition, which might be additive with the effects of oral anticoagulants. Broad-spectrum antibacterials may decrease the gut flora and thereby possibly decrease production of vitamin K. Other factors relating to the disease may be important, see ‘Coumarins + Antibacterials’ p.365.

Importance and management

The reduced effect of warfarin with dicloxacillin and nafcillin appears to be established. If these penicillins are used, increase monitoring of the INR and anticipate the need to increase the warfarin dose. Some patients taking nafcillin have been warfarin resistant, and needed heparin treatment.
Documented reports of interactions between oral anticoagulants and other penicillins are relatively rare, bearing in mind how frequently these drugs are used, so that the broad picture is that no clinically relevant interaction normally occurs with most other penicillins. This lack of interaction was supported by one clinical study. However, in one case-control study, action normally occurs with most other penicillins. This lack of interaction drugs are used, so that the broad picture is that no clinically relevant interactions have been seen quite unpredictably in isolated cases in patients taking warfarin with ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, nalidixic acid, norfloxacin or ofloxacin; or while taking acenocoumarol when given nalidixic acid, norfloxacin or pefloxacin, or phenprocoumon with norfloxacin. Furthermore, two studies suggest that there may be an increased risk of over-anticoagulation in patients taking acenocoumarol or phenprocoumon with norfloxacin, and warfarin with gatifloxacin.

Clinical evidence

(a) Ciprofloxacin

In a randomised, placebo-controlled study in 32 patients stabilised on warfarin and without infections, ciprofloxacin 750 mg twice daily for 12 days had no clinically relevant effect on measures of anticoagulation. There was a mean increase in prothrombin time ratio of just 3% (range 0 to 6%), with a 10 to 13% decrease in the levels of clotting factors II and VII. In this study, ciprofloxacin had no effect on S-warfarin levels, but did slightly increase R-warfarin levels by 14.7%. Similarly, no clinically relevant effects on warfarin anticoagulation were seen in two other studies in a total of 16 patients without infections given ciprofloxacin 500 mg twice daily for 7 or 10 days. In a population-based cohort study, there were no cases of over-anticoagulation (INR greater than 6) in patients taking acenocoumarol or phenprocoumon with ciprofloxacin (just 19 received ciprofloxacin). Note that this study did find an increased risk for norfloxacin, see below.

In contrast, there are reports where ciprofloxacin has apparently been responsible for moderate to markedly increased prothrombin times and/or bleeding in patients taking warfarin. The FDA in the US has a total of 64 such cases over the 10 year period 1987 to 1997 on its Spontaneous Reporting System database. Those cases where details were available, plus an additional 2 cases, showed that the median prothrombin time was 38 seconds, the INR 10, and the median time to detection after starting ciprofloxacin was 5.5 days. Hospitalisation was reported in 15 cases, bleeding in 25 cases and death in one case. There are a number of other individual published case reports from the USA describing moderate to marked increases in prothrombin times and/or bleeding in a total of 8 patients stabilised on warfarin, which was associated with taking ciprofloxacin. For the period December 1989 to January 2004, Health Canada had received 10 reports of suspected coagulation disorders associated with ciprofloxacin and warfarin, 7 of which were considered serious, and in one case, fatal. Similarly, in February 2006, the Australia Adverse Drug Reactions Advisory Committee stated they had received 9 reports of a suspected interaction between warfarin and ciprofloxacin.

(b) Cinoxacin

Cinoxacin 200 mg twice daily for 14 days had no effect on the steady-state levels of S-warfarin in healthy subjects, but the levels of the less active enantiomer R-warfarin were increased by 32% and the mean INR was increased by 13%.

(c) Enoxacin

When a single 25-mg dose of warfarin was given to 6 healthy subjects on day 8 of a 14-day course of enoxacin 400 mg twice daily, the pharmacokinetics of S-warfarin were not altered, but the clearance of R-warfarin was decreased by 32% and its elimination half-life was prolonged from 36.8 to 52.2 hours. The overall anticoagulant response to the warfarin was unaltered. Another report about one patient taking warfarin also suggested that the use of enoxacin does not alter the prothrombin time ratio.

(d) Floxacin

The pharmacokinetics of R- and S-warfarin, the prothrombin time and factor VII clotting time were unaffected when 12 healthy subjects were given a single 25-mg dose of warfarin on day 4 of a 9-day course of floxacin 400 mg daily.

(e) Gatifloxacin

The manufacturer notes that gatifloxacin 400 mg daily for 11 days had no effect on the pharmacokinetics of a single 25-mg dose of warfarin, nor was the prothrombin time altered. In contrast, in a review of 94 patients taking warfarin and given antibacterials for community-acquired pneumonia, 22 of the 40 patients treated with gatifloxacin (55%) had INRs greater than 3 during or within 48 hours after stopping gatifloxacin therapy, compared with 20 of 54 patients treated with ceftriaxone and/or azithromycin (37%). In the gatifloxacin group, 38% needed a warfarin dose adjustment, compared with 18% of patients taking other antibacterials. There was no difference in infection severity between the two groups.

For the period February 2001 to January 2004, Health Canada had received 13 reports of suspected coagulation disorders associated with gati-

**Coumarins + Antibacterials: Quinolones**

Most studies show that the quinolones have, at most, a small, clinically insignificant effect on the pharmacokinetics and pharmacodynamics of warfarin. Despite this, increased effects and even bleeding have been seen quite unpredictably in isolated cases in patients taking warfarin with ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, nalidixic acid, norfloxacin or ofloxacin; or while taking acenocoumarol when given nalidixic acid, norfloxacin or pefloxacin, or phenprocoumon with norfloxacin. Further...
From the image and the given text, the content can be represented as follows:

(f) Gemifloxacin
A double-blind, randomised, placebo-controlled study found that healthy subjects taking fixed doses of warfarin and with INRs in the range of 1.3 to 1.8 had no INR changes when they were given gemifloxacin 320 mg daily for 7 days.

(g) Levofloxacin
Levofoxacin 500 mg twice daily for 9 days had no effect on the pharmacokinetics or pharmacodynamics of R- and S-warfarin in 15 healthy subjects. There were no significant INR changes when 10 healthy subjects were stabilised on warfarin for 7 days.

(h) Moxifloxacin
The pharmacokinetics of R- and S-warfarin were not altered when a single 25-mg dose of warfarin was given on day 5 of an 8-day course of moxifloxacin 400 mg once daily in healthy subjects.

(i) Nalidixic acid
A patient stabilised on warfarin (prothrombin ratio 2), developed a purpuric rash and bruising within 6 days of starting nalidixic acid 500 mg four times daily. Her prothrombin ratio had risen to 3.46. Another patient, previously well controlled on warfarin, developed a prothrombin time of 60 seconds 10 days after starting nalidixic acid 1 g three times daily.

(j) Norfloxacin
In 10 healthy subjects norfloxacin 400 mg twice daily for 9 days was found not to alter either the pharmacokinetics or anticoagulant effects of a single 30-mg dose of warfarin given on day 4.

In contrast, a 91-year-old woman taking warfarin and digoxin developed a brain haemorrhage within 11 days of starting to take norfloxacin (precise dose not stated). Her prothrombin times had risen from 21.6 to 36.5 seconds. At this time, the manufacturer of norfloxacin said they were given 320 mg daily for 7 days.

(k) Ofloxacin
Ofloxacin 200 mg daily for 7 days did not significantly affect the prothrombin times of 7 healthy subjects stabilised on phenprocoumon. In a population-based cohort study, there were no cases of over-anticoagulation (INR greater than 6) in patients taking acenocoumarol or phenprocoumon with ofloxacin. Note that this study did not find an increased risk of over-anticoagulation for ofloxacin.

(l) Pefloxacin
A patient had a marked increase in the effects of acenocoumarol (Quick ratio reduced from 26% to less than 5%) within 5 days of starting to take pefloxacin 800 mg daily and rifampicin 1.2 g daily.

(m) Trovafloxacin
Healthy subjects stabilised on warfarin with INRs in the range of 1.3 to 1.7 were additionally given trovafloxacin 200 mg daily for 7 days. No changes in the pharmacokinetics of either S- or R-warfarin occurred and there were no significant changes in mean INRs were seen.

Mechanism
Uncertain. It is not clear what other factors might have been responsible in those cases where the effects of the anticoagulants were increased. Factors relating to acute infection rather than the antibacterial used to treat it might be responsible for increased INRs, see also ‘Coumarins + Antibacterials’, p.365. However, one study that controlled for severity of infection indicated this is not the case and that an interaction between the quinolone and anticoagulant probably occurs.

In vitro experiments have shown that nalidixic acid can displace warfarin from its binding sites on human plasma albumin, but this mechanism is not well understood. In a single-dose study enoxacin was shown to inhibit the metabolism of the less potent R-warfarin isomer, without affecting the anti-coagulant activity of the R-warfarin.

Importance and management
The minor pharmacokinetic interaction between ciprofloxacin and warfarin in patients taking warfarin would appear to be established, but unlikely to be clinically relevant. Similarly no other quinolone has been shown to have a clinically significant interaction with warfarin. Despite this, there are isolated published case reports of marked over-anticoagulation with many of the quinolones, and other known unpublished cases reported to regulatory authorities. Given the widespread use of warfarin and quinolones, these interactions would appear to be rare.

The overall picture is that no adverse interaction normally occurs between these quinolones and coumarin anticoagulants, but rarely and unpredictably increased anticoagulant effects and even bleeding can occur with some of them. There is no need to avoid using any of the quinolones with oral anticoagulants but it would be prudent to monitor the effects when any quinolone antibacterial is first added to treatment with any coumarin so that any problems can be quickly identified.
The anticoagulant effects of warfarin are markedly reduced by rifampicin (rifampin), with two to fivefold increases in dose needed to maintain efficacy in a number of case reports. Acenocoumarol and phenprocoumon are similarly affected.

Clinical evidence
(a) Acenocoumarol

The dosage of acenocoumarol needed to maintain the targetQuick value within the therapeutic range in 18 patients stabilised on acenocoumarol who were given rifampicin 450 mg twice daily for 7 days. The effect was apparent 5 to 8 days after starting the rifampicin, and had not reached a maximum at 14 days, at which point a mean 76% increase in the acenocoumarol dosage was needed.1 In another study the Quick time of a single dose of acenocoumarol, measured 35 hours after the dose, was reduced by 44% when rifampicin 10 mg/kg was given daily for 2 weeks.2

(b) Phenprocoumon

In a study in healthy subjects, rifampicin 600 mg daily for 14 days increased the clearance of a single dose of phenprocoumon by 2.2-fold.3 Similarly, two patients stabilised on phenprocoumon required the dose to be doubled while taking rifampicin 600 mg daily (plus isoniazid with or without ethambutol). In one case, the patient developed severe gross haematuria 3 months after rifampicin had been discontinued because the phenprocoumon dose had not been reduced.4

c) Warfarin

In one controlled study in 8 healthy subjects, rifampicin 600 mg daily for 21 days reduced the steady-state plasma warfarin levels by 85% (range 64% to 100%). In addition, rifampicin abolished the anticoagulant effect of warfarin (the prothrombin time averaged 27% of normal during warfarin alone, and 85% of normal when rifampicin was taken).5 Similar findings were seen in 2 other single-dose warfarin studies.6,7 One of these measured the isoemers of warfarin separately and found that rifampicin increased the clearance of R-warfarin threefold and S-warfarin twofold. This interaction has also been described in a number of case reports.8-11 In these reports the dosage of warfarin was doubled 12 or even tripled 13 to accommodate this interaction, and reduced by an equivalent amount over two 9 to 3 weeks12 following withdrawal of the rifampicin. In one more-recent well-described case, a threefold increase in warfarin dose from 5 to 15 mg daily over 4 months failed to achieve a therapeutic INR during long-term rifampicin therapy, and eventually a fivefold increase in dose (25 mg daily) attained an INR of 1.7 and 1.9. A gradual 70% dose reduction over 4 to 5 weeks was required when the rifampicin was discontinued.14

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism and clearance of the anticoagulants from the body, thereby reducing their effects.2 Other mechanisms may also be involved.12 See also ‘antibacterials’, (p.365).

Importance and management

The interaction between rifampicin and the coumarins is very well documented,1,2 especially important, and occurs in most patients. A marked reduction in the anticoagulant effects may be expected within a week of starting the rifampicin, and persisting for about 2 to 5 weeks after the rifampicin has been withdrawn. With warfarin there is evidence that the dosage may need to be markedly increased (two to fivefold) over a number of weeks to accommodate this interaction, and reduced slowly by an equivalent amount following withdrawal of the rifampicin. Warfarin dose titrations should be carried out with close monitoring. There does not seem to be any information regarding the other rifamycins, rifabutin (a weak enzyme inducer) and rifapentine (a moderate enzyme inducer). However, the manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including oral anticoagulants.15,16

Another patient who had recently started taking warfarin developed haematuria and had a prolonged prothrombin time 7 days after also starting sulfafurazole.21

(d) Sulfamethoxazole

The half-life of warfarin was increased by over 40% (from 65 to 93 hours) in 2 patients taking sulfamethizole 1 g four times daily for a week.22

(e) Sulfaphenazole

Sixteen patients given single oral doses of phenindione and sulfaphenazole 500 mg had prothrombin time increases after 24 hours of 16.8 seconds, compared with 10.3 seconds in 12 other patients who took phenindione alone.23

(f) Trimethoprim

Trimethoprim combined with sulfamethoxazole (co-trimoxazole) is known not to interact with coumarins, see (a) above. However, there appear to be no controlled studies of the effect of trimethoprim alone on these drugs, and no case reports of any interaction. In one cohort study, 12 patients taking warfarin had a small INR increase of about 0.36 when given trimethoprim, but this was not statistically significant.24 In another cohort study in patients taking acenocoumarol or phenprocoumon, the use of trimethoprim was associated with an increased risk of over-anticoagulation (INR greater than or equal to 6). The adjusted relative risk of over-anticoagulation was noted to be 5.6 (range 1.3 to 23.1), and the greatest risk was in the first 3 days of concurrent use. The risk from trimethoprim alone in this study was less than that for co-trimoxazole.17

Mechanism

Not fully understood. Sulfamethoxazole is a known inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which S-warfarin is predominantly metabolised. The finding that co-trimoxazole caused a modest 22% increase in S-warfarin levels supports this mechanism.16,25 Acenocoumarol and phenprocoumon are also metabolised by CYP2C9 and might be expected to be similarly affected. Plasma protein binding displacement has been suggested as a mechanism,26,27 but on its own it does not provide an adequate explanation because the interaction is sustained.17,25 Sulfonamides can drastically reduce the intestinal bacterial synthesis of vitamin K, but this is not normally an essential source of the vitamin unless dietary sources are exceptionally low,28,29 see also ‘Coumarins + Antibacterials’, p.365.

Importance and management

The interaction between co-trimoxazole and coumarin anticoagulants is well documented and well established. The incidence appears to be high. If bleeding is to be avoided the INR should be well monitored and the warfarin, acenocoumarol, or phenprocoumon dosage should be reduced. Anecdotal evidence suggests that co-trimoxazole may not interact with the indanedione phenindione, but note that sulfaphenazole did, so some caution is still appropriate.

The other interactions are poorly documented. However, it would seem prudent to follow the precautions suggested for co-trimoxazole if any sulfonamide is given with a coumarin or indanedione.

The relative silence in the literature for trimethoprim alone would suggest that, in practice, any interaction, if it occurs, is of only minor importance, and the anticoagulant dosage probably needs little or no adjustment, but note that 2 cohort studies have shown some increased risk when trimethoprim was given with warfarin, acenocoumarol or phenprocoumon so an interaction cannot entirely be dismissed.

Cumarins and related drugs + Antibacterials; Sulfonamides and/or Trimethoprim

Co-trimoxazole modestly inhibits the metabolism of S-warfarin, and a number of case reports show that the anticoagulant effects of the coumarins warfarin, acenocoumarol, and phenprocoumon are increased by co-trimoxazole. Case reports suggest that sulfafurazole, sulfadoxine, and sulfamethizole may have similar effects. Two cohort studies have suggested that trimethoprim alone is associated with an increased risk of overt-anticoagulation, but this was less than that for co-trimoxazole in one of these studies. Anecdotal evidence suggests that the indanedione phenindione might not interact with co-trimoxazole, but in one study sulfaphenazole increased the effect of phenindione.

Clinical evidence

(a) Co-trimoxazole (Sulfamethoxazole with trimethoprim)

1. Coumarins. Six out of 20 patients taking warfarin had an increase in their prothrombin ratios (to about 4 to 6) within 2 to 6 days of starting to take co-trimoxazole 960 mg twice daily.1 One patient had a gastrointestinal haemorrhage and needed to be given vitamin K. The warfarin was temporarily withdrawn from 5 patients and the dosage was reduced in one patient to control excessive hypoprothrombinemia.2 Similarly, an increase in the effects of warfarin, with or without bleeding complications, in patients given co-trimoxazole has been described in a number of other case reports.3–14

In one study in healthy subjects, co-trimoxazole 480 mg four times daily for 8 days increased the prothrombin time had risen to 60 seconds.20

Another patient who had recently started taking warfarin developed haematuria and had a prolonged prothrombin time 7 days after also starting sulfafurazole.21

**Coumarins + Antibacterials; Teicoplanin or Vancomycin**

An isolated case report describes a marked reduction in the effects of warfarin, which was attributed to teicoplanin, but which could be equally be explained by rifampicin treatment. One study found that vancomycin possibly causes a small increase in the effects of warfarin, and a cohort study suggested that vancomycin increased risk of over-anticoagulation with acenocoumarol or phenprocoumon.

**Clinical evidence, mechanism, importance and management**

(a) Teicoplanin

A 60-year-old woman taking digoxin, furosemide and warfarin (INR 3.5 to 5) developed a fever after mitral valve replacement surgery and was given rifampicin 450 mg twice daily and teicoplanin 400 mg twice daily. Within 3 days her INR began to fall and by day 6 the anticoagulant effect was completely lost. Despite progressive warfarin increases to 10, 15, and then 20 mg daily, her INR stayed between 1.2 and 1.6, even when the rifampicin was stopped, and remained low for a further 20 days, at which point the teicoplanin was also stopped.

Some of this resistance to warfarin was undoubtedly due to the rifampicin (a known and potent inducer of warfarin metabolism) but as the INRs remained suppressed for a further 20 days after rifampicin was withdrawn the authors suggested that the teicoplanin had its own part to play. However, rifampicin has been shown in several cases to decrease the effects of warfarin for 3 or more weeks after its withdrawal (see ‘Coumarins + Antibacterials; Rifamycins’ p.375), so an interaction with teicoplanin would seem doubtful.

(b) Vancomycin

In a retrospective review of 60 patients undergoing heart valve replacement surgery and receiving prophylactic antibacterials, 44 patients given cefamandole had a much greater anti-coagulant response to their first dose of warfarin than 16 patients given vancomycin. In a later prospective study by the same workers, in patients taking warfarin with an antibacterial, after 3 days the prothrombin times as a percentage of activity were as follows: cefamandole 29%, ceftazolin 38%, and vancomycin 51%, suggesting that ‘ceftamandole’, (p.367) had a much greater effect on anti-coagulant response than vancomycin.

In a cohort study, the use of vancomycin was associated with an increased risk of over-anticoagulation (an INR greater than 6) in patients stabilised on acenocoumarol or phenprocoumon. The relative risk was 13.6; however, the confidence interval was very large (1.7 to 107), so it is not possible to draw any firm conclusions from this. Consider also ‘Coumarins + Antibacterials’, p.365.

**Coumarins and related drugs + Antibacterials; Tetracyclines**

Isolated cases suggest that doxycycline and tetracycline can increase the effects of coumarins. Similarly, some small studies (none controlled) suggest that chlorotetracycline (alone or with oxytetracycline), doxycycline, or the tetracyclines as a class may increase the risks of over-anticoagulation. This appears to be supported by studies of the effect of tetracyclines on the pharmacokinetics of warfarin. However, the related antibiotic, tigecycline, increased the AUC of warfarin, and has been shown to increase the prothrombin time when given alone.

**Clinical evidence**

There are no controlled studies of the effect of any tetracycline on the pharmacokinetics or pharmacodynamics of warfarin or other coumarins, although there are data for tigecycline, a new glycylcycline antibacterial structurally related to tetracyclines.

(a) Chlorotetracycline

Six out of 9 patients taking an unnamed antibacterial had a fall in their prothrombin-proconvertin concentration from a range of 10 to 30% to less than 6% when given chlorotetracycline 250 mg four times a day for 4 days. Although the anti-coagulant effects were increased, there was no evidence of bleeding. In one early study of dicoumarol and ethyl biscoumacetate, the authors briefly comment that 4 cases of combined use with chlorotetracycline plus oxytetracycline increased the prothrombin response.

(b) Doxycycline

A woman stabilised on warfarin developed menorrhagia after taking doxycycline 100 mg twice daily for 10 days, and her prothrombin time ratio had increased from about 2 to 4.3. Two other patients stabilised on acenocoumarol or warfarin developed markedly increased prothrombin ratios (3.82 and 4.09, respectively) with bruising, haematomas and bleeding when they took doxycycline. Another patient with multiple medical problems, taking warfarin and a range of drugs (alendronate, atorvastatin, salbutamol, diltiazem, fluticasone) developed peritoneal bleeding and an INR of 7.2 (previously 2.6) 6 days after starting doxycycline 100 mg twice daily.

In a population-based cohort study in patients taking acenocoumarol or phenprocoumon, doxycycline was found to increase the risk of over-anticoagulation (INR greater than or equal to 6) with an adjusted relative risk of 4.3 (range 1.8 to 10.4). The risks were greatest after 4 or more days of concurrent use.

(c) Oxytetracycline

In one early study of dicoumarol and ethyl biscoumacetate, the authors briefly comment that 4 cases of combined use with chlorotetracycline plus oxytetracycline increased the prothrombin response.

(d) Tetracycline

In one analysis of haemorrhagic events in patients taking dicoumarol and antibacterials, 1 patient out of 20 who received tetracycline had a bleeding event. A patient stabilised on warfarin had a marked increase in INR (from about 2 to 7.7) 6 weeks after starting to take tetracycline 250 mg four times daily. Warfarin was withheld for a few days, then restarted at a 40% lower dose. The INR decreased over the following months, broadly in parallel with decreases in the tetracycline dosage. A patient taking warfarin bled (right temporal lobe haematoma) and had an extended pro-
tissue coagulant and the tetracycline have additive hypoprothrombinemic effects. Although tigecycline decreased the clearance of warfarin, and because it could cause an increase in INR, it is recommended that the INR be closely monitored in patients taking warfarin when given tigecycline.10,11 There appears to be no information about the indanediones, but if the mechanism suggested is correct they may also interact like the coumarins.

Importance and management

A relatively sparsely documented interaction, bearing in mind that the tetracyclines have been in very widespread use for many years. It can therefore reasonably be concluded that normally any changes are of little clinical relevance. As a few patients have unpredictably shown increased anticoagulant effects and even bleeding, bear this interaction in mind when a tetracycline is first added to established anticoagulant treatment with a coumarin. Because tigecycline decreased the clearance of warfarin, and because it could cause an increase in INR, it is recommended that the INR be closely monitored in patients taking warfarin when given tigecycline.10,11 There appears to be no information about the indanediones, but if the mechanism suggested is correct they may also interact like the coumarins.

Coumarins + Anticholinesterases; Centrally acting

Donepezil, galantamine, rivastigmine and tacrine do not appear to alter the pharmacokinetics or effects of warfarin.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In an open-label, crossover study, 12 healthy men were given donepezil 10 mg daily for 19 days with a single 25-mg dose of warfarin on day 14. The pharmacokinetics of R- and S-warfarin and the prothrombin times were unchanged by the presence of the donepezil, and vital signs, ECG and laboratory tests were unaltered.1

(b) Galantamine

The manufacturers of galantamine2,3 say that galantamine 12 mg twice had no effect on the pharmacokinetics of R- and S-warfarin after a single 25-mg dose of warfarin. In addition, galantamine did not alter the prothrombin time.3

(c) Rivastigmine

The manufacturers of rivastigmine4,5 say that no pharmacokinetic interaction has been noted between rivastigmine and warfarin in healthy subjects. In addition, rivastigmine did not affect the increase in prothrombin time seen with warfarin.

(d) Tacrine

A study in 10 patients stabilised on warfarin found that the addition of tacrine 20 mg four times daily for 5 days had no significant effect on prothrombin times.6

4. Exelon (Rivastigmine tartrate). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2006.

In a double-blind, randomised, placebo-controlled study, 24 healthy subjects were given miglitol 100 mg three times daily for 7 days, with a single 25-mg oral dose of warfarin on day 4. Neither the pharmacokinetics nor the pharmacodynamics of R- or S-warfarin was affected by the miglitol.3 No special precautions would therefore appear to be needed if these two drugs are used concurrently.

(c) Voglibose

Twelve healthy male subjects were given individually adjusted doses of warfarin to give Quick values of 30 to 40%, and then from day 11 to 15 they were also given voglibose 5 mg three times daily. It was found that the voglibose had no effect on the pharmacokinetics of the warfarin nor on its anticoagulant effects.4 No special precautions would therefore appear to be needed if these two drugs are used concurrently.

Clinical evidence

(a) Phenprocoumon

The Quick value of a 58-year old woman stabilised on metformin 1.7 g twice daily and phenprocoumon 3 to 4.5 mg daily fell from a range of 20 to 30% down to 0% when she stopped taking the metformin while on holiday. Despite the increased anticoagulant effect no signs of bleeding were observed, and she was eventually reestablished on the original doses of both drugs.1 This case prompted a further observational study in 13 patients with type 2 diabetes. It was found that the 7 patients taking metformin 1.1 to 3 g daily were less well anticoagulated than those taking only 400 mg to 1 g of phenprocoumon, even though the mean phenprocoumon dosage was slightly higher in those taking the higher metformin dose (2.57 mg daily versus 2.27 mg daily).1 In another study, the half-life of phenprocoumon was reduced by about one-third (from 123 to 85 hours) by phenprocoumon was reduced by about one-third (from 123 to 85 hours) by phenprocoumon.2 Phenprocoumon was reduced by about one-third (from 123 to 85 hours) by phenprocoumon.

(b) Warfarin

An elderly woman taking warfarin 5 mg daily and metformin 1 g twice daily developed fatigue, epistaxis, haematuria and gingival bleeding, with an INR of 16.9, which was treated with vitamin K. The following morning, she was given metformin, then she was found to have a retroperitoneal haematoma and bilateral perinephric blood with obstruction of both renal collecting systems. Over the next 8 hours, she developed progressive metabolic acidosis and suffered a cardiopulmonary arrest. Her metformin level was 7.3 micrograms/mL (therapeutic range 1 to 2 micrograms/mL). It was suggested that metformin accumulation occurred because of renal insufficiency caused by the site of renal bleeding secondary to the excessive effects of warfarin. This then resulted in metabolic acidosis.2

Haematuria occurred in a patient taking warfarin 3 months after phenformin was started. Her prothrombin values were normal.3 Phenformin may have increased fibrinolysis to the point where it was additive with the effects of the warfarin.

Mechanism

Metformin possibly reduces the effects of phenprocoumon by altering blood flow to the liver and interfering with enterohepatic circulation.

Importance and management

The information about a biguanide interaction with warfarin appears to be limited to these isolated reports, neither of which definitely suggest that the biguanide altered anticoagulant effects. In general no interaction would be expected between metformin or phenformin and warfarin. There is some evidence that a small increase in the dosages of phenprocoumon may be necessary if metformin is given but it seems likely that this can be managed with routine anticoagulant monitoring.

Nateglinide and repaglinide do not appear to interact with warfarin, and nateglinide does not interact with acenocoumarol.

Clinical evidence, mechanism, importance and management

(a) Nateglinide

In a randomised, double-blind study, 11 healthy subjects were given nateglinide 120 mg three times daily for 5 days, with a single 10-mg dose of acenocoumarol on day 3. Nateglinide had no effect on the tolerability, pharmacokinetics or anticoagulant activity of acenocoumarol.1 In another study, 12 healthy subjects were given nateglinide 120 mg three times daily for 4 days with a single 30-mg dose of warfarin on day 2. No pharmacokinetic or pharmacodynamic interaction was noted.2 No dosage adjustments would therefore be expected to be necessary if nateglinide is taken with either acenocoumarol or warfarin.

(b) Repaglinide

In a double-blind, placebo-controlled study in 28 healthy subjects who were stabilised on warfarin, repaglinide did not alter the anticoagulant effects of warfarin or the steady-state warfarin pharmacokinetics.3 Therefore, no warfarin dosage adjustment would be anticipated on concurrent use.

2. Anderson DM, Shelley S, Crick N, Buraglio M. No effect of the novel antidiabetic agent nateglinide is taken with either acenocoumarol or warfarin.

Pioglitazone does not appear to alter the pharmacokinetics or anticoagulant effect of warfarin or phenprocoumon. Rosiglitazone did not affect the pharmacokinetics of warfarin.
DICOMAROL inhibits the metabolism of tolbutamide and increases its effects; cases of hypoglycaemic coma have been reported. Chlorpropamide may be affected similarly. Although isolated cases of interactions (raised prothrombin times, bleeding or hypoglycaemia) have been seen in patients taking sulfonylureas and coumarins, in general, no important interaction appears to occur. There also appears to be no interaction between phenindione and tolbutamide.

**Clinical evidence**

A. Coumarins

(a) Chlorpropamide

1. Acenocoumarol. A woman with normal renal function had an increase in the half-life of chlorpropamide to 88 hours (normally about 36 hours) when she took acenocoumarol.1

2. Dicoumarol. A 67-year-old non-diabetic man taking chlorpropamide for Parkinson’s disease developed severe hypoglycaemia about 3 months after starting dicoumarol. He had high chlorpropamide levels with a half-life of 80 to 90 hours. Dicoumarol was withdrawn, and 3 weeks later his chlorpropamide half-life was 30 hours.2 This observation prompted further study in 3 other patients and 2 non-diabetics. Dicoumarol doubled the serum chlorpropamide levels within 3 to 4 days and also more than doubled the half-life.2

(b) Glibenclamide (Glyburide)

1. Phenprocoumon. The pharmacokinetics of glibenclamide remained unchanged by phenprocoumon.3 Similarly, the plasma levels and half-life of single doses of phenprocoumon did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking glibenclamide (9 patients).4

2. Warfarin. There do not appear to be any controlled studies on the effect of glibenclamide on the pharmacokinetics of coumarins, although recent in vitro data suggest that an effect is possible because glibenclamide inhibited S-warfarin hydroxylation (a 7 to 37% in vivo inhibition was predicted).5 Moreover, isolated reports describe increased warfarin effects (INR increased from 2.3 to 6.6 with haematomas in one instance6) in 2 patients given glibenclamide.5,7

(c) Glibormide

Phenprocoumon, given to 3 subjects for 4 days, slightly increased the half-life of a single 25-mg dose of glibormide by 29%.8 The plasma levels and half-life of a single dose of phenprocoumon did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking glibormide (12 patients).4

(d) Glimipiride

In healthy subjects, glimepiride 4 mg daily caused only minor, clinically unimportant changes in the prothrombin times (about 10% decrease in mean maximum prothrombin time) in response to single 25-mg doses of warfarin. In addition, glimepiride had no effect on the pharmacokinetics of R- and S-warfarin.9
Findings from a retrospective review suggest that the anticoagulant effects of acenocoumarol may be reduced by loratadine, ebastine, or cetirizine. Conversely, an isolated report describes bleeding and a markedly raised INR in an elderly man taking acenocoumarol and cetirizine.

Clinical evidence, mechanism, importance and management

A retrospective review of patients taking acenocoumarol with loratadine, ebastine, or cetirizine found that INRs were decreased during concurrent use, but no thromboembolic event was noted. The authors consider that temporary increases in the anticoagulant dosage might be required. In contrast, there is a case report of an 88-year-old man taking acenocoumarol for a deep vein thrombosis who developed acute and severe epistaxis after a fall, and within 3 days of starting to take cetirizine 10 mg daily for allergic rinitis. His INR was found to have risen from 1.5 to 1.4. The cetirizine concentration may have been particularly high because of some renal impairment and because cetirizine may have displaced acenocoumarol from its plasma protein binding sites, although this mechanism on its own is now largely discredited as an explanation for interactions between anticoagulants and highly bound drugs.

Information is limited, and given the widespread use of these drugs any consistent clinically significant interaction might have been expected to have come to light by now. No specific precautions seem necessary if these drugs are given in combination, but bear the interaction in mind in the case of an unexpected response to treatment.

Coumarins + Antihistamines

17. Pouchet RL, Vecchio TJ. Absence of tolbutamide effect on anticoagulant therapy. JAMA (1966) 197, 1069–70.

Coumarins + Antineoplastics; Fluorouracil and related prodrugs

Capcitabine markedly increases warfarin levels and increases its anticoagulant effects. A number of case reports describe over-anticoagulation in patients taking warfarin with capcitabine. Similarly, case reports describe over-anticoagulation in patients taking warfarin and fluorouracil, florasuf or tegafur.

Clinical evidence

(a) Capcitabine

In an open study, 4 patients with breast or colorectal cancer received a single 20-mg dose of warfarin 8 days before starting oral capcitabine (3 cycles of capcitabine 1250 mg/m² twice daily for 14 days, then 7 days rest), then again on day 12 of the third cycle of capcitabine. Capcitabine increased the AUC of S-warfarin by 57%, and its elimination half-life by 51%, without any significant changes to R-warfarin. The maximum INR was increased by 1.9-fold and the AUC of the INR increased 2.8-fold. Three of the patients required vitamin K administration. Because of the clear, statistically significant findings in these 4 patients, the study was terminated early. In one of these reports, 2 patients starting warfarin developed gastrointestinal bleeding with an INR of greater than 10, after 2 cycles of capcitabine. In another case, a patient who had been taking long-term warfarin required a gradual 85% reduction in warfarin dose to 0.78 mg daily over 3 cycles of capcita-bine and irinotecan, and required an increase to 4 mg daily over the 3 weeks after stopping chemotherapy. Another patient required a 50% reduction in warfarin dose while taking capcitabine. The manufacturers of capcitabine also report that this interaction has occurred with the coumarins including phenprocoumon.

In an early clinical study, 25 patients with colon cancer were given bolus fluorouracil 15 to 20 mg/kg weekly plus warfarin daily, titrated to maintain the prothrombin time in the 20 to 30% range, and modified weekly as necessary. Three patients developed blood loss from the gut, which was controlled by giving a transfusion and stopping the warfarin. This study did not report the required dose of warfarin, or how often it needed adjusting in these patients.

Various case reports have described clinically important over-anticoagulation with concurrent use of dose adjusted warfarin (for treatment of deep vein thrombosis, or in patients with prosthetic heart valves) and fluorouracil, either alone, with folinic acid (leucovorin), or levamisole. In one well-described case, an elderly man taking warfarin long-term was found to have an INR of almost 40 (usual INR 3) four weeks after he started taking fluorouracil (450 mg/m² daily for 5 days then once weekly) and levamisole (50 mg every 8 hours for 3 days every other week). He required a two-thirds reduction in warfarin dose. Later, when the chemotherapy was withheld for 5 weeks his INR became subtherapeutic, and then increased again when the chemotherapy was re-started. In another retrospective case series, 4 patients taking warfarin long-term (target INR 2 to 3) required an 18 to 74% reduction in warfarin dose during treatment with fluorouracil and folinic acid or levamisole. The maximum INR in 3 of these patients was 3.66 to 8.15, and the other patient had a maximum INR of 23.7 and a retroperitoneal bleed.

Other cases of overanticoagulation have been reported with warfarin and fluorouracil-based regimens including CMF (cyclophosphamide, methotrexate and fluorouracil), CMF plus vincristine and prednisone, fluorouracil, cisplatin and etoposide, and fluorouracil, cisplatin and mitomycin. A case has also been reported with the use of fixed dose warfarin (1 mg daily) for prophylaxis of venous catheter-associated thrombosis in a patient receiving fluorouracil with vinblastine. Similarly, in a large retrospective analysis of fixed dose warfarin, 31 of 95 patients given regimens based on continuous infusions of fluorouracil had INR elevations above 1.5, and, of these, 18 had an INR of 3 to 4.9 and seven had an INR of more than 5. Epistaxis and haematuria occurred in 8 of the patients. The regimens used were fluorouracil plus folinic acid; folinic acid, fluorouracil plus oxaliplatin (FOLFOX), and folinic acid, fluorouracil plus irinotecan (FOLFIRI). In a further analysis of the use of fixed dose warfarin with the FOLFIRI regimen, 25 of 50 patients had an INR greater than 1.5 (range 1.55 to 9.4). Two of these developed haematuria, and one had a nosebleed.

(c) Flora or fur

Increased INRs and bleeding (haemoptysis) were seen in a patient taking warfarin when Orzel (uracil/florasur) in a 4:1 molar ratio was given, and a 63% reduction in the warfarin dose was needed.

(d) Tegafur

The manufacturers of Uftoral (tegafur/uracil) say that marked elevations in prothrombin times and INRs have been reported in patients taking warfarin when Uftoral was added.

Mechanism

Uncertain. However, in a pharmacokinetic study in rats, fluorouracil significantly reduced the total clearance of S-warfarin by inhibiting its metabolism. Data from the clinical study with the fluorouracil produg, capcitabine, suggests this interacts similarly.

Importance and management

Fairy well-documented and established interactions of clinical importance. Prothrombin times should be regularly monitored in patients taking warfarin and other coumarins and requiring fluorouracil, capcitabine or other fluorouracil pro-drugs, anticipating the need to reduce the warfarin dose. Note that, from a disease perspective, when treating venous throm-
boembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.28

A number of case reports describe an increase in the effects of warfarin, accompanied by bleeding in some cases, caused by antineoplastic regimens containing carboplatin, chlorothemine, cyclophosphamide, doxorubicin, etoposide, gefitinib, gemcitabine, ifosfamide with mesna, methotrexate, procarbazine, trastuzumab, vincristine or vindesine. A decrease in the effects of warfarin has been seen with azathioprine, cyclophosphamide, mercaptopurine and mitotane, a decrease in the effects of acenocoumarol has been seen with azathioprine, and a decrease in the effects of phenprocoumone and a third taking warfarin2 had marked falls in their INRs during treatment with azathioprine, and another woman needed an almost fourfold increase in the dose of warfarin when she was given azathioprine.27

A woman taking warfarin had a marked rise in her prothrombin time when her treatment with cyclophosphamide was withdrawn.9

A 63-year-old man needed a reduction in his weekly warfarin dosage from 59.23 mg to 50.75 mg in order to keep his INR at about 2.5 during 2 cycles of gemcitabine. When the gemcitabine was stopped his warfarin dosage had to be increased again.12 The manufacturers have information on 4 cases of suspected interactions between gemcitabine and warfarin, and one with phenprocoumone (reported by December 2000).13 Based on 724 reports of the concurrent use of gemcitabine and anticoagulants,13 they suggest that the incidence of the suspected interaction is 0.8%.

A woman stabilised on warfarin required a gradual decrease in the dose from 4 mg to 2.5 mg daily after starting gefitinib 250 mg/m² daily for lung cancer. In contrast, a second patient did not have an increase in warfarin effect while taking gefitinib.11

A 3-man taking warfarin had a marked and very rapid increase in their INRs when they took ifosfamide with mesna.14

The prothrombin times of an elderly man given warfarin increased by 50 to 100% in the middle of three cycles of treatment with ProMace-Mopp (cyclophosphamide, doxorubicin, etoposide, chlorothemine, vincristine, procarbazine, methotrexate and prednisone), and he developed a subconjunctival haemorrhage during the first cycle.19

Two women stabilised on warfarin developed nosebleeds after 10 and 8 weekly doses of trastuzumab, respectively, and were found to have INRs of 6 and 5.8, respectively.20 However, the manufacturer notes that in an analysis of clinical study data the rate of bleeding events was similar for patients receiving or not receiving trastuzumab, with or without anticoagulants.21

Coumarins + Antineoplastics; Miscellaneous

A number of case reports describe an increase in the effects of warfarin, accompanied by bleeding in some cases, caused by antineoplastic regimens containing carboplatin, chlorothemine, cyclophosphamide, doxorubicin, etoposide, gefitinib, gemcitabine, ifosfamide with mesna, methotrexate, procarbazine, trastuzumab, vincristine or vindesine. A decrease in the effects of warfarin has been seen with azathioprine, cyclophosphamide, mercaptopurine and mitotane, a decrease in the effects of acenocoumarol has been seen with azathioprine, and a decrease in the effects of phenprocoumone and a third taking warfarin2 had marked falls in their INRs during treatment with azathioprine, and another woman needed an almost fourfold increase in the dose of warfarin when she was given azathioprine.27

Clinical evidence

(a) Azathioprine

A survey of 103 patients with antiphospholipid syndrome found that azathioprine appeared to increase warfarin requirements.1 A woman who was resistant to warfarin, needing 14 to 17 mg daily while taking azathioprine, began to bleed (epistaxes, haematemesis) when the azathioprine was stopped. She was restabilised on warfarin 5 mg daily.2 Reduced warfarin effects were seen in 2 other patients taking azathioprine,2,14 one of whom had a marked fall in serum warfarin levels during azathioprine treatment.2 A woman with systemic lupus erythematosus taking phenprocoumone2 and a third taking warfarin2 had marked falls in their INRs during treatment with azathioprine, and another woman needed an almost fourfold increase in the dose of warfarin when she was given azathioprine.27

(b) Carboplatin

The INR of a man taking warfarin increased from a baseline range of 1.15 to 2.11 up to 12.6 within 16 days of a first course of chemotherapy with carboplatin and etoposide.8

(c) Cyclophosphamide

A woman taking warfarin had a marked rise in her prothrombin time when her treatment with cyclophosphamide was withdrawn.9

(d) Etoposide

The INR of a man taking warfarin increased from a baseline range of 1.15 to 2.11 up to 12.6 within 16 days of a first course of chemotherapy with carboplatin and etoposide.8 Another elderly man taking warfarin had a marked increase in prothrombin times (prolongation of 8 to 15 seconds) on two occasions when he took etoposide 500 mg and vindesine 5 mg.10

(e) Gefitinib

A woman stabilised on warfarin required a gradual decrease in the dose from 4 mg to 2.5 mg daily after starting gefitinib 250 mg/m² daily for lung cancer. In contrast, a second patient did not have an increase in warfarin effect while taking gefitinib.11

(f) Gemcitabine

A 63-year-old man needed a reduction in his weekly warfarin dosage from 59.23 mg to 50.75 mg in order to keep his INR at about 2.5 during 2 cycles of gemcitabine. When the gemcitabine was stopped his warfarin dosage had to be increased again.12 The manufacturers have information on 4 cases of suspected interactions between gemcitabine and warfarin, and one with phenprocoumone (reported by December 2000).13 Based on 724 reports of the concurrent use of gemcitabine and anticoagulants, they suggest that the incidence of the suspected interaction is 0.8%.

(g) Ifosfamide

Three patients taking warfarin had a marked and very rapid increase in their INRs when they took ifosfamide with mesna.14

(h) Mercaptopurine

A man well stabilised on warfarin had a marked reduction in his anticoagulant response on two occasions while taking mercaptopurine, but no changes occurred when he took busulfan, cyclophosphamide, etarabine, hydroxyurea, mitobronitol, demecolcine or melphalan.15 A woman needed a marked increase in her dosage of acenocoumarol, from 21 to 70 mg weekly, when she was given mercaptopurine 100 mg daily.16 Another patient required about a 25% increase in warfarin dose while taking mercaptopurine 100 mg daily.17

(i) Mitotane

The anticoagulant effects of warfarin were progressively reduced in a woman taking mitotane.18 Later this effect began to reverse.

(j) ProMace-Mopp

The prothrombin times of an elderly man given warfarin increased by 50 to 100% in the middle of three cycles of treatment with ProMace-Mopp (cyclophosphamide, doxorubicin, etoposide, chlorothemine, vincristine, procarbazine, methotrexate and prednisone), and he developed a subconjunctival haemorrhage during the first cycle.19

(k) Trastuzumab

Two women stabilised on warfarin developed nosebleeds after 10 and 8 weekly doses of trastuzumab, respectively, and were found to have INRs of 6 and 5.8, respectively.20 However, the manufacturer notes that in an analysis of clinical study data the rate of bleeding events was similar for patients receiving or not receiving trastuzumab, with or without anticoagulants.21
Mechanism

Not well understood. Mercaptopurine possibly increases the synthesis or activation of prothrombin. Azathioprine is metabolised to mercaptopurine, and would therefore be expected to interact similarly.

Importance and management

The absence of problems in early small studies using warfarin as an adjunct to chemotherapy, and the small number of reports describing difficulties, suggest that many of these interactions may be uncommon events. The concurrent use of these drugs need not be avoided but there is clearly a need to be aware that any antineoplastic regimens might increase the response to anticoagulants. It would also be prudent to note that mercaptopurine and azathioprine may decrease the anticoagulant response.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, placebo-controlled study involving 43 patients who had been taking warfarin for at least 2 months, the addition of clopidogrel 75 mg daily for 8 days had no effect on plasma warfarin levels or INRs. No bleeding occurred with clopidogrel and no serious adverse events were reported.

Nevertheless, as with other antiplatelet drugs, combined use might increase the risk or intensity of bleeding. Therefore, in the UK, the manufacturers of clopidogrel state that the concurrent use of warfarin is not recommended, whereas the US manufacturers recommend caution. This caution would be prudent with clopidogrel and any coumarin or indandione.

Clopidogrel does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, concurrent use might increase the bleeding risk.

Cilostazol does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, as with other antiplatelet drugs, concurrent use might increase the bleeding risk.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, two-way crossover study in 15 healthy subjects, cilostazol 100 mg twice daily for 13 days did not alter the pharmacokinetics of a single 25-mg dose of warfarin given on day 7. Also, prothrombin times, aPTT time and Ivey bleeding time were unaffected. This suggests that no interaction is likely during concurrent use. Nevertheless, because cilostazol is an antiplatelet drug, the manufacturer advises caution with the concurrent use of anticoagulants, with more frequent monitoring to reduce the possibility of bleeding.

Cilostazol does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, concurrent use might increase the bleeding risk.

Coumarins and related drugs + Antiplatelet drugs; Clopidogrel

The combination of dipryidamole and coumarin anticoagulants does not alter the prothrombin time, but might cause an increased risk of serious bleeding when compared with anticoagulants alone. There is some evidence that the risk of bleeding may be lower, without a reduction in efficacy, if the INR is maintained within a lower range.

Clinical evidence

(a) Prosthetic heart valves

In a short-term study in 6 patients stabilised on warfarin, the addition of dipryidamole 75 mg three times daily did not alter prothrombin time ratios measured 8 times over 17 days. A meta-analysis of 6 randomised, controlled studies of the combined use of an oral anticoagulant and dipryidamole compared with an oral anticoagulant alone, found no increased risk of any bleeding events when dipryidamole was given (odds ratio 1.001). In contrast, in a later meta-analysis of the same studies, the risk of major bleeding with the addition of dipryidamole was increased (odds ratio 2.22). In addition to the difference in classification of bleeding events, the authors of the second analysis stated that they had used published data from two studies, which showed a slightly higher bleeding risk, whereas the earlier meta-analysis had used unpublished data from these studies, showing a lower bleeding risk.

In one randomised study, the risk of excessive bleeding was 4% in patients taking warfarin and dipryidamole 400 mg daily, compared with 14% in patients taking warfarin and aspirin 500 mg daily. When compared with a non-randomised control group taking warfarin alone, the risk of bleeding did not appear to be increased.
of excessive bleeding was not increased by dipyridamole (4% combined therapy versus 5% warfarin alone). In another randomised study, the risk of bleeding was lower (1% versus 3.7%) in patients receiving dipyridamole 225 mg daily with phenindione at a target INR range of 2 to 2.5 than in patients receiving phenindione alone with a target INR of 2.5 to 3.5, and the combination was more effective. Similary, the risk of bleeding was lower with a lower target INR of 2 to 3 than with a target INR of 3 to 4.5 (3.9% versus 20.8%) in patients taking acenocoumarol, aspirin 330 mg twice daily and dipyridamole 75 mg twice daily.

(b) Other conditions

Thirty patients with glomerulonephritis stabilised on either warfarin (28 patients) or phenindione (2 patients) with a prothrombin activity of between 20 to 30% of control had no significant changes in prothrombin times when they were given dipyridamole in doses increased from 100 mg daily up to a maximum of 400 mg daily over about a month. Twelve to 19 days after starting dipyridamole, 3 patients with normal renal function developed mild bleeding (epistaxis, bruising, haematuria), which resolved when either drug was withdrawn or the dosage reduced.7

Mechanism

Dipyridamole reduces platelet adhesiveness or aggregation, which prolongs bleeding time. This may increase the risk or severity of bleeding if overanticoagulation occurs.

Importance and management

The combination of dipyridamole with coumarin anticoagulants is in established clinical use for the prophylaxis of thromboembolism associated with prosthetic heart valves. There is clearly some uncertainty regarding the increased risk of bleeding with the combination, with one analysis showing no increased risk, and a second showing about a doubling of risk of serious bleeding. The authors of the second analysis consider that their results represent a more conservative estimate of bleeding risk. There is some evidence that maintaining anticoagulant control at the lower end of the therapeutic range minimises possible bleeding complications and it would therefore seem prudent to consider this wherever possible.

**Coumarins + Antiplatelet drugs; Picotamide**

Picotamide did not alter the anticoagulant effects of warfarin. Nevertheless, as with other antiplatelet drugs, concurrent use might increase bleeding risk.

Clinical evidence, mechanism, importance and management

Picotamide 300 mg three times daily for 10 days did not alter the anticoagulant effects of established warfarin therapy in 10 patients with aortic or mitral valve prostheses. No warfarin dose adjustments would therefore be expected to be needed on concurrent use. Nevertheless, as with other antiplatelet drugs, combined use with oral anticoagulants might increase the risk or intensity of bleeding. Some caution is therefore appropriate on concurrent use.

**Coumarins + Antiplatelet drugs; Ticlopidine**

In a retrospective analysis, the anticoagulant effects of acenocoumarol were modestly reduced by ticlopidine in 80% of patients, whereas, in a small prospective study, the anticoagulant effects of warfarin were unchanged by ticlopidine. As with other antiplatelet drugs, combined use might possibly increase bleeding risk. Cholestatic hepatitis has been reported in some patients given warfarin and ticlopidine.

Clinical evidence

(a) Acenocoumarol

A retrospective study of 36 patients with heart valve prostheses found that when they took ticlopidine 250 mg daily, 29 of them needed a mean 13% increase in acenocoumarol dosage from 15.5 to 17.5 mg weekly, accompanied by a small INR rise from 3.05 to 3.13. One patient needed a dosage increase from 14 to 22 mg weekly. INR changes were detectable with a week of starting the ticlopidine.1

(b) Warfarin

Ticlopidine 250 mg twice daily for 2 weeks given to 9 men taking warfarin long-term increased the mean R-warfarin levels by 25.7% but did not change S-warfarin levels or their INRs.2 R-warfarin is the much less active of the two enantiomers.

In a Japanese study, 4 out of 132 patients (3%) given both warfarin and ticlopidine after cardiovascular surgery developed cholestatic hepatitis.3

Mechanism

It seems possible that ticlopidine inhibits the metabolism of R-warfarin, but the interaction with acenocoumarol is not understood. Ticlopidine alone can cause raised liver enzymes and cholestatic hepatitis, and whether these cases represent an interaction is unclear.

Importance and management

Information seems to be limited to the reports cited. A small to moderate increase in the acenocoumarol dosage may be needed if ticlopidine is added, but none seems to be necessary with warfarin. However, as with other antiplatelet drugs, an increased risk of bleeding (a combination of anticoagulant and platelet anti-aggregant activity) might be anticipated on concurrent use. The manufacturer states that the long-term safety of concurrent use of ticlopidine with oral anticoagulants has not been established, and they recommend that if a patient is switched from an anticoagulant to ticlopidine, the anticoagulant should be discontinued prior to ticlopidine administration.4 Whether the incidence of cholestatic hepatitis is higher with the combination of warfarin and ticlopidine than with ticlopidine alone is unclear.

**Coumarins and related drugs + Antiplatelet drugs; Dizatole**

Ditazole does not alter the anticoagulant effects of acenocoumarol. Nevertheless, as with other antiplatelet drugs, concurrent use might increase bleeding risk.

Clinical evidence, mechanism, importance and management

Fifty patients with artificial heart valves taking acenocoumarol had no changes in their prothrombin times while taking ditazole 800 mg daily.1 Nevertheless, as with other antiplatelet drugs, combined use with oral anticoagulants might increase the risk or intensity of bleeding. Some caution is therefore appropriate on concurrent use.

Coumarins + Aprepitant

Aprepitant modestly reduces warfarin levels and slightly decreases the INR in healthy subjects. It is expected to interact similarly with acenocoumarol.

Clinical evidence, mechanism, importance and management

In a double-blind study, healthy subjects were stabilised on warfarin and then given either aprepitant (125 mg on day one, then 80 mg daily on days 2 and 3) or placebo. On day 3, there was no change in warfarin levels. However, by day 8 (5 days after stopping aprepitant) there was a 34% decrease in trough S-warfarin levels, and a 14% decrease in INR in the aprepitant group.1

Aprepitant is an inducer of the cytochrome P450 isoenzyme CYP2C9, by which S-warfarin is metabolised. The manufacturer recommends that, in patients taking warfarin, the INR should be monitored closely that, in patients taking warfarin gradually needed about a threefold increase in the dosage to maintain adequate anticoagulation when they took aminoglutethimide, the INR should be monitored closely by which the metabolism of the anticoagulants, thereby reducing their levels and efficacy. Alternatively, it has been suggested that aminoglutethimide may affect blood steroid levels, which in turn might affect coagulation.2

Importance and management

An established and clinically important interaction. Monitor the effects of adding aminogluthethimide to patients already taking warfarin or acenocoumarol and increase the anticoagulant dosage as necessary. Up to four times the dosage may be needed. The extent of the effects would appear to be related to the dosage of aminogluthethimide used. Monitor the INR and reduce the anticoagulant dosage accordingly if aminogluthethimide is withdrawn. Information about other coumarins is lacking but it would be prudent to apply the same precautions with any of them.

Conversely, controlled studies have shown no interaction between anastrozole or letrozole and warfarin. This suggests that coumarin dose adjustments are unlikely to be needed when these aromatase inhibitors are used.

Coumarins + Aromatase inhibitors

The anticoagulant effects of warfarin and acenocoumarol can be markedly reduced by aminogluthethimide. The extent of the reduction appears to be related to the aminogluthethimide dosage. However, in controlled studies, anastrozole and letrozole did not interact with warfarin.

Clinical evidence

(a) Aminogluthethimide

In a study in 9 patients being treated for breast cancer, a low-dose aminogluthethimide regimen (125 mg twice daily) increased the clearance of a single-dose of R- or S-warfarin by 41.2% with marked variability between individuals (range 15 to 103%). A high-dose regimen (250 mg four times daily) increased the clearance by 90.8%. The effects of the interaction had developed fully by 14 days. Both enantiomers of warfarin were equally affected.1

One 79-year-old woman taking aminogluthethimide 250 mg four times daily showed resistance to warfarin requiring a dose of 17.5 to 20 mg daily. Two weeks after the aminogluthethimide was stopped, the required dose of warfarin gradually declined, eventually reaching a level of 3.75 and 5 mg on alternate days (about a fourfold reduction).2 Another patient stabilised on warfarin gradually needed about a threefold increase in the warfarin dosage after starting aminogluthethimide 250 mg four times a day.2 The increased requirement persisted for 2 weeks after the aminogluthethimide was stopped, and then declined. A study briefly mentions a patient who required greatly increased doses of warfarin after starting aminogluthethimide.3 Three patients taking acenocoumarol needed a doubled dosage to maintain adequate anticoagulation when they took aminogluthethimide 250 mg four times daily for 3 to 4 weeks.4

(b) Anastrozole

A randomised, double-blind, placebo-controlled, crossover study5 in 16 healthy men found that anastrozole (7 mg loading dose followed by 1 mg daily for a further 10 days) had no effect on the pharmacokinetics or pharmacodynamics of a single dose of warfarin given on day 3.

(c) Letrozole

The manufacturers report that letrozole had no clinically relevant effect on the pharmacokinetics of warfarin.6,7

Mechanism

Uncertain. The most likely explanation is that aminogluthethimide, like glutethimide, stimulates the activity of the liver enzymes concerned with the metabolism of the anticoagulants, thereby reducing their levels and efficacy. Alternatively, it has been suggested that aminogluthethimide may affect blood steroid levels, which in turn might affect coagulation.2

Coumarins and related drugs + Aspirin

Low-dose aspirin (75 to 325 mg daily) increases the risk of bleeding when given with warfarin by about 1.5 to 2.5-fold, although, in most studies the absolute risks have been small. The overall benefits of concurrent use outweigh the risks in certain patient groups; however, for some warfarin indications, there is not enough data to assess this. In addition to increased bleeding, high doses of aspirin (4 g daily or more) can increase prothrombin times. Therefore, aspirin is not considered a suitable analgesic or anti-inflammatory drug for those taking oral anticoagulants.

Clinical evidence

A. Analgesic-dose aspirin

In a pharmacological study in patients stabilised on acenocoumarol, aspirin 2.4 g daily for one week increased faecal blood loss from an average of 1.1 mL to 4.7 mL. While taking aspirin, 11 of 17 patients required a 29% reduction in their acenocoumarol dose from a mean of 3.1 mg to 2.2 mg. One patient required a slight increase of 0.5 mg, and the remaining 5 required a dose reduction of less than 0.5 mg.1

In another study in healthy subjects, aspirin 1.95 g daily for 11 days had no effect on the prothrombin time response to a single dose of warfarin given on day 4. When 11 healthy subjects were stabilised on dicoumarol or warfarin and given aspirin 1.95 g daily, 7 had no significant change in prothrombin time activity, and 4 had a slight reduction (of 5 to 10% points). Of the 2 subjects showing signs of bleeding, neither had a reduction in prothrombin time activity. A further 4 subjects stabilised on warfarin received a higher dose of aspirin (3.9 g daily), and all 4 had a reduction in prothrombin time activity of 6 to 12% points and signs of bleeding occurred. Bleeding time was significantly prolonged by the combination of aspirin 1.95 g daily and warfarin than by warfarin alone (10.3 minutes versus 4 minutes).3 In 2 further studies in healthy subjects, aspirin 6 g daily moderately prolonged prothrombin times,3,4 and in one study this effect tended to be reversed by vitamin K.3

6. Femara (Letrozole). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteris-

Anticoagulants 385
In contrast, in another study in 10 patients, adding aspirin 3 g daily to warfarin for 2 weeks had no effect on prothrombin times (20.9 versus 21.2 seconds).5

B. Antiplatelet-dose aspirin

In a study in healthy subjects, low-dose aspirin 75 mg daily doubled the normal blood loss from the gastric mucosa. However, concurrent warfarin (dose individualised to achieve an INR of 1.4 to 1.6) did not increase the gastric mucosal bleeding any further.6

(a) Atrial fibrillation

In a large study in patients with atrial fibrillation, the cumulative incidence of bleeding events after 3 years was no different in those receiving fixed low-dose warfarin 1.25 mg daily plus aspirin 300 mg daily (24.4%) than with fixed low-dose warfarin alone (24.7%) or aspirin 300 mg daily alone (30%).7 This study also contained an adjusted-dose warfarin-only group, which proved more effective than the other group, so the study was terminated early. Other studies have found similar results.8

In another study, the combination of adjusted dose fluindione (INR 2 to 2.6) plus aspirin 100 mg daily was associated with a much higher incidence of haemorrhagic complications than fluindione alone (13.1% versus 1.2%). The overall balance of benefit to risk could not be assessed because of the low incidence of the primary endpoint (ischaemic events).9

(b) Coronary stents

In a retrospective analysis, a 20% incidence of severe upper gastrointestinal bleeding was seen in 138 coronary stent patients given heparin post-procedure, then warfarin with aspirin 325 mg daily. Ten of the patients needed a blood transfusion.10 In another analysis of patients who had been taking warfarin long-term and who underwent stent implantation and were then discharged taking aspirin, clopidogrel and warfarin, the incidence of major bleeding was 6.6% and of minor bleeding was 14.9%. This compared with 0% and 3.8% for major and minor bleeding, respectively, in patients not given aspirin with clopidogrel post-procedure (no warfarin).11 Another study reported an incidence of 9.2% of bleeding to patients who had undergone stent placement and received warfarin, aspirin and clopidogrel.12

(c) Myocardial infarction

1. Primary prevention. In a large primary prevention study in men at high risk of ischaemic heart disease, the incidence of haematuria was twofold higher in those receiving both low-dose aspirin 75 mg daily and low-intensity warfarin (INR 1.5) than in those receiving low-dose aspirin alone, or low-intensity warfarin alone. Similarly, the incidence of minor episodes of bleeding (nose bleeds, bruising, rectal bleeding, pink/red urine) was 1.27-fold higher in those receiving the combination than in those receiving low-dose aspirin alone, or low-intensity warfarin alone (40% versus 38% and 39%, respectively), although the difference was not statistically significant. There was no difference in incidence of major and intermediate episodes of bleeding.13

2. Secondary prevention. In a meta-analysis of randomised, controlled studies14 in patients following myocardial infarction or acute coronary syndrome, intensive warfarin (INR greater than 2) plus aspirin 80 to 325 mg daily was associated with 2.5-fold increased risk of major bleeding, when compared with aspirin alone, although the actual incidence was low (1.5% versus 0.6%). This analysis excluded studies of coronary stenting, see (b) above. In another similar meta-analysis, combined use of aspirin and warfarin (INR 2 to 3) was associated with a 2.3 odds ratio of a major bleed, when compared with aspirin alone.15 The number needed to treat to cause one major bleed was 100. This compared with a number needed to treat to avoid one major adverse event (death, myocardial infarction or stroke) of 33. Similarly, in an observational cohort study of elderly survivors of acute myocardial infarction, the rate of bleeding was higher in patients receiving warfarin with aspirin (0.08 per patient year), or the triple drug combination of warfarin and aspirin with either clopidogrel or ticlopidine (0.09 per patient-year), than in patients receiving aspirin alone (0.03 per patient-year).16

Using lower intensity warfarin with the low-dose aspirin was still associated with more major bleeding than aspirin alone (1.77 in one study, although this is less than higher intensity warfarin; 2.3 as mentioned above). Nevertheless, low-intensity warfarin with low-dose aspirin does not appear to be any more effective than aspirin alone.15,17

(d) Peripheral arterial disease

In a meta-analysis of studies of patients with peripheral arterial disease, combined use of oral anticoagulants together with aspirin increased the risk of major bleeding about twofold when compared with aspirin alone, and appeared to be associated with increased mortality.18

(e) Prosthetic heart valves

In one randomised study in patients with artificial heart valves, the risk of bleeding episodes requiring blood transfusion or hospitalisation was much higher among those taking aspirin 500 mg daily and warfarin (14%), compared with those taking warfarin and dipyridamole 400 mg daily (4%), and compared with a non-randomised control group taking warfarin alone (5%). Bleeding was mainly gastrointestinal or cerebral. All of those with intracerebral bleeding died.6

A further study found that aspirin 1 g daily combined with unannounced anticoagulants was associated with a threefold higher incidence of bleeding episodes than those taking anticoagulants alone (13.9 versus 4.7 per 100 patients per year).20 However, in another study there was no difference in haemorrhagic risk between patients receiving aspirin 500 mg daily and acenocoumarol or acenocoumarol alone.21

More recent studies have used lower doses of aspirin. In one study in patients stabilised on warfarin with a target INR range of 3.0 to 4.5, the addition of aspirin 100 mg daily increased the risk of any bleeding by 55%, when compared with placebo (35% versus 22% per year), mainly due to an increase in minor haematuria, nosebleeds and bruising. However, the risk was more than offset by the overall reduction in mortality.23 The preliminary report of a meta-analysis of these four studies, concluded that the combined use of oral anticoagulants and aspirin (100 mg to 1 g daily) significantly reduced mortality and embolic complications in patients with prosthetic heart valves, with an estimated increased odds ratio of major bleeds of 1.7 and of total bleeds of 1.98. Nevertheless the overall picture was that the benefits possibly outweighed the problems.24 In a more recent meta-analysis,25 which included one non-randomised study,14 but included 2 other randomised controlled studies, the risk of major bleeding for the combination of warfarin and aspirin was 1.53. For the two low-dose aspirin (100 mg daily) trials, there did not appear to be an excess risk of major bleeding.26 Another analysis of these studies provided essentially the same risk of increased major bleeding with the combination.20

Mechanism

Aspirin has a direct irritant effect on the stomach lining and can cause gastrointestinal bleeding, even in doses as low as 75 mg daily.27 It also decreases platelet aggregation and prolongs bleeding times. In addition, large doses of aspirin (4 g daily or more) alone are known to have a direct hypoprothrombinemic effect, which is reversible by vitamin K.3,4 The effects of the aspirin can be additive with the effects of the anticoagulant.

Importance and management

The interaction of aspirin and warfarin at high doses is not well documented, but is clinically important. It is usual to avoid normal analgesic and anti-inflammatory doses of aspirin while taking any coumarin anticoagulant, although only dicoumarol, acenocoumarol and warfarin appear to have been investigated. Patients should be told that many non-prescription analgesic, antipyretic, cold and influenza preparations may contain substantial amounts of aspirin. Warn them that it may be listed as acetylsalicylic acid. Paracetamol is a safer analgesic substitute (but not entirely without problems, see ‘Coumarins + Paracetamol (Acetaminophen)’, p.438).

The effect of low-dose aspirin (used for its antiplatelet effects) combined with warfarin has been far more extensively studied. Overall, the evidence shows that the combination is still associated with an increased risk of bleeding over either drug alone, and this is in the region of 1.5 to 2.5-fold. Nevertheless, the absolute risk is small. A twofold increased risk of haematuria and a slight increased risk of minor bleeding of 1.27 was still seen in the study using the lowest dose of warfarin (INR 1.5) combined with just 75 mg of aspirin a day.11 In certain patient groups the benefits of combined use have been clearly shown to outweigh this increased risk of bleeding, such as patients with prosthetic heart valves at high risk of thromboembolism. However, in many of the common indications for war-
farin such as atrial fibrillation, there is insufficient evidence to answer the question of whether the combination should be used.

sure that in patients with normal hepatic function and identical body surface area, the plasma levels of warfarin and Coumarins + Azoles: Fluconazole

Fulconazole causes a dose-related interaction of the warfarin, and increases its anticoagulant effect. Cases of minor to

Mechanism

In vitro studies using human liver microsomes clearly demonstrate that fluconazole inhibits the cytochrome P450 isozyme CYP2C9-mediated 7-hydroxylation of S-warfarin and the CYP3A4-mediated metabolism of R-warfarin, and possibly other isozymes involved in the metabolism of warfarin.  
In vivo, this results in the accumulation of warfarin and in an increase in its effects, possibly leading to bleeding.  

Importance and management

An established and clinically important interaction. If fluconazole is added to treatment with warfarin or acenocoumarol the prothrombin times should be very well monitored and the anticoagulant dosage reduced as necessary. On the basis of pharmacokinetic studies it has been predicted that the warfarin dosage may need to be reduced by about 20% when using fluconazole 50 mg daily, ranging to a reduction of about 70% when using fluconazole 600 mg daily. These larger reductions should be gradual over 5 days or so.  
However, remember that individual variations between pa-

of the other azole antifungals, ‘ketocanazole’, (p.388) and ‘itraconazole’, (p.388), appear less likely to interact.

Coumarins + Azoles; Itraconazole

An isolated report describes a very marked increase in the anticoagulant effects of warfarin, accompanied by bruising and bleeding, in a patient given itraconazole. Limited evidence suggests that itraconazole may increase the risk of over-anticoagulation with acenocoumarol or phenprocoumon.

Clinical evidence

A woman stabilised on warfarin 5 mg daily and also taking itraipropium bromide, salbutamol, budesonide, quinine sulfate and omeprazole, was given itraconazole 200 mg twice daily for oral candidiasis caused by the inhaled steroid. Within 4 days she developed generalised bruising and recurrent nosebleeds. Her INR had risen to more than 8. The warfarin and itraconazole were stopped, but next day she had to be admitted to hospital for intractable headache and bruising, for which she was treated with fresh frozen plasma. Two days later when the bleeding had stopped, and her INR had returned to 2.4, she was restarted on warfarin and later restarted on her original dosage.1

In one cohort study in patients taking acenocoumarol or phenprocoumon, itraconazole significantly increased the risk of over-anticoagulation (INR greater than 6: relative risk of 13.9, range 1.7 to 115). However, the authors say this figure should be interpreted cautiously since it was based on just one case.2

Mechanism

Itraconazole is a known potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, but this isoenzyme is involved only in the metabolism of the less potent R-warfarin, and therefore inhibition would not be expected to have a marked effect on ‘warfarin metabolism’, (p.358). However, there appear to be no pharmacological studies to confirm this. ‘Omeprazole’ (p.444) may also have had some minor part to play in the case described.1

Importance and management

A minor to modest pharmacokinetic interaction would be predicted, but as yet there appear to be no studies to confirm this. The case report and cohort study suggest that this interaction might be clinically important in some individuals. Therefore, it would be prudent to increase monitoring of anticoagulant control when any patient on a coumarin anticoagulant is given itraconazole. Further study is needed.

Coumarins + Azoles; Miconazole

In two healthy subjects the anticoagulant effect of warfarin was unchanged when they were given ketoconazole. However, there are three isolated cases of an increase in the anticoagulant effects of warfarin in patients also taking ketoconazole. Some evidence suggests that topical ketoconazole does not interact with acenocoumarol or phenprocoumon.

Clinical evidence

Two healthy subjects had no changes in their anticoagulant response to warfarin when they were given ketoconazole 200 mg daily over a 3-week period.1,2 However, an elderly woman, stabilised on warfarin for 3 years, complained of spontaneous bruising 3 weeks after starting a course of ketoconazole 200 mg twice daily. Her British Comparative Ratio was found to have risen from 1.9 to 5.4. Her liver function was normal. She was restabilised on her previous warfarin dosage 3 weeks after the ketoconazole was withdrawn.1 In 1984, the CSM in the UK had one report of an 84-year-old man taking warfarin whose British Comparative Ratio rose to 4.8 when he was given ketoconazole, and fell to 1.4 when it was withdrawn.3 In 1986, the manufacturers of ketoconazole had one other report of an elderly man taking warfarin whose prothrombin time rose from a range of 34 to 39 seconds to over 60 seconds when he was given ketoconazole 400 mg daily.4 In one cohort study in patients taking acenocoumarol or phenprocoumon, topical ketoconazole did not significantly increase the relative risk of over-anticoagulation (INR greater than 6; relative risk 1.1, range 0.3 to 4.3). However, this figure should be interpreted cautiously since it was based on just two patients.5

Mechanism

In rats,6 ketoconazole potentiated the anticoagulant effect of acenocoumarol, but at much higher doses than ‘miconazole’, (p.388). It is now known that ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but this isoenzyme has only a minor role in the ‘metabolism of warfarin’ (p.358), specifically the less active R-isomer.

Importance and management

Information about this interaction seems to be limited to the reports cited. Its general importance and incidence is therefore uncertain, but it is probably quite small. However, it would seem prudent to monitor the anticoagulant response of any patient given both drugs, particularly the elderly, to ensure that excessive anticoagulation does not occur.

Coumarins and related drugs + Azoles; Miconazole

The anticoagulant effects of acenocoumarol, and warfarin can be markedly increased if miconazole is given orally as an oral (buccal) gel, and bleeding can occur. Oral miconazole has also been reported to interact with ethyl biscoumacetate, fluindione, phenindione and tiocolomar in a few reports. The interaction has also rarely been seen in some women using intravaginal miconazole, and in those using a miconazole cream on skin. In one cohort study, use of oral miconazole markedly increased the risk of over-anticoagulation with acenocoumarol and phenprocoumon, whereas intravaginal miconazole caused a non-statistically significant minor increase, and cutaneous miconazole barely increased the risk.

Clinical evidence

(a) Oral gel

In one early report, a patient with a prosthetic heart valve and stabilised on warfarin developed blood blisters and bruised easily 12 days after starting miconazole gel 250 g four times a day for a presumed fungal mouth...
infection. Her prothrombin time ratio had risen from less than 3 to about 16. She was subsequently rehospitalised in the absence of miconazole on her former dose of warfarin. 1

Numerous other cases of this interaction with warfarin have been reported, and, where stated, often involved the use of 5 mL (125 mg) of the gel four times daily for oral candidiasis. 2,5 One case of an increase in INR to 11.4 with frank haematoma and spontaneous bruising was reported in a woman who had used 30 g of non-prescription miconazole (Daktarin) over 8 days (estimated daily dose of 75 mg). 7 In 1996, the New Zealand Centre for Adverse Reactions Monitoring reported 5 patients taking warfarin whose INRs rose from normal values to between 7.5 and 18 within 7 to 15 days of starting to use miconazole oral gel. 6 In 2002, the Australian Adverse Drug Reactions Advisory Committee (ADRAC) stated that they had received 18 reports of this interaction. In the 17 cases for which it was documented, the INR was above 7.5. Eight of the cases had bleeding complications, 9 required vitamin K, and 5 fresh frozen plasma. 6

A few similar cases have also been reported for acenocoumarol 12,14 or fluindione 5 with miconazole oral gel. In addition, in one cohort study in patients taking acenocoumarol or phenprocoumon, use of oral miconazole (form and doses not stated) markedly increased the risk of over-anticoagulation (INR greater than 6: adjusted relative risk 36.6; range 12.4 to 108). When analysed separately, the adjusted relative risk was higher for acenocoumarol than phenprocoumon (35.1 versus 16.5). 15

(b) Tablets

In a study in 6 healthy subjects, miconazole 125 mg daily for 18 days (in the form of tablets) caused a very marked fivefold increase in prothrombin time response to a single dose of warfarin given on day 3. In addition, there was a threefold increase in the AUC of warfarin, with S-warfarin most affected (fourfold), and R-warfarin increased 1.7-fold. 15 In one early case report with warfarin, one patient with a prosthetic heart valve and stabilised on warfarin was found to have a prothrombin time ratio of 23.4 within 10 days of starting miconazole tablets 250 mg four times a day for a suspected fungal diarrhoea. He developed two haematomas soon after both drugs were withdrawn, and was subsequently rehospitalised, in the absence of miconazole, on his former dose of warfarin. 1

The Centre de Pharmacovigilance Hospitalière in Bordeaux have on record 5 cases of oral doses of 500 mg daily, where stated; form not mentioned) was responsible for a marked increase in prothrombin times and/or bleeding (haematomas, haematuria, gastrointestinal bleeding) in patients taking acenocoumarol (2 cases), ethyl biscoumacetate (1 case), ticlopidine (1 case) and phenindione (1 case). 18 Other cases and reports of this interaction involving acenocoumarol have been described elsewhere. 19,21

(c) Skin creams

An 80-year-old man stabilised on warfarin with an INR of 2.2 to 3.1 was found to have an INR of 21.4 at a routine check 2 weeks after starting to use miconazole cream for a fungal infection in his groin. 11 He showed no evidence of bruising or bleeding. 22 In 2001, Health Canada reported that a 62-year-old woman, who had used miconazole cream. 11

In 1999, the Netherlands Pharmacovigilance Foundation LAREB reported 2 elderly women patients taking acenocoumarol whose INRs rose sharply and rapidly when they were given a 3-day course of 400-mg miconazole pessaries. 24 Another report describes the development of bruising and an INR of about 9.78 in a 55-year-old woman taking warfarin on the third day of using 200-mg miconazole pessaries. For a subsequent course of intravaginal miconazole 100 mg daily for 7 days, the dose of warfarin was decreased by 28%, and her INR was 3.27. 25 Yet another report describes haemorrhage of the kidney in a 52-year-old woman taking warfarin after she used vaginal miconazole for 12 days. 23

In one cohort study in patients taking acenocoumarol or phenprocoumon, use of vaginal miconazole was associated with a small increased risk of over-anticoagulation (INR greater than 6: adjusted relative risk 4.3) but this was not statistically significant. Note that this was markedly less than the increased risk seen with oral miconazole (relative risk 36.6). 16

**Mechanism**

There is evidence that miconazole is a very potent inhibitor of the metabolism of S-warfarin by the cytochrome P450 isoenzyme CYP2C9, and that it also inhibits the metabolism of R-warfarin to a lesser extent. 17 Even low oral doses of miconazole (125 mg daily) markedly inhibit warfarin metabolism, so it is not surprising that prescription doses of miconazole oral gel (480 to 960 mg daily) interact, since this is swallowed after retaining in the mouth. Very unusually, absorption of miconazole from the vagina (see also comments below) and even exceptionally through the skin, can result in increased anticoagulant effects.

**Importance and management**

The interaction of miconazole oral gel and miconazole tablets with and coumarin anticoagulants is a very well established and potentially serious interaction. Most of the reports are about warfarin or acenocoumarol, but many other oral anticoagulants have been implicated. In some cases the bleeding has taken 7 to 15 days to develop, 13 whereas others have bled within 2 to 4 days. 22,25 Raised INRs have been seen even sooner. Usual prescription doses of miconazole oral gel [5 to 10 mL (120 to 240 mg) four times daily] should therefore not be given to patients taking any oral anticoagulant unless the prothrombin times can be closely monitored and suitable dosage reductions made. Given the very large increased relative risk of over-anticoagulation seen in one cohort study, the authors suggest that the concurrent use of oral miconazole and coumarins should be discouraged. 16 The interaction has been seen with a lower oral dose of about 75 mg daily (one 30 g tube given over 8 days), which is not surprising in the context of the pharmacokinetic study, and suggests that patients taking oral anticoagulants should also avoid using non-prescription miconazole.

Nevertheless, the UK patient information leaflet for non-prescription Daktarin oral gel contains no specific cautions regarding anticoagulants. 26 Nystatin and amphotericin are possible alternative antifungals to miconazole for mouth infections.

An interaction with intravaginal miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age. 22 However, the reports cited above show that significant absorption could apparently occur in a few patients with particular conditions (possibly in postmenopausal women with inflamed vaginal tissue), which allows an interaction to occur. Appropriate monitoring is therefore needed even with this route of administration in potentially at-risk women.

**Topical (cutaneous) miconazole** would also not be expected to interact, but the few reports cited shows that some caution might be warranted.

Benzbromarone 200 mg three times daily for 2 days then 100 mg three times daily thereafter was given to 90 patients taking various anticoagulants. To maintain constant prothrombin-proconvertin percentages the coumarin anticoagulant dosages were reduced as follows: ethyl biscoumacetate 17% (9 patients), acenocoumarol 25% (7) and warfarin 46% (15). No changes in dose were needed in patients taking dicoumarol (9) or phenprocoumon (8). For the indanedione anticoagulants, a dose reduction of 42% was required in 8 patients taking diphenadione, but no changes were needed in those taking clorindione (5 patients) or phenindione (10 patients). A parallel study in healthy subjects also found that benzbromarone 300 mg or 600 mg daily increased the effects of a single dose of warfarin.

In another study, benzbromarone 300 to 600 mg daily increased the anticoagulant effects of phenprocoumon in just 9 out of 29 patients. Plasma levels of ethyl biscoumacetate after a single intravenous dose were increased by pre-treatment with benzbromarone 600 mg daily for 6 days.7

**Mechanism**

Benzbromarone selectively inhibits the metabolism of S-warfarin by the cytochrome P450 isoenzyme CYP2C9 so that its effects are increased. The metabolism of the R-warfarin remains unchanged.8 Acenocoumarol and phenprocoumon are also known to be metabolised by CYP2C9, and would therefore be expected to interact similarly. Benzbromarone is another benzofuran derivative with a similar structure to benzembrone, and therefore probably interacts via a similar mechanism.

**Importance and management**

The interaction between warfarin and benzbromarone or benziodarone is established and clinically important. If benzbromarone is added to warfarin monitor prothrombin times and be alert for the need to reduce the dosage by about one-third to prevent over-anticoagulation. Information about other coumarins is limited, but what is known about the mechanism of action suggests that acenocoumarol and phenprocoumon would also be predicted to interact, and this has been shown for benzbromarone and acenocoumarol or phenprocoumon, in a few patients. The limited evidence suggesting an interaction with some indanediones also suggests that some caution is appropriate with these drugs as well.

**Coumarins + Benzodiazepines and related drugs**

The anticoagulant effects of warfarin are not affected by chlor Diazepoxide, diazepam, flurazepam, or nitrazepam, or the related hypnotics, eszopiclone, zaleplon, or zolpidem. The effects of phenprocoumon are not affected by nitrazepam or oxazepam, and those of ethyl biscoumacetate are not affected by chlor Diazepoxide. An interaction between any oral anticoagulant and a benzodiazepine is unlikely, but there are three unexplained and unconfirmed cases of increased or decreased anticoagulant responses, which were attributed to an interaction.

**Clinical evidence**

A. Benzodiazepines

1. Benzodiazepines

In a placebo-controlled study in 7 patients stabilised on warfarin, chlor Diazepoxide 10 mg three times daily for 2 weeks had no effect on anticoagulant control.1 Other studies in healthy subjects2,3 and patients4 have similarly shown that chlor Diazepoxide does not alter the anticoagulant ef-
effect or the half-life of warfarin. Similarly, chlor Diazepoxide 10 mg three times daily for 10 days had no effect on the half-life of a single intravenous dose of ethyl biscoumacetate in healthy subjects. However, one patient stabilised on warfarin had a small 18% fall in mean plasma warfarin levels with a corresponding change in the anticoagulant response when given chlor Diazepoxide 15 mg daily.

(b) Diazepam
In 4 patients stabilised on warfarin, diazepam 5 mg three times daily for 30 days had no effect on anticoagulant control (thromboplastin). In one of the patients, the half-life of warfarin was measured, and this was not changed by diazepam. Similarly, diazepam 5 mg daily did not alter the anticoagulant response or the half-life of a single dose of warfarin in healthy subjects.

However, there are two discordant reports. A patient stabilised on dicoumarol developed multiple ecchymoses and a prothrombin time of 53 seconds within 2 weeks of starting to take diazepam 5 mg four times daily.7 The New Zealand Committee on Adverse Drug Reactions has received one report of an increased anticoagulant effect in a patient taking warfarin with diazepam.8 It is by no means certain that these responses were due to an interaction.

(c) Flurazepam
In healthy subjects, flurazepam 30 mg at bedtime for 28 days had no effect on the half-life of a single dose of warfarin given on day 14 and 28, but there was a slight statistically significant reduction in prothrombin time. In a further placebo-controlled study in 12 patients stabilised on warfarin, flurazepam 30 mg at night for 28 days had no effect on prothrombin time or plasma warfarin concentrations.

(d) Nitrazepam
In 2 reports by the same researchers, nitrazepam 10 mg at night for 30 days had no effect on steady-state warfarin levels or anticoagulant control in a few patients stabilised on warfarin.4,6 In a placebo-controlled study in 21 patients stabilised on phenprocoumon, nitrazepam 5 mg at night for 2 weeks had no effect on thrombostest times.

(e) Oxazepam
Oxazepam 10 mg in the morning and 10 to 20 mg in the evening for 3 weeks had no effect on anticoagulant response in 21 patients stabilised on phenprocoumon.11

B. Non-benzodiazepine hypnotics
(a) Eszopiclone
In a study in healthy subjects, eszopiclone 3 mg daily for 5 days had no effect on the AUC of S- or R-warfarin after a single 25-mg dose of warfarin and there was no change in the INR.12

(b) Zaleplon
In a study in healthy subjects, zaleplon 20 mg daily for 12 days had no effect on the AUC of S- or R-warfarin after a single 25-mg dose of warfarin. There was a minor 17% increase in the maximum serum levels of S-warfarin. However, zaleplon did not alter the prothrombin time response to warfarin.13,14

(c) Zolpidem
The prothrombin times of 8 healthy subjects given warfarin were unaffected by zolpidem 20 mg daily for 4 days.15

Mechanism
The three discordant reports are not understood. Enzyme induction is a possible explanation in one case with chlor Diazepoxide,6 because increases in the urinary excretion of 6-beta-hydroxycortisol (a marker of enzyme induction) have been described during chlor Diazepoxide use.4,6

Importance and management
The weight of evidence and common experience shows that the benzodiazepines do not interact with the anticoagulants. Not all of the anticoagulant and benzodiazepines have been examined, but none of the possible pairs would be expected to interact. Similarly, based on pharmacodynamic studies, no interaction would be anticipated with the newer non-benzodiazepine hypnotics eszopiclone, zaleplon or zolpidem.

Coumarins and related drugs + Beta blockers

The effects of the coumarins are not normally altered by any beta blocker. However, propranolol has caused small increases in warfarin levels in a couple of studies, and one or two isolated cases of increased warfarin and phenindione effects have been reported.

Clinical evidence
(a) Acenocoumarol
In a study in 4 patients stabilised on acenocoumarol there was no difference in anticoagulation tests when atenolol 100 mg daily, metoprolol 100 mg twice daily, or placebo, was given for 3 weeks.1

(b) Phenindione
In one early clinical study, haemorrhagic tendencies without any changes in Quick value or any other impairment of coagulation were described in three patients stabilised on phenindione within 6 weeks of starting propranolol.2

(c) Phenprocoumon
In healthy subjects, a single dose of atenolol 100 mg or metoprolol 100 mg did not affect the AUC of a single dose of phenprocoumon, although phenprocoumon levels were slightly higher at 4 and 6 hours after the metoprolol dose. Nevertheless, neither beta blocker altered the prothrombin time response.2

In healthy subjects, carvedilol 25 mg daily for 7 days had no effect on the pharmacokinetics of a single 15-mg dose of phenprocoumon given on day 5 phenprocoumon.4

In 12 patients stabilised on phenprocoumon, there was no difference in Quick time between those randomised to receive pindolol 5 mg three times daily for 6 weeks and those who received placebo.5

(d) Warfarin
In 6 patients stabilised on warfarin, acebutolol 300 mg three times daily for 3 days had no effect on prothrombin time response.6 Similarly, in one patient taking warfarin, neither atenolol 100 mg daily nor metoprolol 100 mg twice daily for 3 weeks had any effect on prothrombin time.1 Similarly, in studies in healthy subjects the following beta blockers had no clinically relevant effects on the pharmacokinetics and/or anticoagulant response to warfarin; atenolol 100 mg daily, betaxolol 20 mg daily, bisoprolol 10 mg daily, esmolol,9 or metoprolol 100 mg twice daily.7

In contrast, the minimum steady state plasma warfarin levels of healthy subjects rose by 15% when they took propranolol 80 mg twice daily in one study.11 Similarly, in another study in 6 healthy subjects given propranolol 80 mg twice daily for 7 days with a single dose of warfarin on day 4, the AUC of warfarin was increased by 16.3% and the in maximum serum level was increased by 23%, but there was no change in the prothrombin time.7 A patient stabilised on warfarin had a rise in his Brit-
ish Corrected Ratio from a low of 1.3 up to 2.5 while taking propranolol 80 mg twice daily.\textsuperscript{12}

**Mechanism**

None known.

**Importance and management**

Overall, the findings of these pharmacological studies in patients and healthy subjects confirm the general clinical experience that the effects of the coumarin anticoagulants are not normally altered by the beta blockers. No special precautions are needed on concurrent use. The only uncertainty is with propranolol, which has shown a small rise in warfarin levels in two studies, and for which there are a couple of reports of possible increased anticoagulant responses of warfarin and phenindione. Even so, a clinically significant interaction would seem to be extremely rare.

### Coumarins + Bile-acid binding resins

The anticoagulant effects of phenprocoumon and warfarin can be reduced by colesevelam, especially if the coumarin is given at the same time. An isolated report describes unexpected sensitivity to warfarin in a patient taking colesevelam, which was attributed to a possible reduction in vitamin K absorption with colesevelam. Colestipol did not alter the absorption or effect of phenprocoumon or warfarin and colesevelam did not alter the pharmacokinetics of warfarin.

#### Clinical evidence

**Colestevam**

Colestevam 4.5 g had no effect on the pharmacokinetics of warfarin 10 mg in a single-dose study in 24 healthy subjects.\textsuperscript{1}

**Colestipol**

In a placebo-controlled, single-dose study in 4 healthy subjects, phenprocoumon plasma levels and the prothrombin response were unaffected by colestipol 8 g given at the same time as phenprocoumon 12 mg.\textsuperscript{2} Similarly, in an study quoted in a review,\textsuperscript{3} the concurrent use of colestipol 10 g did not cause any changes in the absorption of a single 10-mg dose of warfarin in healthy subjects.

**Colestyramine**

In a study using intravenous phenprocoumon, colestyramine reduced the effect of the anticoagulant by this route, presumably by reducing enterohepatic recycling.\textsuperscript{4} This fact has been used clinically to enhance the elimination of phenprocoumon after phenprocoumon overdose. In one case, the half-life of phenprocoumon was measured as 6.8 days without colestyramine, and 3.5 days with colestyramine 4 g three times daily.\textsuperscript{5}

A patient stabilised on phenprocoumon developed a fatal valve thrombosis after starting colestyramine, despite separation of doses in accordance with the manufacturer’s instructions.\textsuperscript{6}

#### Coumarins + Bicalutamide, Flutamide or Nilutamide

The manufacturer has on record a few cases of flutamide possibly increasing the anticoagulant effects of warfarin. In vitro, bicalutamide displaced warfarin from its protein binding sites. The clinical relevance of this, if any, has not been assessed. In vitro, nilutamide inhibited P450 isoenzymes, and might therefore interact with coumarins, although there does not appear to be any further information on this.

#### Clinical evidence, mechanism, importance and management

**Bicalutamide**

The manufacturers say\textsuperscript{1,2} that in vitro studies show that bicalutamide can displace warfarin from its protein binding sites. They therefore recommended close monitoring of the prothrombin time. It used to be thought that the displacement of warfarin from its protein binding sites by other drugs normally resulted in clinically important interactions, but that is now known to rarely be true (see ‘Protein-binding interactions’, (p.3)). In 1995, the manufacturers said that they did not know of any reports of an interaction between warfarin and bicalutamide, apart from an isolated case of a raised INR in one patient taking warfarin with bicalutamide 150 mg, but no causal link with bicalutamide was established.\textsuperscript{3} In a clinical study of bicalutamide and finasteride, it was briefly stated that one patient developed a prolonged prothrombin time while also taking warfarin.\textsuperscript{4} To date, there appear to be no published cases of an interaction. There would therefore seem little reason to believe that bicalutamide interacts with warfarin, but until more is known it would seem prudent to remain aware of the possibility if it is started in any patient taking warfarin.

**Flutamide**

In 1990, the manufacturer had on record, 5 cases of patients with prostatic cancer receiving warfarin whose prothrombin times had increased when they were given flutamide. For example, one patient needed reductions in his warfarin dosage from 35 to 22.5 mg weekly over a 2-month period. Another had a prothrombin time rise from 15 to 37 seconds within 4 days of starting flutamide 750 mg daily.\textsuperscript{5} There appears to be no published information about this interaction, but the manufacturer recommends that prothrombin times are monitored if flutamide is given to patients taking warfarin, reducing the dosage when necessary.\textsuperscript{6}

**Nilutamide**

The manufacturer notes that, in vitro, nilutamide has been shown to inhibit cytochrome P450 isoenzymes (specific isoenzymes not stated). Because of this, they suggest that nilutamide might increase the toxicity of drugs with a low therapeutic margin such as the vitamin K antagonists (i.e. coumarins and indanediones). They therefore recommend that the prothrombin time be carefully monitored when nilutamide is given with these drugs, and their dosages reduced if necessary.\textsuperscript{7} There does not appear to be any further information about this potential interaction.

5. Schering-Plough Ltd. Personal communication, March 1990.

### Coumarins + Bile-acid binding resins

The anticoagulant effects of phenprocoumon and warfarin can be reduced by colesevelam, especially if the coumarin is given at the same time. An isolated report describes unexpected sensitivity to warfarin in a patient taking colesevelam, which was attributed to a possible reduction in vitamin K absorption with colesevelam. Colestipol did not alter the absorption or effect of phenprocoumon or warfarin and colesevelam did not alter the pharmacokinetics of warfarin.
comparing with warfarin alone. However, when warfarin was taken 6 hours after colestevramine, peak warfarin levels were reduced by only 16%, and the prolongation in prothrombin times was the same as with warfarin alone.\textsuperscript{9} Comparable results were found in another similar study; simultaneous administration of warfarin and colestevramine reduced the prothrombin time response by 21%, and separation by 3 hours still caused an 11% reduction in the prothrombin time response.\textsuperscript{9} Another study using intravenous warfarin has shown that colestevramine also reduces the effect of warfarin by this route, presumably by reducing enteroherepatic recycling.\textsuperscript{10}

Another report describes a patient taking colestevramine 4 g three times daily who was successfully stabilised on warfarin with alternating doses of 5 mg and 7.5 mg daily. The warfarin was given at 8 am, then the colestevramine at 12 noon with lunch, with dinner, and with an evening snack.\textsuperscript{11} In contrast, an isolated report describes a 77-year-old patient taking multiple medications, including colestevramine who was found to have a very high prothrombin time of 78.9 seconds and microscopic haematuria 6 weeks after starting warfarin 5 mg daily. Four days after starting the warfarin her prothrombin time was 17.1 seconds, and it had not been checked again.\textsuperscript{12} However, as it is not certain that this patient was properly stabilised on warfarin this may simply have been an effect of the warfarin alone.

**Mechanism**

Colestevramine binds to coumarin antiocoagulants in the gut, thereby preventing their absorption.\textsuperscript{4,9,13,14} Data with intravenous warfarin and phenprocoumon show that they undergo enteroherepatic recycling, and that colestevramine can reduce this as well.\textsuperscript{3,10} Long-term use of colestevramine also reduces the absorption of fat-soluble vitamins such as vitamin K so that it can have some direct hypoprothrombinamic effects of its own.\textsuperscript{15,16} This may to some extent offset the full effects of its interaction with antiocoagulants. Colestipol on the other hand appears not to bind to any great extent at the pH values in the gut.\textsuperscript{2} The paradoxical increase in the effects of warfarin in the isolated case cited above was attributed to the effect of colestevramine on vitamin K.\textsuperscript{12}

**Importance and management**

The interaction of colestevramine with phenprocoumon and warfarin is established, and can be clinically important. If concurrent use is thought necessary, prothrombin times should be monitored and the dosage of the antiocoagulant increased appropriately. Giving the colestevramine 4 to 6 hours after the antiocoagulant has been shown to minimise the effects of this interaction.\textsuperscript{8,11} and it is a standard recommendation that other drugs be given 1 hour before or 4 to 6 hours after colestevramine. However, despite adequate separation of doses, one patient taking phenprocoumon developed fatal valve thrombosis when given colestevramine, leading the authors to suggest that colestevramine should not be used in patients taking oral antiocoagulants.\textsuperscript{7} Information about other antiocoagulants is lacking but as colestevramine interacts with dicumarol and ethyl biscoumacetate in animals\textsuperscript{15} it would be prudent to expect all coumarins to interact similarly. Bear in mind that long-term colestevramine can reduce vitamin K absorption and can cause hypoprothrombinamia. This might result in an increased effect of warfarin, as has been suggested in one unconfirmed case report but there seems to be no other evidence to suggest that this is clinically relevant.

No special precautions appear necessary if warfarin or phenprocoumon and colestipol or colesovelam are given concurrently.\textsuperscript{1}

### Coumarins + Bosentan

Bosentan modestly enhanced the metabolism of warfarin and reduced its antiocoagulant effects in one study and in one case a patient needed a 64% increase in her warfarin dose after taking bosentan.

### Clinical evidence

In a double-blind, randomised, placebo-controlled, crossover study, 12 healthy subjects were given bosentan 500 mg twice daily or placebo for 10 days, with a single 26-mg dose of warfarin on day 6. Bosentan reduced the AUC of R-warfarin by 38% and of S-warfarin by 29%. A significant decrease in the antiocoagulant effects of warfarin was also noted, with a 23% reduction in prothrombin time occurring with bosentan.\textsuperscript{1}

One case highlights the clinical significance of this interaction. A 35-year-old woman taking warfarin with a stable INR of 2 to 3 over three months started taking bosentan 62.5 mg twice daily. After 10 days her INR was 1.7, and remained at this level over the next 4 weeks, despite an increase in her weekly warfarin dose from 27.5 to 40 mg. The bosentan dose was then increased to the maintenance dose of 125 mg twice daily, and two further weekly increases in warfarin dose were made. The INR was then high (3.2 to 4.1) for 3 weeks, before she was finally stabilised on warfarin 45 mg each week.\textsuperscript{2}

However, the manufacturer of bosentan notes that, in clinical experience, the use of bosentan with warfarin did not result in clinically relevant changes in the INR or warfarin dose. There was no difference in the frequency of warfarin dose changes (due to INR changes or adverse effects) between bosentan or placebo recipients.\textsuperscript{3}

### Mechanism

It has been suggested that bosentan induces both cytochrome P450 isozymes CYP3A4 and CYP2C9, which are involved in the metabolism of R-warfarin and S-warfarin, respectively.\textsuperscript{1}

### Importance and management

Both the reports suggest that a clinically significant interaction between warfarin and bosentan is possible, although exactly how frequently this may occur is unclear, since it was not detected in clinical studies. However, the INR should be closely monitored in any patient taking warfarin during the period that bosentan is started or stopped, or if the dose is altered.\textsuperscript{3}

### Coumarins + Broxuridine

A case report describes an increase in the effects of warfarin in a patient taking broxuridine.

### Clinical evidence, mechanism, importance and management

A man taking warfarin and with grade III anaplastic astrocytoma was given intravenous broxuridine as a radiosensitizer. His prothrombin times were unaffected by the first course of broxuridine 1.4 g daily for 4 days, but became more prolonged with successive courses, and after the fourth course his prothrombin time reached about 45 seconds. This which was
managed with 10 mg of vitamin K. Warfarin was stopped after a significant increase also took place with a fifth cycle of broxuridine 990 mg daily.1 The clinical relevance of this single case is uncertain.

**Coumarins + Bucolome**

Bucolome increases the anticoagulant effects of warfarin by inhibiting its metabolism.

**Clinical evidence**

A study in Japanese patients stabilised on warfarin found that the addition of bucolome 300 mg daily increased the INR of 21 patients 1.5-fold despite a 58% reduction in the warfarin dose, when compared with another group of 34 patients taking warfarin and not receiving bucolome.1 In another 7-day study, 25 Japanese patients with heart disease on warfarin and bucolome 300 mg daily were compared with another control group of 30 patients taking warfarin alone. It was found that bucolome had no effect on the serum levels of R-warfarin but both the serum levels of S-warfarin and the prothrombin times rose. These changes were complete within 7 days.2 In one analysis, the daily dose of warfarin was found to be about 40% lower in 78 patients taking bucolome, when compared with 99 patients not taking bucolome, although the thrombotest values were lower in those also taking bucolome (suggesting greater anticoagulation). Bucolome appeared to reduce the between patient variation in intrinsic hepatic clearance of warfarin.3

A patient who had been taking warfarin with bucolome for 18 days developed gross haematuria. He was found to have an intraluminal ureteral haematoma and an excessively prolonged prothrombin time, and was treated with intravenous vitamin K.4

**Mechanism**

*In vitro* studies show that the bucolome can inhibit the metabolism of the more potent enantiomer S-warfarin by the cytochrome P450 isoenzyme CYP2C9, thereby reducing its clearance and increasing its effects.1

**Importance and management**

Information appears to be limited to the reports cited here but the interaction would seem to be established and clinically important. Monitor the INR closely. A reduced warfarin dosage (the study cited above suggests a Quick value of 30 to 40%).1 Similarly, another patient stabilised on phenprocoumon was found to have an intraluminal ureteral haematoma complicating anticoagulant therapy [In Japanese]. Nippon Hinyokika Gakkai Zasshi (2005) 96, 564–7.

In healthy subjects given warfarin until at steady state, felodipine 10 mg daily for 14 days did not alter the dose of warfarin required to maintain a stable INR, or the pharmacokinetics of S- or R-warfarin.5 Because felodipine does not interact with warfarin it has been used as a control drug in retrospective cohort studies assessing warfarin drug interactions.5,6

**Mechanism**

Diltiazem is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4. However, this isoenzyme has only a minor role in the metabolism of warfarin, (p.358), specifically in the metabolism of the less active R-isomer of warfarin. Consequently, only minor increases in the levels of warfarin have been seen in pharmacokinetic studies, which would generally not be expected to be clinically relevant. Verapamil is also an inhibitor of CYP3A4, but the dihydropyridine calcium-channel blockers are not.

**Importance and management**

No special precautions would seem to be necessary during the concurrent use of warfarin and dihydropyridine calcium-channel blockers. Although the minor pharmacokinetic interaction between diltiazem and warfarin would appear to be established, in the studies cited this did not change anticoagulant control, and is therefore unlikely to be of clinical importance. Verapamil would be expected to cause a similar pharmacokinetic interaction, although no data appear to be available on this.

The absence of adverse reports about these very widely used drugs suggests that concurrent use is normally uneventful.

**Coumarins + Carbamazepine or Oxcarbazepine**

The anticoagulant effects of warfarin can be markedly reduced by carbamazepine, and two case reports suggest phenprocoumon is similarly affected. Oxcarbazepine appears not to interact significantly with warfarin.

**Clinical evidence**

(a) Carbamazepine

1. Phenprocoumon. A man in his mid-twenties developed multiple thrombotic episodes due to hereditary resistance to activated protein C. Because of cerebral embolic strokes he developed epileptic seizures and was given carbamazepine 400 mg daily, followed 6 days later by phenprocoumon. It was found that relatively large doses of phenprocoumon (8 mg daily) had to be given without achieving adequate anticoagulation (Quick value 50 to 60%; target 10 to 20%) until the carbamazepine was withdrawn, whereupon the phenprocoumon dosage could be reduced to 1.5 mg daily with a Quick value of 30 to 40%.1 Similarly, another patient stabilised on phenprocoumon was found to have a markedly reduced anticoagulant effect (a

**Coumarins + Calcium-channel blockers**

In pharmacological studies neither amiodipine nor felodipine affected the anticoagulant effects of warfarin. Similarly, although diltiazem may cause a minor decrease in warfarin metabolism, this did not alter the anticoagulant effect in two studies.

**Clinical evidence**

(a) Dihydropyridine calcium-channel blockers

The manufacturers say that amiodipine did not significantly alter the effect of warfarin on prothrombin times in healthy subjects.1,2

approximately half the dose of warfarin in the absence of the carbamazepine. She was restabilised on approximately half the dose of warfarin in the absence of the carbamazepine.2

2. Warfarin. In one study, 2 patients taking warfarin with carbamazepine (200 mg daily for the first week, 400 mg daily for the second and 600 mg for the third) had a fall of about 50% in serum warfarin levels, and sharp rises in their prothrombin-proconvertin percentages.3 The half-life of a single intravenous dose of warfarin in three other patients fell by about 11%, 53%, and 60%, respectively, when they were similarly treated.4 In another analysis, warfarin dose requirements were 2.3-fold higher in 5 patients stabilised on warfarin and carbamazepine than in 54 patients not taking any interacting drugs (median 9 mg daily versus 3.86 mg daily). These 5 patients had higher clearances of both R- and S-warfarin, and had about 11-fold higher plasma levels of the 10-hydroxymetabolite of warfarin.4

This interaction has been described in 5 case reports.2–9 One of them describes a patient stabilised on warfarin and carbamazepine who developed widespread dermal ecchymoses and a prothrombin time of 70 seconds, one week after stopping the carbamazepine. She was restabilised on approximately half the dose of warfarin in the absence of the carbamazepine.9

(b) Oxcarbazepine

In a study in 7 healthy subjects given warfarin until steady-state, oxcarbazepine 450 mg twice daily for one week slightly increased the mean Quick values from 36.6% to only 38.1%, which was not statistically significant.10

Mechanism

Carbamazepine is a known enzyme inducer, and increases the metabolism of warfarin. Phenprocoumon anticoagulation by carbamazepine. The same precautions would be prudent to monitor concurrent use in any patient, being alert for the need to increase the phenprocoumon dosage. The precautions would seem sensible with any other coumarin but information appears to be lacking.

Importance and management

The interaction between warfarin and carbamazepine is moderately well documented, established and clinically important. The incidence is uncertain, but monitor the anticoagulant response if carbamazepine is added to established treatment with warfarin and anticipate the need to double the dosage. Oxcarbazepine appears to be a relatively non-interacting alternative.

Information about an interaction between phenprocoumon and carbamazepine seems to be limited to the two reports cited. Nevertheless it would be prudent to monitor concurrent use in any patient, being alert for the need to increase the phenprocoumon dosage. The same precautions would seem sensible with any other coumarin but information appears to be lacking.

This value was about the same after another day even though the dicumarol had been withdrawn, and marked hypoprothrombinemia persisted for another 5 days.1

The probable reason for this reaction is that carbon tetrachloride is very toxic to the liver, the changed anticoagulant response being a manifestation of this. Carbon tetrachloride, once used as an anthelmintic in man, is no longer used in human medicine, but is still employed as an industrial solvent and degreasing agent. On theoretical grounds it would seem possible for anticoagulated patients exposed to substantial amounts of the vapour to experience this interaction, but this has not been reported.1

Coumarins and related drugs + Colchicine

One report describes five cases of a possible marked increase in the effect of fludione when colchicine was given for acute gout.

Clinical evidence, mechanism, importance and management

The national pharmacovigilance system in France have reported 5 cases where colchicine appeared to increase the anticoagulant effect of fludione. All 5 patients were stabilised on fludione and were given short-term colchicine 1 to 6 mg daily for an acute attack of gout. All 5 patients had markedly raised INRs (6.5 to in excess of 18), but only one had clinical bleeding (haemorrhoidal bleeding). The authors consider that colchicine may have been a factor in a case of raised INR with warfarin, which was attributed to the ‘SSRI’, (p.448), fluvoxamine.

Mechanism

Not known. Based on in vitro data, both entacapone and tolcapone were thought to potentially interfere with the metabolism of drugs by the cytochrome P450 isoform CYP2C9, such as S-warfarin. However, the above study shows that entacapone does not alter S-warfarin pharmacokinetics, and tolcapone is also thought not to interact by this mechanism because it does not interact with ‘tolbutamide’, (p.516), another CYP2C9 substrate.

Importance and management

The minor pharmacokinetic interaction between entacapone and warfarin would appear to be established, but its clinical relevance is uncertain. Changes of this magnitude would not generally be expected to be clinically relevant, and there do not appear to be any published case reports of problems. Nevertheless, it is possible that some patients might show a greater effect, and the manufacturers in the UK recommend that the INR be monitored when entacapone is started in patients taking warfarin.

Similarly, although the manufacturers do not predict a pharmacokinetic interaction between tolcapone and warfarin, they still recommend monitoring because of the limited clinical information on the combination.

Coumarins and related drugs + Corticosteroids or Corticotropin

In two early studies, small increases or decreases in anticoagulation were reported when dicoumarol or phenindione were used with low-to-moderate doses of corticosteroid or prednisone. In the most recent analysis, use of unspecified corticosteroids appeared to be associated with a slightly higher incidence of INRs over the target range in children taking warfarin. In one study, very marked prothrombin time increases were seen in patients taking fludione or acenocoumarol when given high-dose intravenous methylprednisolone, and two cases of this interaction have been reported with warfarin.

Clinical evidence

(a) Corticosteroids

Ten out of 14 patients receiving long-term treatment with either dicoumarol or phenindione had a small but definite increase in their anticoagulant responses when they were given intramuscular or intravenous corticosteroids for 4 to 9 days. A patient stable on ethyl bisoumacetate developed frank melaena and microscopic haematuria within 3 days of starting treatment with intravenous corticosteroid 10 mg twice daily.

In contrast, a decrease in the anticoagulant effects of ethyl bisoumacetate was described in one patient given corticosteroid and one patient given cortisone.

(b) Methylprednisolone

A sharp increase in the INR of a patient with APS (antiphospholipid syndrome) occurred after methylprednisolone was added to treatment with an unnamed oral anticoagulant. This prompted a controlled study in 10 patients stabilised on anticoagulants (8 taking fludione and 2 taking acenocoumarol) and 5 patients not taking an anticoagulant. It was found that pulse high-dose intravenous methylprednisolone (500 mg or 1 g) increased the mean INR of those taking an anticoagulant from a baseline of 2.75 to 8.04, but had no effect on the prothrombin time in those taking methylprednisolone alone. Two patients stabilised on warfarin are also reported to have shown significant prolongations in their prothrombin times when given high-dose methylprednisolone (960 mg or 1 g, follow-up) only short-lived because the warfarin molecules become exposed to metabolism by the liver, so the warfarin level is reduced.

Importance and management

The interaction between warfarin and cloral hydrate is well documented and well understood, but normally of little or no clinical importance. There is very good evidence that concurrent use need not be avoided. However, it may be prudent to keep an eye on the anticoagulant response during the first 4 to 5 days, just to make sure it does not become excessive. It is not certain whether other anticoagulants behave in the same way because the evidence is sparse, indirect and inconclusive, but what is known suggests that the coumarins probably do. Triclofos and cloral betaine appear to behave like cloral hydrate. Dichlorophenazole on the other hand interacts quite differently (see ‘Coumarins + Dichlorophenazole’, p.399).

lowed by dexamethasone (60 mg three times daily for 3 days in one case) for the treatment of multiple sclerosis.6

(c) Prednisone

A study in 24 patients anticoagulated for several days with dicoumarol found that 2 hours after receiving prednisone 10 mg their silicone coagulation time had decreased from 28 to 24 minutes, and 2 hours later was down to 22 minutes.7

(d) Unspecified corticosteroids

In an analysis of a cohort of children receiving warfarin, there was no difference in dose of warfarin required to achieve and maintain the target INR between warfarin courses if corticosteroids were given (38 courses) and courses where corticosteroids were not given (314). However, courses with corticosteroids were associated with a higher percentage of INR measurements greater than the target (21% versus 14%).5

Mechanism

Not understood. Corticotropin, cortisone and prednisone can increase the coagulability of the blood in the absence of anticoaguants.9,10 It has been suggested that methylprednisolone may inhibit the metabolism of anticoaguants.5

Importance and management

The interaction of low to moderate doses of corticosteroids with coumarins is by no means established, and is very poorly documented. Most of the few reports are from the 1950s and 60s, with very little appearing to have been published since then, suggesting that any effects are generally not clinically relevant. In an analysis from the 1990s, the use of corticosteroids appeared to be associated with a slightly higher incidence of INRs over the target range in children. The most constructive thing that can be said is that if either corticotropin (corticophin, ACTH) or any corticosteroid is given to patients taking anticoaguants, be aware that an interaction might very rarely occur. Also note that corticosteroids are associated with a weak increase in peptic ulceration and gastrointestinal bleeding, and the risk of this could theoretically be increased if over-anticoagulation occurs.

The interaction of low dose methylprednisolone is clearly different. Although the evidence is limited, marked INR increases have been reported and INRs should be closely monitored (daily has been recommended) if this or other high-dose corticosteroids are added to established treatment with any coumarin or indanedione oral anticoagulant. More study is needed.

Clinical evidence

In September 2003, the CSM in the UK noted that they had received 5 reports suggesting an interaction between warfarin and cranberry juice (Vaccinium macrocarpon) since 1999.1 The most serious case involved a man taking warfarin whose INR markedly increased (INR greater than 50) 6 weeks after starting to drink cranberry juice. He died from gastrointestinal and pericardial haemorrhages.1 Further details of this case included that he had recently been treated with cefalexin (not known to interact, although consider ‘antibacterials’, (p.365)) for a chest infection, and had been eating virtually nothing,2 a fact that would have contributed to increased anticoagulation. Less marked INR increases (not specified) were seen in two other patients, one of whom was stabilised on a lower warfarin dosage, while the other regained normal INR values after cranberry juice was stopped.3 A further patient had unstable INRs, while the final patient had a decrease in INR.1

In a further case,3 a patient stabilised on warfarin was found to have INRs of 10 to 12 in the days prior to a surgical procedure, although he had no previous record of an INR greater than 4. Vitamin K was given, and heparin was substituted for warfarin. When warfarin was restarted postoperatively, the INR quickly rose to 8 and then to 11 with haematuria, and postoperative bleeding. The patient was drinking almost 2 litres of cranberry juice daily, because of recurrent urinary tract infections, and was advised to stop drinking this. After three days the INR had stabilised at 3.

In October 2004, the MHRA/CSM in the UK noted that they had now received 12 reports of a suspected interaction.4 These included 5 additional cases of bleeding episodes and two additional cases of unstable INRs in patients drinking cranberry juice while taking warfarin.

In a US major bleeding and a high INR have been reported, which occurred shortly after cranberry juice was started.5

Mechanism

Not known. It was suggested that one or more of the constituents of cranberry juice might have inhibited the metabolism of warfarin by the cytochrome isoenzyme CYP2C9, thereby reducing its clearance from the body and increasing its effects.1 However, doubt has been cast on this mechanism, since cranberry juice had no effect on flurbiprofen pharmacokinetics, a drug used as a surrogate index of CYP2C9 activity, and had only weak CYP2C9-inhibitory activity in vitro.6 Alternatively, the salicylate constituent of cranberry juice might cause hypoprothrombinaemia,7 similarly to high-dose ‘aspirin’, (p.385).

Importance and management

The incidence and general clinical importance of this interaction is unknown, but the current recommendation of the CSM/MHRA in the UK is that patients taking warfarin should avoid drinking cranberry juice unless the health benefits are considered to outweigh any risks. They recommend increased INR monitoring for any patient taking warfarin and a regular intake of cranberry juice.4 They also advise similar precautions with other cranberry products (such as capsules or concentrates).4 Further study is needed.

Coumarins + Cranberry juice

A number of case reports suggest that cranberry juice can increase the INR of patients taking warfarin, and one patient has died as a result of this interaction. Limited evidence suggests that the use of cranberry juice in patients taking warfarin can result in unstable INRs, or, in one isolated case, a reduced INR.

Coumarins + Danazol or Gestrinone

Increased anticoagulant effects and bleeding have been seen in a few patients taking warfarin with danazol. A case describes similar effects in a patient taking warfarin and gestrinone.
**Clinical evidence**

(a) Danazol

A 40-year-old woman stabilised on warfarin 6 mg daily with a prothrombin ratio of 2.3 presented after vomiting blood. She was found to have a prothrombin ratio of 14, and required fresh frozen plasma and 2 litres of blood. Three weeks previously she had been prescribed danazol 200 mg twice daily. Four other similar cases of this interaction with danazol have been reported. In two of the cases the patients were subsequently stabilised on warfarin and danazol, but with 50 to 70% lower warfarin doses.

(b) Gestrinone

A bulletin includes a brief mention of an increased INR with vaginal bleeding and multiple bruising in a woman taking warfarin and gestrinone.

**Mechanism**

The reason for this interaction is unknown, but both danazol and gestrinone have androgenic properties, and ‘anabolic steroids,’ (p.364), are known to increase the effects of warfarin.

**Importance and management**

Although data are limited, the interaction with danazol would appear to be established, and close monitoring of the INR is advisable if danazol is added to established coumarin anticoagulant therapy. Some suggest that the initial dosage of anticoagulant should be halved when danazol is started. However, others note that this may not be appropriate in patients at high thrombogenic risk, such as those with mechanical valves. In these patients, they recommend a cautious reduction in dose with weekly monitoring of the INR until it becomes stable (several weeks). Gestrinone might be expected to interact similarly, and some caution is therefore appropriate.

**Coumarins + Dichloralphenazone**

The anticoagulant effects of warfarin are reduced by dichloralphenazone.

**Clinical evidence**

Five patients stabilised taking warfarin long-term and given dichloralphenazone 1.3 g each night for 30 days had a reduction of about 50% (range 20.2 to 68.5%) in plasma warfarin levels and a fall in the anticoagulant response during the last 14 days of concurrent use. Another patient given dichloralphenazone 1.3 g nightly for one month had a 70% fall in plasma warfarin levels and a thrombotest percentage rise from 9 to 55% (indicating a reduced anticoagulant effect). These values returned to normal when the hypnotic was withdrawn.

**Mechanism**

The ‘phenazone’, (p.434) component of dichloralphenazone is a potent liver enzyme inducer, which increases the metabolism and clearance of the warfarin, thereby reducing its effects. The effects of the ‘cloral hydrate’, (p.396) component appear to be minimal.

**Importance and management**

Information is limited, but the interaction between warfarin and dichloralphenazone appears to be an established and clinically important interaction, probably affecting most patients. The dosage of warfarin will need to be increased to accommodate this interaction. If the effect of warfarin has been reduced by using dichloralphenazone, it may take up to a month for it to restabilise. There does not appear to be any information about other anticoagulants, but other coumarins would be expected to be similarly affected. The ‘benzodiazepines’, (p.391) would now be preferred hypnotics, and do not interact.

**Anticoagulants + Dietary supplements; Ascorbic acid (Vitamin C)**

Although two isolated cases have been reported in which the effects of warfarin were reduced by ascorbic acid, four subsequent prospective studies have not found any interaction.

**Clinical evidence**

In a woman recently stabilised on warfarin 7.5 mg daily, who began to simultaneously take ascorbic acid (dose not stated) with her warfarin, the prothrombin time fell steadily from 23 seconds, to 19, 17, and then 14 seconds, with no response to an increase in the dosage of warfarin to 10, 15, and finally 20 mg daily. The prothrombin time returned to 28 seconds within 2 days of stopping the ascorbic acid.

Another woman recently stabilised on warfarin 5 mg daily had a recurrence of acute thrombophlebitis with a prothrombin time of 12 seconds. She was unusually resistant to the actions of warfarin and required 25 mg daily before a significant increase in prothrombin times was achieved. On questioning, she had been taking massive amounts of ascorbic acid (about 16 g daily) for several weeks. She was eventually stabilised on warfarin 10 mg daily.

In contrast, in prospective studies no changes in the effects of warfarin were seen:

- in 5 patients given ascorbic acid 1 g daily for a fortnight.
- in 11 patients (some taking dicoumarol) given ascorbic acid 4 g daily for 2 weeks.
- in 14 patients given ascorbic acid 3 g then 5 g daily for one week or 5 patients given 10 g daily for one week: a mean fall of 17.5% in total plasma warfarin concentrations was seen at all doses.
- in a 10-week study, where the proportion of patients requiring a change in warfarin dose did not differ between 84 patients given ascorbic acid (dose unstated) and 96 control patients (31 versus 18 patients required a dose reduction, and 7 versus 13 required a dose increase, respectively).

---

Mechanism

Not understood. One animal study has demonstrated this interaction and others have not, but none of them has provided any definite clues about why it ever occurs. One suggestion is that high doses of ascorbic acid can cause diarrhoea, which might prevent adequate absorption of the anticoagulant.

Importance and management

Four clinical studies in patients stabilised on warfarin have failed to confirm that ascorbic acid alters the anticoagulant effect of warfarin, even using very large doses of ascorbic acid (up to 10 g daily), even though there are two isolated reports of reduced warfarin efficacy. All these data are from the 1970s, and nothing further seems to have been published. Coumarin dose adjustments are therefore unlikely to be needed when ascorbic acid is also used.

References

Coumarins + Dietary supplements; Fish oils

The use of warfarin with fish oils did not alter the INR in two studies, nor the incidence of bleeding episodes in another. However, in one study, fish oil significantly prolonged bleeding time, and there is one report of an increased INR in a patient taking warfarin who doubled her fish oil dose.

Clinical evidence

Clinical evidence

In one early study, 40 patients took 4 g of a fish oil preparation daily for 4 weeks: 18 of these patients were taking warfarin. In the group as a whole (40 patients), the bleeding time was significantly prolonged from 240 to 270 seconds. In the subset of patients taking warfarin who had stable anticoagulant control in the preceding 3 months (15 patients), the thrombotest was shortened from 114 to 90 seconds, although no changes in warfarin dosage were made. One patient taking warfarin had a minor nosebleed. In a large randomised study of the effect of fish oils or placebo, taken with either aspirin or warfarin over 9 months, there was no difference in the frequency of bleeding episodes between 132 patients taking warfarin and fish oil and 154 taking warfarin alone (17 versus 14, respectively). One case of a possible interaction with a rise in INR has been reported. A woman who had taken INRs in the range of 2 to 3 for five months while taking warfarin 1.5 mg and 1 mg on alternate days. During this time, she started taking 1 g of a fish oil preparation daily with no change in her INR. Her warfarin was then increased to 1.5 mg daily, with stable INRs for about 5 months. A routine INR was then found to be 4.3 (raised from 2.8 one month earlier). One week previously, she had started to take double the dose of fish oil (to 2 g daily). The dose of warfarin was reduced to 1.5 mg and 1 mg on alternate days, and she was asked to reduce the fish oil back to 1 g daily. Eight days later her INR was 1.6, and the warfarin was increased back to 1.5 mg daily.

Mechanism

Fish oils contain omega-3 fatty acids particularly eicosapentaenoic acid and docosahexaenoic acid. These are considered to have some antithrombotic activity, and may prolong the bleeding time.

Importance and management

This interaction is not established. One large study found no increase in bleeding episodes in over 150 patients taking warfarin and fish oils, suggesting that most patients do not show any interaction. However, based on the possible moderate increase in bleeding times with high-dose fish oils, the manufacturers of one product, Omacor (omega-3-acid ethyl esters), say that patients receiving anticoagulants should be monitored, and the dose of anticoagulant adjusted as necessary.

Clinical evidence, mechanism, importance and management

A 69-year-old man stabilised on warfarin 47.5 mg weekly had an increase in his INR from 2.58 to 4.52 four weeks after starting to take 6 capsules of Cosamin DS (glucosamine hydrochloride 500 mg, sodium chondroitin sulfate 400 mg, manganese ascorbate per capsule) daily. His warfarin dose was reduced to 40 mg weekly, and his INR returned to the target range of 2 to 3 (INR 2.15) with continued Cosamin DS therapy. A comment on this report noted that this is the twice the usual dose of glucosamine. The Canadian Adverse Drug Reaction Monitoring Program briefly reported that an increase in INR had been noted when glucosamine was given to patients on warfarin, and that INR values decreased when glucosamine was stopped. Moreover, in 2006 the CHM in the UK reported that they had received 7 reports of an increase in INR in patients taking warfarin after they started taking glucosamine supplements.

In contrast, a 71-year-old man stabilised on acenocoumarol 15 mg weekly had a decrease in his INR to 1.6 after taking glucosamine sulfate (Xicil) 1.5 g daily for 10 days. The glucosamine was stopped and the INR reached 2.1. When the glucosamine was restarted, with an increase of acenocoumarol dose to 17 mg weekly, the INR only reached 1.9. The glucosamine was eventually stopped.

There do not appear to have been any controlled studies of the effects of glucosamine supplements on the pharmacodynamics or pharmacokinetics of oral anticoagulants. The cases described suggest it would be prudent to monitor the INR more closely if glucosamine is started. If a patient shows an unexpected change in INR, bear in mind the possibility of self-medication with supplements such as glucosamine. Note that the CHM in the UK recommend that patients taking warfarin do not take glucosamine.

Mechanism

Fish oils contain omega-3 fatty acids particularly eicosapentaenoic acid and docosahexaenoic acid. These are considered to have some antithrombotic activity, and may prolong the bleeding time.

Importance and management

This interaction is not established. One large study found no increase in bleeding episodes in over 150 patients taking warfarin and fish oils, suggesting that most patients do not show any interaction. However, based on the possible moderate increase in bleeding times with high-dose fish oils, the manufacturers of one product, Omacor (omega-3-acid ethyl esters), say that patients receiving anticoagulants should be monitored, and the dose of anticoagulant adjusted as necessary.

Endoscopy and colonoscopy revealed diffuse bleeding from superficial erosions in the gut. She was discharged 10 days later with the same dose of acenocoumarol and an INR of 2.1 without the carnitine. A similar case has been described in a man stabilised on acenocoumarol (INR 1.99 to 2.94) who had a rise in INR to 4.65 despite a dose correction. The increases in INR occurred when he was using levocarnitine 1 g daily for 10 weeks in the form of a drink (Maxicarnitine) promoted for bodybuilding and fitness training. When this product was discontinued, the INR returned to the therapeutic range. The reason for this apparent interaction is not known. These seem to be the only recorded cases of an interaction between an oral anticoagulant and levocarnitine, but it may be prudent to bear this interaction in mind if levocarnitine is taken with acenocoumarol, or possibly any coumarin, being alert for an increased response.

**Coumarins + Dietary supplements; Ubidecarenone (Coenzyme Q10)**

Ubidecarenone did not alter the INR or required warfarin dose in a controlled study in patients stabilised on warfarin. However, two reports describe reduced anticoagulant effects of warfarin in four patients taking ubidecarenone. A transient increase in INR has been reported in one patient taking ubidecarenone and warfarin.

**Clinical evidence**

In a randomised, double-blind, crossover study in 21 patients stabilised on warfarin, ubidecarenone 100 mg daily (Bio-Quinone) for 4 weeks did not alter the INR or the required dose of warfarin, when compared with placebo. Similarly, 2 patients taking ubidecarenone to treat alopecia caused by warfarin treatment did not have any notable changes in INR, except that one had a transient INR increase when ubidecarenone was started.

In contrast, another report describes 3 patients taking warfarin who had a drop in INR while taking ubidecarenone. In two of these INR reductions from about 2.5 to 1.4 occurred when they took ubidecarenone 30 mg daily for 2 weeks. The INRs rapidly returned to normal when the ubidecarenone was stopped. In another case, a patient appeared to have a reduced response to warfarin while taking ubidecarenone, and responded normally when it was stopped.

**Mechanism**

The reasons for these INR changes are not known but it may be that ubidecarenone has some vitamin K-like activity. In a study in rats, ubidecarenone reduced the anticoagulant effect of warfarin and increased the clearance of both enantiomers of warfarin.

**Importance and management**

The well-controlled study suggests that ubidecarenone does not interact with warfarin, and that no warfarin dose adjustment would be expected to be necessary in patients who take this substance. However, the finding in 2 reports of a decrease in warfarin effect introduces a note of caution. The authors of the controlled study do recommend close monitoring of the INR if a patient decides to use ubidecarenone, because the underlying health problem resulting in them choosing to take this substance may alter their response to warfarin.

**Coumarins + Dietary supplements; Vitamin E substances**

In two studies in patients the anticoagulant effects of warfarin were unchanged by small to large doses of vitamin E, although there is an isolated case of bleeding attributed to concurrent use. In three healthy subjects, the effects of dicoumarol were slightly increased by vitamin E.

**Clinical evidence**

(a) Dicoumarol

A study in 3 healthy subjects found that 42 units of vitamin E daily for a month increased the response to a single dose of dicoumarol after 36 hours (decrease in prothrombin activity from 52 to 33%).

(b) Warfarin

In a double-blind, placebo-controlled study in 25 patients stabilised on warfarin, moderate to large daily doses of vitamin E (800 or 1200 units) for a month caused no clinically relevant changes in prothrombin times and INRs. Similarly, in another study in 12 patients taking warfarin, the anticoagulant effects of warfarin were unchanged by smaller daily doses of 100 or 400 units of vitamin E given for 4 weeks.

However, in one case, a patient taking warfarin (and multiple other drugs) developed ecchymoses and haematuria, which was attributed to him taking 1200 units of vitamin E daily over a 2-month period. His prothrombin time was found to be 36 seconds. A later study in this patient showed that 800 units of vitamin E daily for 6 weeks reduced his blood clotting factor levels, increased the prothrombin time from about 21 to 29 seconds, and caused ecchymoses.

**Mechanism**

Not understood. The suggested explanation is that vitamin E interferes with the activity of vitamin K in producing the blood clotting factors, and increases in the dietary requirements of vitamin K.

**Importance and management**

Information is limited but the evidence suggests that most patients taking warfarin are unlikely to have problems if given even quite large daily doses (up to 1200 units) of vitamin E. Nevertheless the isolated case cited here shows that occasionally and unpredictably the warfarin effects can be changed. It has been recommended that prothrombin times should be monitored when vitamin E is first given (within 1 to 2 weeks has been recommended). The same precautions could be applied to dicoumarol as well. However, as only one case of bleeding has been reported this does seem somewhat over-cautious. Information about other oral anticoagulants is lacking.

**Coumarins + Dietary supplements; Vitamin K₁-containing**

In patients with normal vitamin K status, multivitamin supplements containing 10 to 50 micrograms of vitamin K₁ (phytomenadione) will generally have no clinically important effect on the INR or anticoagulant requirements. Vitamin K doses of 150 micrograms daily are likely to require a dose adjustment in a proportion of patients. However, in patients with poor vitamin K status, even low vitamin K doses of 25 micrograms daily may have an important effect.
Clinical evidence

In a controlled study in healthy subjects stabilised on individual doses of acenocumarol, the dose of vitamin K$_{1}$ tablets required to cause a statistically significant reduction in INR was 150 micrograms daily (INR 1.59 versus 2.04). Each dose of vitamin K$_{1}$ was taken daily for a week, and in successive weeks the dose was increased in increments of 50 micrograms from 50 to 300 micrograms daily, then 500 micrograms daily for the final week. The authors noted that their usual clinical criteria requiring an adjustment in acenocumarol dose would have been met in 3 of the 12 subjects at a dose of vitamin K$_{1}$ of 150 micrograms daily. However, in another study in 9 patients stabilised on warfarin with low vitamin K levels the median INR dropped by 0.51 requiring a warfarin dose increase of 5.3% after they took just one multivitamin tablet containing vitamin K$_{1}$ 25 micrograms daily for 4 weeks. Conversely, in a control group with normal plasma vitamin K levels, the same multivitamin did not change the INR or warfarin requirement. In another study in patients taking phenprocoumon, supplementation with vitamin K$_{1}$ 50 micrograms daily for 3 weeks had little effect on the INR, and required just a 3% increase in phenprocoumon dose. A higher dose of vitamin K$_{1}$ of 100 micrograms daily resulted in a mean dose increase of 9%. On stopping the supplements, a mean 7% decrease in dose was needed. However, there was wide variation between patients.

A patient who required warfarin 15 to 17.5 mg daily to maintain an INR of about 3 was found to be taking vitamin K (dose not stated) as part of a vitamin supplement. When he stopped taking the vitamin K, his warfarin dose requirement decreased to 10.5 to 12.5 mg daily. In another report, a woman required an increase in her warfarin dose from 45 mg to 60 mg weekly when she started taking a daily multivitamin containing vitamin K$_{1}$ 25 micrograms (Centrum Plus). Two weeks after stopping the multivitamin, she had haematuria and flank pain and was found to have a haematoma of the kidney and an INR of 13.2. A second patient had an acute occlusion of an aorto-bifemoral graft, requiring emergency surgery, 4 weeks after starting Centrum Plus. His INR had fallen from a mean of 2.48 to 1.1. A third patient had a fall in INR from a mean of 2.54 to 1.65 after taking Centrum Plus for 2 weeks. It was postulated that all three patients had low levels of vitamin K.

Mechanism

Vitamin K$_{1}$ reduces the effect of vitamin K-antagonists (coumarins and indanediones). The dose of vitamin K$_{1}$ at which this becomes clinically important appears to depend on the vitamin K status of the individual.

Importance and management

The data from the controlled studies suggest that taking multivitamin supplements containing 10 to 50 micrograms of vitamin K$_{1}$ is probably acceptable in most patients taking anticoagulants, and is likely to require no change or only small changes to the anticoagulant dose. However, in patients with poor vitamin K status, even these low levels of vitamin K may be sufficient to antagonise the effect of their therapy. Note that a review of selected US supplements found that they contained 10 to 80 micrograms of vitamin K$_{1}$. Therefore, patients should be advised to not take a multivitamin preparation containing vitamin K$_{1}$ (phytomenadione) without increased monitoring when starting or stopping treatment. Because of this, and because of the increasing recognition of the importance of vitamin K in bone health, some consider that patients taking anticoagulants should be advised to consume sufficient vitamin K to meet the recommended adequate intakes, see also ‘Coumarins and related drugs + Foods: Vitamin K$_{1}$-rich’, p.409. Others have even suggested that a low and steady vitamin K supplement may reduce the risk of excessive anticoagulation without altering efficacy.

Coumarins + Disulfiram

The anticoagulant effects of warfarin were increased by disulfiram in two studies, and two cases showing this effect have also been reported.

Clinical evidence

In one study in 7 healthy subjects, warfarin (adjusted to maintain a prothrombin activity of 40%) was given alone for 21 days, then given with disulfiram 500 mg daily for 21 days. The plasma warfarin levels of 5 of the 7 subjects rose by an average of 20% and their prothrombin activity fell from about 34% to 24% of normal (suggesting an increased anticoagulant effect); one of the subjects had little change, and the other had the opposite effect. Other experiments with single doses of warfarin confirm these results. However, a further study found that, although disulfiram potentiated the effect of S-warfarin, it did not change the plasma levels of either R- or S-warfarin.

An alcoholic patient stabilised on warfarin had an increase in his prothrombin time associated with gross haematuria when disulfiram 250 mg daily was given. Two subsequent attempts to introduce disulfiram 250 mg on alternate days also had a similar effect. He was eventually stabilised on a 43% lower daily dose of warfarin and disulfiram 250 mg daily. Another case of increased prothrombin time and the need for a reduced warfarin dose has been reported.

Mechanism

Not fully understood. The suggestion that disulfiram inhibits the liver enzymes concerned with the metabolism of warfarin has not been confirmed by later studies. It has instead been suggested that disulfiram may

Coumarins + Disopyramide

In two small uncontrolled studies, the anticoagulant effects of warfarin were slightly reduced by disopyramide. In contrast, there is an isolated report of a patient who needed his warfarin dose to be doubled after stopping disopyramide.

Clinical evidence

In a preliminary report of a study in 10 patients with recent atrial fibrillation taking warfarin and with a British Corrected Ratio of 2 to 3, disopyramide (dose not stated) increased the clearance of warfarin by 21%. Similarly, another study found that 2 out of 3 patients needed a slight warfarin dosage increase of about 10% after cardioversion and after starting disopyramide 200 mg three times daily for atrial fibrillation.

In contrast, another report describes a patient who, following a myocardial infarction, was given warfarin 3 mg daily and disopyramide 100 mg every 6 hours with digoxin, furosemide and potassium supplements. When the disopyramide was withdrawn his warfarin requirements doubled over a 9-day period.

Mechanism

Unknown. One idea is that when the disopyramide controls fibrillation, changes occur in cardiac output and in the flow of blood through the liver, which might have an effect on the synthesis of the blood clotting factors. But the discordant response in the isolated case remains unexplained.

Importance and management

Very poorly documented and not established. Limited data suggest only a minor interaction occurs (a slight reduction in anticoagulant effect), but an isolated case suggests a greater and opposite effect. Bear the possibility of an interaction in mind in the case of an unexpected response to warfarin in a patient starting or stopping disopyramide.

chelate with the metal ions necessary for the production of active thrombin, thereby augmenting the actions of warfarin.

**Importance and management**

An interaction appears to be established, although direct information about patients is very limited. What is known suggests that most individuals will demonstrate this interaction. If concurrent use is thought appropriate, the effects of warfarin should be monitored and suitable dosage adjustments made when adding or withdrawing diuretics. Care should be taken when starting warfarin in patients already taking diuretics, and consideration should be given to using a smaller loading dose.

---

### Coumarins + Diuretics

The loop diuretics, bumetanide, furosemide and torasemide, the potassium-sparing diuretic spironolactone, and the thiazides chlortalidone and chlorothiazide, have all been shown either not to interact or to cause only a small reduction in the effects of the coumarin anticoagulants of minimal or no clinical importance. The lack of reports of clinically relevant interactions suggests that, in general, diuretics do not interact with anticoagulants. The possible exception is etacrynic acid, which on rare occasions has caused a marked increase in the effects of warfarin.

#### Clinical evidence

**A. Loop diuretics**

**(a) Bumetanide**

In 10 healthy subjects, bumetanide 1 mg daily for 14 days did not alter the anticoagulant effect of a single-dose of warfarin given on day 8, and did not alter serum warfarin levels. This confirms findings of a previous study in 5 healthy subjects given single-dose warfarin after bumetanide 2 mg daily for 5 days.

**(b) Etacrynic acid**

A case report describes a marked increase in the anticoagulant effects of warfarin in a woman with hypoalbuminaemia on two occasions when she was given etacrynic acid 150 mg to 300 mg daily. In a preliminary report of a cohort study, it was stated that a therapeutically significant interaction between warfarin and etacrynic acid was documented, but no details are given.

**(c) Furosemide**

In 6 healthy subjects, plasma levels, half-lives and prothrombin times were not altered when a single 50-mg dose of warfarin was given after furosemide 80 mg daily for 5 days. However, a 28% decrease in the INR of one patient taking warfarin was seen when furosemide was taken on a regular basis. This was attributed to volume depletion caused by the diuretic, although interpretation of this case is complicated by the patient’s admission of previous non-compliance and abuse of alcohol and cocaine.

In a pharmacokinetic study in 17 healthy subjects, furosemide 40 mg twice daily had no effect on the pharmacokinetics of a single 0.22-mg/kg dose of phenprocoumon. In another study in 22 patients with congestive heart failure stabilised on phenprocoumon, furosemide 40 mg daily for 8 days did not alter the anticoagulant effects or required dose of phenprocoumon.

**(d) Tienilic acid (Ticrynafen)**

In 6 healthy subjects, tienilic acid 250 mg daily for about 14 days caused a mean 265% increase in the anticoagulant effect of a single dose of warfarin given on day 4. Analysis showed the interaction was stereoselective, with the AUC of S-warfarin increased by 192%, with the AUC for R-warfarin increased by only 8%. Two patients taking ethyl biscoumacetate began to bleed spontaneously (haematuria, ecchymoses of the legs and gastrointestinal bleeding) when they started to take tienilic acid 250 mg daily. The thrombotest percentage of one of them was found to have fallen by 10%. Increased anticoagulant effects and/or bleeding, which began within a few days, have been described in a number of other case reports in patients given tienilic acid while taking ethyl biscoumacetate, or warfarin.

**(e) Torasemide**

In a study in 24 patients with congestive heart failure stabilised on phenprocoumon, torasemide 20 mg daily for 8 days did not alter the anticoagulant effects or required dose of phenprocoumon.

**B. Potassium-sparing diuretics**

**(a) Spironolactone**

In a study in 9 healthy subjects, spironolactone 50 mg four times daily for about 16 days reduced the prothrombin time response to a single dose of warfarin given on day 8 by 24%, when compared with warfarin alone. Plasma warfarin levels remained unchanged.

**(c) Thiazides**

**(a) Chlortalidone**

Six healthy subjects given a single 1.5-mg/kg dose of warfarin showed reduced hypoprothrombinemia (prothrombin activity reduced from 77 to 58 units) when they were also given chlortalidone 100 mg daily for 7 days with the warfarin given on the first day, although the plasma warfarin levels remained unaltered. Similarly, reduced anticoagulant effects have been described when chlortalidone was given with phenprocoumon, but no significant effects were seen when chlortalidone was given with acenocoumarol.

**(b) Chlorothiazide**

A study in 8 healthy subjects given single 40 to 60-mg doses of warfarin before and after chlorothiazide 1 g daily for 21 days found that the mean half-life of the anticoagulant was increased from 39 to 44 hours, but the prothrombin time was only decreased by 0.3 seconds.

**Mechanism**

It has been suggested that the diuresis induced by chlortalidone, furosemide and spironolactone reduces plasma water, which leads to a concentration of the blood clotting factors. Etacrynic acid can displace warfarin from its plasma protein binding sites, and it was originally thought that other diuretics also interacted by drug displacement. Only 3% of total plasma warfarin is in the free active form, thus a small displacement could result in marked enhancement of activity, but it is almost certain that this, on its own, does not explain the interaction described. Tienilic acid (ticrynafen), which is structurally related to etacrynic acid, reduces the metabolism of S-warfarin (but not R-warfarin) thereby prolonging its stay in the body and increasing its effects. It is possible that etacrynic acid interacts via a similar mechanism.

**Importance and management**

The documentation relating to diuretics in general (other than tienilic acid) is limited and seems to be confined to the reports cited here, most of which are single-dose pharmacological studies. The evidence suggests that these diuretics either do not interact at all with the coumarin anticoagulants, or only to an extent which is of little clinical relevance. This seems to be supported by the lack of case reports of problems with these combinations, and is in general agreement with common experience. No special precautions normally seem to be necessary, except possibly with etacrynic acid where it might be prudent to monitor the outcome particularly in those with hypoalbuminaemia or renal impairment.

The interaction between the coumarins and tienilic acid is established and of clinical importance, but the incidence is uncertain. Concurrent use should be avoided. If that is not possible, prothrombin times should be closely monitored and the anticoagulant dosage reduced as necessary. Tienilic acid has been withdrawn in many countries because of its hepatotoxicity.

Dofetilide did not alter the anticoagulant effect of warfarin in one study.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 14 healthy subjects dofetilide 750 micrograms twice daily for 8 days had no effect on the prothrombin time in response to a single 40-mg dose of warfarin given on day 5. No dose adjustment of warfarin would be anticipated to be needed on current use.

Etapenecet did not alter the pharmacodynamics or pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, subcutaneous etanercept 25 mg twice weekly for 7 doses did not alter the pharmacodynamics (INR) of a single dose of warfarin given with the last dose of etanercept. In addition, there was no change in the AUC of R- and S-warfarin. This study suggests that no warfarin dose adjustments would be expected to be needed if etanercept is used in patients taking warfarin.

The anticoagulant effects of dicoumarol and warfarin are reduced by ethchlorvynol.

Clinical evidence

Six patients who had recently started taking dicoumarol had a rise in their Quick index from 38 to 55% (suggesting a reduction in anticoagulant effect) while taking ethchlorvynol 1 g daily over an 18-day period. Another patient stabilised on dicoumarol became over-anticoagulated and developed haematuria on two occasions when ethchlorvynol was withdrawn for periods of 6 days and 4 days. A marked reduction in the anticoagulant effects of warfarin occurred in another patient given ethchlorvynol.

Importance and management

Information is very sparse and limited to dicoumarol and warfarin, but the interaction seems to be established. Be alert for other coumarins to behave similarly. Anticipate the need to alter the anticoagulant dosage if ethchlorvynol is started or stopped. The benzodiazepines may be a useful non-interfering alternative to ethchlorvynol, see ‘Coumarins + Benzodiazepines and related drugs’, p.391.

Coumarins and related drugs + Ezetimibe

No clinically significant interaction occurred between ezetimibe and warfarin in one study. However, raised INRs have been seen in patients taking warfarin after they were also given ezetimibe.

Clinical evidence, mechanism, importance and management

In a two-way, crossover study, 12 healthy subjects were given ezetimibe 10 mg or placebo daily for 11 days, with a single 25-mg dose of warfarin on day 7. The pharmacokinetics and pharmacodynamics (prothrombin time) of warfarin were not significantly altered by ezetimibe. In addition, the pharmacokinetics of ezetimibe were similar to those previously seen with the drug alone. However, the manufacturers of ezetimibe state that raised INRs have been seen in patients taking warfarin after they were also given ezetimibe. They therefore advise that the INR should be monitored if ezetimibe is given with any coumarin or fluidione, this is probably a prudent precaution for any indanedione.

2. Ezetrol (Ezetimibe). MSD-SP Ltd. UK Summary of product characteristics, December 2006.

Coumarins and Felbamate

An isolated case report describes a marked increase in the effects of warfarin, which were attributed to felbamate.

Clinical evidence, mechanism, importance and management

A 62-year-old man with a seizure disorder who was receiving warfarin had his antiepileptic treatment with carbamazepine, phenobarbital and sodium valproate discontinued and replaced by felbamate 2.4 g daily and later 3.2 g daily. Within 14 days his INR had risen from a normal range of 2.5 to 3.5 up to 7.8. After stopping and later restarting the warfarin his INR rose within about another 14 days to 18.2. He was eventually restabilised on about half his former warfarin dosage. The authors of the report suggest that the withdrawal of the carbamazepine and phenobarbital was an unlikely reason for this reaction because no increases in warfarin dosage had been needed when they were started. Suspicion therefore falls on the felbamate, but it is clearly difficult to be sure that the withdrawal of the enzyme-inducing antiepileptics did not have some part to play. A letter commenting on this report favours the idea that what occurred was in fact due to the withdrawal of the ‘carbamazepine’, (p.395) and ‘phenobarbital’, (p.390).
Clofibrate increases the effects of coumarin and indanedione anticoagulants. This has been fatal in some cases. Other fibrates appear to interact similarly, although data in many cases is limited to case reports.

Clinical evidence

(a) Bezafibrate

In a study in patients with hyperlipidaemia and stabilised on phenprocoumon, it was necessary to reduce the anticoagulant dosage by about 20% when bezafibrate 450 mg daily was given for 4 weeks to 10 patients, and by 33% when bezafibrate 600 mg daily was given to 5 patients. In another study in 22 patients taking bezafibrate 400 mg daily the dosage of acenocoumarol had to be reduced by 20% to maintain a constant INR. A patient (with hypoalbuminaemia due to nephrotic syndrome and chronic renal failure) stabilised on acenocoumarol developed severe haematoma when he stopped taking bezafibrate 400 mg daily.2 A woman stabilised on acenocoumarol and bezafibrate 400 mg daily had an increase in her INR to 5.29 after being given an incorrect double dose of bezafibrate for a few days, and a man had a reduced response to warfarin (INR 1.5) when he stopped taking bezafibrate for a week.4

(b) Ciprofibrate

In a randomised, placebo-controlled, crossover study, 12 young healthy men were given a single 25-mg dose of warfarin on day 21 of a 26-day course of ciprofibrate 100 mg daily. The ciprofibrate increased the anticoagulant response to warfarin by 50% and caused a 28% decrease in the apparent intrinsic clearance of S-warfarin, which is the more active enantiomer.5

(c) Clofibrate

1. Coumarins. In a study including 11 patients stabilised on warfarin, clofibrate/androsterone (Atromid) given for 5 to 7 months, reduced the weekly warfarin dose requirement in all patients by a mean of 32%, with variability between patients.57 This interaction has been confirmed in a number of other similar studies in patients stabilised on warfarin and given clofibrate,8,9 or clofibrate with androsterone,10 with only 2 of 10 patients affected in one study8 but all 13 patients affected in another study.10 One fatal case of haemorrhage has been reported in a man stabilised on warfarin who was given clofibrate 500 mg four times daily for a week.11 The interaction has been studied in 4 healthy subjects given the enantiomers of warfarin separately. In this study, clofibrate increased the effect of S-warfarin without altering its clearance, whereas there was no alteration of the effect of R-warfarin and an increase in clearance.12 In another study in 10 healthy subjects, clofibrate 500 mg four times daily for 18 days increased the anticoagulant effect of a single dose of dicoumarol given on day 14 without altering the half-life or plasma dicoumarol levels.13

2. Indanediones. Ten out of 15 patients stabilised on phenindione needed a 33% reduction in phenindione dose and 5 of them bled (haematuria or haematoma) when they were given clofibrate, or clofibrate with androsterone (Atromid). In another series, of 13 patients stabilised on phenindione and given clofibrate/androsterone (Atromid) there were 5 cases of haemorrhagic episodes, two of which were not associated with a prolonged prothrombin time, and one of which was fatal.14,15 In yet another study, clofibrate/androsterone appeared to be less effective in reducing serum cholesterol in the patients taking phenindione than in 12 other patients taking clofibrate alone.16

(d) Fenofibrate

In an early clinical study of fenofibrate, 2 patients stabilised on acenocoumarol needed a 30% reduction in their dosage to maintain the same prothrombin time when they were given long-term fenofibrate 200 mg in the morning and 100 mg in the evening.17 In other similar studies, reductions in the dose of unnamed coumarins of 12% (range 0 to 21%)18 or about one-third19 were needed when fenofibrate was given. One patient developed haematuria.20 A number of case reports of this interaction have subsequently been published, as follows:

- A patient taking warfarin had a rise in his INR to 8.5 (from a previous range of 2 to 2.5) within a week of starting to take fenofibrate 200 mg daily. His INR later stabilised when the warfarin dosage was reduced by 27%.21
- A patient taking warfarin had a marked INR rise from a range of 2.8 to 3.5 up to 5.6 within 10 days of starting to take fenofibrate (dosage not stated).21
- A patient taking warfarin bled, and was found to have an INR of 18 when his gemfibrozil was replaced by fenofibrate.22
- In 2 cases 30 to 40% reductions in the warfarin dose were required when fenofibrate was given.23

Mechanism

Uncertain. Clofibrate can displace warfarin from its plasma protein binding sites,27–29 but this does not adequately explain the interaction. Another suggestion is that the fibrates have an additive pharmacodynamic effect.1,12 Altered metabolism may also account for the interaction with ciprofibrate, since this decreased the clearance of S-warfarin.5 However, this did not occur with clofibrate12,13 or gemfibrozil.24

Importance and management

The interactions of clofibrate with dicoumarol, warfarin and phenindione are established, clinically important and potentially serious. Severe bleeding (fatal in some instances) has been seen. The incidence of the interaction is reported to be between 20 and 100%, but it would be prudent to assume that all patients will be affected. Dosage reductions of one-third to one-half may be needed to avoid the risk of bleeding. Monitor the INR and adjust the dose accordingly. Information about other coumarins and indanediones is lacking but it would be prudent to assume that they will interact with clofibrate in a similar way.

Information about other fibrates is much less conclusive, and limited to case reports in many instances. Nevertheless, overall the evidence suggests that it would be prudent to monitor the INR in any patient taking a coumarin or indanedione with a fibrate.

Osmolite and intermittent Ensure Plus (total mean vitamin K1 dose 81 micrograms daily) only achieved satisfactory anticoagulation with warfarin when the Osmolite was stopped, which reduced the vitamin K1 intake to 36 micrograms daily.\textsuperscript{11} Another patient given Osmolite (vitamin K1, 68.4 micrograms daily), only achieved satisfactory anticoagulation with warfarin when the dose was given separately from the Osmolite.\textsuperscript{12} In another case, Isocal 3550 mL daily (equivalent to 460 micrograms of vitamin K1) caused an increase in warfarin requirement from 8 mg daily to 13 mg daily.\textsuperscript{13} A further patient had a decrease in anticoagulant response requiring an increase in warfarin dose when she started a weight-reducing diet consisting solely of Nutrilite 330 (vitamin K content unknown).\textsuperscript{14}

Another patient required twice the dose of acenocoumarol during a period of enteral feeding (vitamin K1 200 micrograms daily).\textsuperscript{15} In a prospective cohort study in 319 children, the use of enteral nutrition (mostly vitamin K1 supplemented formula, and some vitamin K1 supplemented tube feeds) was associated with a higher dose of warfarin to achieve a target INR (0.28 versus 0.16 mg/kg) and similarly a higher dose of warfarin was needed to maintain the INR (0.26 versus 0.11 mg/kg).\textsuperscript{16}

B. Parenteral nutrition

(a) Intravenous lipids

Warfarin resistance was seen in a patient who was given a constant intravenous infusion of soya oil emulsion (Intralipid). In this case intravenous warfarin up to 15 mg daily only slightly prolonged the prothrombin time.\textsuperscript{17} In another patient, an emulsified infusion of propofol containing 10% soya oil antagonised the effect of warfarin; anticoagulation was not achieved until the propofol was discontinued despite an increase in the warfarin dose to 30 mg daily. The dose of propofol given was estimated to provide about 154 to 231 micrograms of vitamin K1 daily. The same effect was later seen when the patient was given parenteral nutrition supplemented with 20% Liposyn II, which also contains soya oil, and was estimated to provide 53 micrograms vitamin K1 daily.\textsuperscript{18}

(b) Multivitamins

The FDA in the US now require that multivitamin products for inclusion in total parenteral nutrition contain 150 micrograms of vitamin K1. The aim of this is to provide a daily physiological amount of the vitamin, rather than the previous practice of giving a large single weekly dose. Previously, patients taking anticoagulants were not given this single large weekly dose, therefore it is anticipated that with the new multivitamin preparation, warfarin doses for anticoagulation may be higher than previously needed. What effect this level of vitamin K1 will have on the fixed dose warfarin used for prophylaxis of catheter-associated thrombosis is not known.\textsuperscript{19}

In the UK, Vitlipid N contains vitamin K1 (phytomenadione) 15 micrograms/mL for adults and 20 micrograms/mL for children under 11 years.

Mechanism

The coumarin and indanedione anticoagulants are vitamin K antagonists, and consequently giving ‘vitamin K1’ (p.458) reduces their effects. The dose at which this might become clinically important is not firmly established, but in one controlled study 150 micrograms of vitamin K1 daily produced a clinically relevant effect in 25% of subjects (see ‘Dietary supplements; Vitamin K1-containing’, (p.401)). There is also some evidence that a physicochemical interaction (possibly binding to protein) may occur between warfarin and enteral foods in the gut.\textsuperscript{12,20}

Lipid emulsions given as part of parenteral nutrition often contain soya oil, which has a moderate level of vitamin K (see ‘Table 12.3’, (below)). These preparations may also have direct coagulation effects.\textsuperscript{18} Parenteral nutrition may also be supplemented with vitamin K.

Importance and management

Established interactions of clinical importance. Be aware that enteral feeds might contain sufficient vitamin K to alter coagulation status, so starting or stopping these feeds might affect dose requirements of vitamin K antagonists such as warfarin. It is also possible that there is a local interaction in the gut, as in one case separating the administration of the warfarin and an enteral feed by 3 hours or more was effective.\textsuperscript{13} Patients should be advised not to add or substitute dietary supplements such as Ensure without increased monitoring of their coagulation status.

Fat emulsions used for parenteral use containing soya oil may themselves contain sufficient vitamin K1 for daily needs. Parenteral multivitamin preparations may also contain important levels of vitamin K1. It would be advisable to keep the vitamin K1 intake constant in any patient requiring long-term supplemental or total parenteral nutrition and warfarin. If the amount of lipid and/or multivitamins is altered, anticipate a

Data from:
change in warfarin requirement. Although there is only a single case, bear in mind that propofol may interact because it is formulated with soya oil, which contains vitamin K.

---

**Coumarins + Foods; Soya bean products**

**Natto, a Japanese food made from fermented soya bean**, can markedly reduce the effects of warfarin and acenocoumarol, because of the high levels of vitamin K2 substance produced in the fermentation process. In one study, soya bean protein also modestly reduced the effects of warfarin, and a similar case has been reported with soy milk.

**Clinical evidence**

(a) Fermented soya bean products (natto)

In a controlled study in 12 healthy subjects stabilised on acenocoumarol, a single meal containing 100 g of natto decreased the mean INR from 2.1 to 1.5 after 24 hours, and the INR had still not returned to the original level after 7 days (INR 1.75 one week later). The effect was considered clinically important in 6 of the 12 subjects. Similarly, in an earlier retrospective study of 10 patients taking warfarin, eating natto caused the thrombotest values to rise from a range of 12 to 29% up to a range of 33 to 100%. The extent of the rise appeared to be related to the amount of natto eaten. The thrombotest values fell again when the natto was stopped. A healthy sub- ject taking warfarin, with a thrombotest value of 40%, ate 100 g of natto. Five hours later the thrombotest value was unchanged, but 24 hours later it was 86%, and after 48 hours it was 90% (suggesting that the anticoagulant effect was decreased).

(b) Soya milk

In a 70-year-old man stabilised on warfarin 3 mg daily, consumption of soya milk 480 mL daily (240 mL of both Sun Soy and 8th Continent mixed together) decreased the INR from 2.5 to 1.6 after about 4 weeks. One week after stopping the soya milk, his INR was 1.9, and 4 weeks after it was 2.5.

(c) Soya oil

Soya oil is an important source of dietary vitamin K, see ‘Table 12.3’, (p.407). For two cases of ‘warfarin resistance’ with intravenous soya oil emulsions, see ‘Coumarins and related drugs + Foods; Enteral and parenteral nutrition’, p.406.

(d) Soya protein

In a study in 10 patients with hypercholesterolaemia who were stabilised on warfarin, substitution of all animal protein for textured soya protein for 4 weeks caused a marked reduction (Quick value approximately doubled) in the anticoagulant effects of warfarin by the second week.

**Mechanism**

Soya beans are a moderate source of vitamin K1 (19 micrograms per 100 g),2 and soya oil and products derived from it are an important dietary source of vitamin K (see ‘Table 12.3’, (p.407)). However, the soy milk brand taken in the case report did not contain vitamin K3, and another reference source lists soya milk as containing just 7.5 micrograms vitamin K per 250 mL,3 which would not be expected to cause an interaction. Why this product decreased the effect of warfarin is therefore open to specu- lation. The vitamin K content of textured soya protein is unknown. Note that soy recipe made from soy and wheat is reported to contain no vitamin K, and soft tofu made from the curds by coagulating soy milk contains only low levels (2 micrograms per 100 g).4

In contrast, fermented soya bean products such as natto contain very high levels of a particular vitamin K1 substance (MK-7)5,6, because of the fermentation process with Bacillus natto. In addition, the bacteria might con- tinue to act in the gut to increase the synthesis and subsequent absorption of vitamin K1.6 Although the role of vitamin K1 in anticoagulation is less well established than vitamin K1, it appears that this also opposes the actions of coumarins and indanediones, which are vitamin K antagonists.

**Importance and management**

The interaction with fermented soya bean products is established, marked, and is likely to be clinically relevant in all patients. Patients taking cou- marin and probably indanedione anticoagulants should probably be ad- vised to avoid natto, unless they want to consume a regular constant amount.

Although information is limited, it appears that soya protein might also modestly reduce the effect of warfarin. In particular, complete substitution
of animal protein for soya protein appears to reduce the effect of warfarin. A single report suggests that soya milk may also interact. ‘Soya oil’, (p.406) has been reported to interact in a couple of cases. On the basis of known vitamin K-content, whole soya beans could potentially reduce the effect of warfarin, whereas soya sauce should not.2

### Coumarins and related drugs + Foods; Vitamin K₁-rich

Unintentional and unwanted antagonism of warfarin has occurred in patients who ate exceptionally large amounts of some green vegetables, which can contain significant amounts of vitamin K₁. Isolated cases have also been reported with avocado, green tea, liver, and seaweed sushi. Patients should be advised to maintain a constant dietary intake of vitamin K₁. Foods containing significant amounts of vitamin K₂ substances such as fermented soya beans might also interact.

### Clinical evidence and mechanism

The coumarin and indenedione oral anticoagulants are vitamin K antagonists, which inhibit the enzyme vitamin K epoxide reductase so reducing the synthesis of vitamin K-dependent blood clotting factors by the liver. If the intake of vitamin K₁ increases, the synthesis of the blood clotting factors begins to return to normal. As a result the prothrombin time also begins to fall to its normal value. Naturally occurring vitamin K₁ (phytomenadione) is found only in plants.

#### A. Individual foods

**(a) Avocado**

Two women taking warfarin had a reduction in their INRs (from 2.5 to 1.7 and from 2.7 to 1.6, respectively) when they started to eat avocado 100 g daily, or 200 g of avocado on two consecutive days. Their INRs climbed again when the avocado was stopped.1 Avocado contains a small to moderate amount of vitamin K₁, see ‘Table 12.3’, (p.407), so might occasionally reduce the efficacy of warfarin if eaten in these quantities.

**(b) Green tea**

A patient taking warfarin had a reduction in his INR from a range of 3.2 to 3.79 down to 1.37, which was attributed to the ingestion of very large quantities of green tea (about 2 to 4 litres each day for a week). This interaction was attributed to the vitamin-K content of the tea.2 However, although dried tea, including green tea, is very high in vitamin-K₁, the brewed liquid made from the tea contains negligible amounts of vitamin K₁.1,3 and is therefore not considered to contribute any vitamin K₁ to the diet.3 The reason for this interaction is therefore unclear, unless the patient was eating some of the brewed tea leaves. A pharmacokinetic interaction also appears unlikely, because, although black tea inhibited CYP2C9 in vitro, brewed tea had no effect on the CYP2C9 substrate flurbiprofen in healthy subjects.4 For discussion of a case where a patient had an increase in INR after stopping taking a herbal preparation of which green tea leaves were one of 25 ingredients, see ‘Coumarins + Herbal medicines; Vitamin K₁-rich’, p.418.

**(c) Green vegetables**

In a formal study in patients stabilised on warfarin, one day of a high intake of vitamin K₁-rich vegetables (brussels sprouts 400 g, broccoli 400 g, lettuce 750 g, or spinach 300 g, estimated to contain 1 mg of vitamin K, daily) decreased anticoagulant effects: the thrombostet values rose above the normal range of 10 to 25% in 2 of 5 patients in 2 to 3 days. Two days of a high intake of the same vegetable caused values above the therapeutic range in 3 of 7 patients, and 7 days intake did the same in 9 of 13 patients.5 In another similar study, intake of spinach 250 g or broccoli 250 g daily for 7 days increased the mean thrombotest values to above the therapeutic limit of 15%, and the effect was similar to that of a supplement containing phytomenadione 250 micrograms daily. A reduction in the anticoagulant effect of warfarin was also seen in one healthy subject given about 450 g spinach daily.6,7 In a pharmacokinetic study in healthy subjects, a daily intake of 400 g of brussels sprouts for 2 weeks slightly decreased the AUC of warfarin by 16% and increased its metabolic clearance by 27%.8 This is probably because brussels sprouts induce the cytochrome P450 isoenzyme CYP1A2, which has a role in the ‘metabolism of warfarin’, (p.358).

### (d) Liver

A patient taking acenocoumarol had a soft tissue bleed, and was found to have a very low thrombotest value of about 3%. She had always consumed about 142 g daily of green vegetables, but about 4 months previously had been advised to stop eating liver (750 g weekly) as part of a low-fat diet.9 In another case, a man taking warfarin 5 mg daily had diffuse bruising and an INR of 5.6 two weeks after he was advised to stop eating pork liver10 (1 kg per week). He was eventually restabilised on just 1.5 mg of warfarin daily. Early studies showed that liver contained high levels of vitamin K, but more recent studies using more specific detection techniques have shown that liver generally contains very low levels of vitamin K₁ (4 and 7 micrograms in 100 g).11 However, liver may contain vitamin K₂ substances in sufficient levels to be of possible nutritional relevance.12,13 The precise role of vitamin K₂ substances in anticoagulation control is less clear, but ‘Natto’, (p.408), which is a rich source of these, clearly reduces the effects of coumarins.

### (e) Seaweed and Japanese food

A patient taking warfarin had, on two occasions, reduced INRs of 1.6 and 1.8 (usual range 2 to 3) within 24 hours of eating sushi with seaweed (asakusa-nori). It was estimated that she had consumed only about 45 micrograms of phytomenadione, but because her vitamin K stores may have been low, this amount could have accounted for a large percentage of her vitamin K intake or stores.14 In an early report, a Japanese man recently stabilised on warfarin developed bleeding episodes on two occasions shortly after resuming his usual diet of Japanese food (specific foods not mentioned). However, ingestion of 3 similar Japanese meals in a 24-hour period had no effect on the prothrombin time in 6 Caucasian patients taking warfarin.15

### (f) Relationship between dietary vitamin K and INR with anticoagulants

There is evidence that the average dietary vitamin K intake is correlated with the efficacy of warfarin. In one study, patients consuming a diet containing more than 250 micrograms daily of vitamin K₁ had a lower INR five days after starting warfarin than patients consuming less dietary vitamin K₁ (median INR 1.9 versus 3). Also, the high-vitamin K group needed a higher maintenance warfarin dose (5.7 mg/day versus 3.5 mg/day).21 In another study, multiple regression analysis indicated that, in patients taking warfarin, the INR was altered by 1, by a weekly change in the intake of vitamin K of 714 micrograms.22 Similarly, for each increase in daily dietary vitamin K intake of 100 micrograms, the INR decreased by just 0.2 in another study.23
In a randomised, crossover study in patients taking warfarin or phenprocoumon, increasing the dietary intake of vitamin K by 500% relative to the baseline value (from 118 to 591 micrograms daily) for 4 days only modestly decreased the INR from 3.1 to 2.8 on day 4. Decreasing the dietary intake of vitamin K by 80% (from 118 to 26 micrograms daily) for 4 days increased the INR from just 2.6 to 3.3 on day 7.24

(b) Stability of anticoagulant control and dietary vitamin K

There is some evidence that patients with a very low dietary vitamin K intake are more sensitive to alterations in vitamin K intake, and have less stable anticoagulant control. For example, in one study, patients with unstable control of anticoagulation were found to have a much lower dietary intake of vitamin K when compared with another group of patients with stable anticoagulant control (29 micrograms daily versus 76 micrograms daily).25 In another study in 10 patients with poorly controlled anticoagulation taking acenocoumarol, and receiving a diet with a low, controlled vitamin K content of 20 to 40 micrograms daily increased the percentage of INR values within the therapeutic range, when compared with a control group of 10 patients not subjected to any dietary restrictions.26

Importance and management

A very well established, well documented and clinically important drug-food interaction, expected to occur with every coumarin and indanedione anticoagulant because they have a common mode of action. The evidence suggests that, in patients with normal vitamin K status, in general, clinically relevant changes in coagulation status require large continued changes in intake of vitamin K from foods. However, there is some evidence to suggest that, in patients with low dietary vitamin K intake, intake may be sensitive to smaller changes in dietary vitamin K. This suggests that patients taking anticoagulants should be advised to eat a normal balanced diet, maintaining a relatively consistent amount of vitamin-K rich foods. They should be told to avoid making major changes to their diet, including starting a weight-loss diet, without increased monitoring of their INR. It is estimated that a normal Western diet contains 300 to 500 micrograms of vitamin K daily. The minimum daily requirement is about 1 microgram/kg and, in the US, an adequate intake has been determined to be 120 micrograms for adult men and 90 micrograms daily for adult women.12

In one early analysis, the anticoagulant effects of warfarin were markedly increased by very large doses of glucagon (total dose exceeding 50 mg over 2 days), but not by doses of less than 30 mg over 1 to 2 days. Doses of glucagon this high are unlikely to be encountered in clinical use.

Clinical evidence

In an analysis of 24 patients taking warfarin who were given glucagon for inadequate cardiac contractility, no potentiation of the action of warfarin was noted in 11 patients given a total of less than 30 mg of glucagon over 1 to 2 days. However, 8 out of 9 patients who had a marked increase in anticoagulant effects (prothrombin times of 30 to 50 seconds or more) when they took glucagon at least once or more days, the dosage of warfarin should be reduced in anticipation of this interaction, and prothrombin times closely monitored.

Coumarins + Glucagon

In one early analysis, the anticoagulant effects of warfarin were markedly increased by very large doses of glucagon (total dose exceeding 50 mg over 2 days), but not by doses of less than 30 mg over 1 to 2 days. Doses of glucagon this high are unlikely to be encountered in clinical use.

Mechanism

Unknown. Changes in the production of blood clotting factors and an increase in the affinity of warfarin for its site of action have been proposed. A study in guinea pigs using acenocoumarol suggested that changes in warfarin metabolism or its absorption from the gut are not responsible.2

Importance and management

Direct information is limited to the report cited,4 which relates to doses far in excess of those used clinically for hypoglycaemia (1 mg) or in the management of beta blocker overdose (2 to 10 mg then 50 micrograms/kg per hour). As such, its findings are probably of no general relevance. Its authors recommend that if glucagon 25 mg per day or more is given for two or more days, the dosage of warfarin should be reduced in anticipation of this interaction, and prothrombin times closely monitored.

**Coumarins + Glutethimide**

The anticoagulant effects of warfarin and ethyl biscoumacetate can be decreased by glutethimide.

**Clinical evidence**

Ten subjects stabilised on warfarin, with average prothrombin times of 18.8 seconds, had a mean reduction of 2.7 seconds in their prothrombin times after they took glutethimide 500 mg at bedtime for 4 weeks. Other studies have shown that up to 1 g of glutethimide daily for 1 to 3 weeks reduced the half-life of single-dose warfarin by between one-third to one-half. Conversely, an unexplained report describes a paradoxical increase in prothrombin times and severe bruising in a patient stabilised on warfarin who took 3.5 g of glutethimide over a 5-day period.

Glutethimide 500 or 750 mg daily for 10 days has been shown to reduce the half-life of single-dose ethyl biscoumacetate by about one-third, whereas in contrast, an early study in 25 patients taking ethyl biscoumacetate found no evidence of an interaction.

**Mechanism**

Glutethimide is a liver enzyme inducer, which increases the metabolism and clearance of the anticoagulants from the body, thereby reducing their effects. There is no obvious explanation for the reports finding no interaction or increased effects.

**Importance and management**

The interaction of glutethimide with warfarin is established, while the interaction with ethyl biscoumacetate is uncertain. Information about both interactions is limited and there seems to be nothing documented about any other anticoagulant. However, it would be prudent to monitor the effect of adding glutethimide to patients taking any coumarin anticoagulant, being alert for the need to increase the anticoagulant dosage. Other interactions due to enzyme induction can take several weeks to develop fully and persist after withdrawal, so good monitoring and dosage adjustment should continue until anticoagulant stability has been achieved. The benzodiazepines may be a useful non-interacting alternative, see ‘Coumarins + Benzodiazepines and related drugs’, p.391.

**Coumarins + Grapefruit juice**

Preliminary evidence from one study suggests that grapefruit juice might cause a modest rise in the INR of a few patients taking warfarin, and one case report describes a marked rise in INR, which was attributed to grapefruit juice. However, other studies have suggested that grapefruit juice does not interact with warfarin or acenocoumarol.

**Clinical evidence**

(a) Aacenocoumarol

In the preliminary report of a single-dose, placebo-controlled study in 12 healthy subjects, 150 mL of grapefruit juice did not alter the maximum INR of a 10-mg dose of acenocoumarol, and the AUCs of S- and R-acenocoumarol were not altered.

(b) Warfarin

In a study in 9 patients stabilised on warfarin, consumption of grapefruit juice 240 mL three times daily for one week had no effect on the INR or prothrombin times. Similarly, in the preliminary report of a two-way crossover study in 24 patients stabilised on warfarin, the frequency of the warfarin dosage adjustments needed by the group as a whole, when taking 250 mL grapefruit juice daily for 4 weeks was the same as when taking a placebo (orange juice). However, 4 individuals had a clinically significant, progressive and sustained 12 to 25% decrease in the warfarin dose to INR ratio when taking grapefruit juice, but not orange juice. A 64-year-old man stabilised on warfarin was found to have an INR of 6.29 on routine testing 10 days after starting to drink about 1.5 litres of grapefruit juice daily. However, when the author took warfarin to achieve an INR of 2 to 3 and then drank 1.5 litres of grapefruit juice daily there was no clinically relevant change in his INR.

**Mechanism**

The patients who showed some evidence of an interaction between grapefruit juice and warfarin may possibly have had an increased susceptibility to the inhibitory effects of grapefruit juice on the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut.

**Importance and management**

Information is limited. One study with warfarin suggests that some patients might require a slight reduction in dose if they regularly consume grapefruit juice, but further study is needed. Current evidence suggests that routine testing should be sufficient to detect any interaction.

2. van der Meer FJM. Personal communication, April 1994.

**Coumarins + Griseofulvin**

The anticoagulant effects of warfarin might be reduced by griseofulvin in some patients.

**Clinical evidence**

The anticoagulant effects of warfarin were modestly and markedly reduced, respectively, in 2 patients stabilised on warfarin when they were given griseofulvin 1 g daily in divided doses. Griseofulvin 1 g daily had no effect on the prothrombin time in one healthy subject given warfarin, whereas 2 g daily caused a marked reduction in the prothrombin time. Another healthy subject showed no interaction, even when the griseofulvin dosage was raised to 4 g daily for 2 weeks.

In another study there was no change in the mean prothrombin time in 10 patients stabilised on warfarin when they were given griseofulvin 1 g daily in divided doses. Four of the patients had an equivocal average reduction in prothrombin time of 4.2 seconds. One case report describes decreased anticoagulant effects in a man stabilised on warfarin when he took griseofulvin 250 mg twice daily, which took 12 weeks to develop fully. He eventually needed a 41% increase in his daily dose of warfarin. Another report very briefly mentions a case of a coagulation defect in a patient taking warfarin and griseofulvin.

**Mechanism**

Not understood. It has been suggested that the griseofulvin acts as a liver enzyme inducer, which increases the metabolism of the warfarin, thereby reducing its effects.

**Importance and management**

This interaction is poorly documented and not well established. It possibly affects some patients. Because of the uncertainty, the prothrombin times...
of all patients taking warfarin who are given griseofulvin should be monitored, and suitable warfarin dosage increases made as necessary.

**Coumarins and related drugs + H₂-receptor antagonists**

The anticoagulant effects of warfarin can be increased by cimetidine. The effect is generally minor to modest, although severe bleeding has been reported in a few cases. Acenocoumarol seems to interact similarly, but phenprocoumon appears not to be affected. In one patient the effects of phenindione were modestly increased by cimetidine. Famotidine, nizatidine, ranitidine and roxatidine normally do not appear to interact, although isolated cases of bleeding have been reported.

**Clinical evidence**

(a) Cimetidine

A brief report in 1978, published as a letter by the manufacturers of cimetidine, stated that preliminary details of a study in healthy subjects indicated that cimetidine 1 g daily could cause a prothrombin time rise of about 20% in patients stabilised on warfarin. At that time, they were aware of 17 cases worldwide, most of moderate rises in prothrombin times. In another study in 11 healthy subjects, ranitidine 150 mg twice daily for 3 days had no effect on the pharmacodynamics or pharmacokinetics of a single dose of warfarin. The same finding was reported in another similar study. In contrast, in a fourth study in 5 subjects, ranitidine 150 mg twice daily for a week reduced the clearance of a single dose of warfarin by almost 30%, but the half-life was not significantly changed and prothrombin times were not measured. Ranitidine 750 mg daily given to 2 subjects reduced the warfarin clearance by more than 50%. In an isolated case, a patient stabilised on ranitidine 150 mg twice daily and warfarin vomited blood one week after her ranitidine dose was doubled to 300 mg twice daily. Her prothrombin time had risen from 17.6 to 36.7 seconds. She was subsequently restabilised on ranitidine 150 mg twice daily and the original dose of warfarin with a prothrombin time between 19 and 20 seconds.

In one study in 10 patients stabilised on phenprocoumon, ranitidine 150 mg twice daily for 14 days had no effect on anticoagulation or on phenprocoumon plasma levels.

(b) Famotidine

In a study in 8 healthy subjects taking doses of warfarin titrated to prolong the prothrombin time by 2 to 5 seconds (mean dose 4 mg daily), treatment with famotidine 40 mg daily for 7 days did not affect prothrombin times, thromboplast coagulation times or steady-state plasma warfarin levels. No changes in prothrombin times were seen in 3 patients stabilised on acenocoumarol or fluidiine when they were given famotidine.

However, in another report 2 patients taking warfarin are said to have had prolonged prothrombin times and bled when they took famotidine.

(c) Nizatidine

Nizatidine 300 mg daily for 2 weeks had no significant effect on the prothrombin times, kaolin-cephalin clotting times, the activity of factors II, VII, XI and X, or on steady-state serum warfarin levels in 7 healthy subjects taking warfarin. A lack of a pharmacokinetic interaction was also reported in the preliminary results of another study. An isolated case of gastrointestinal bleeding, associated with markedly prolonged prothrombin times, occurred after a 78-year-old took six doses of nizatidine 300 mg.

(d) Ranitidine

Ranitidine 200 mg twice daily for 2 weeks had no effect on warfarin concentrations or prothrombin times in 5 healthy subjects. In another study in 11 healthy subjects, ranitidine 150 mg twice daily for 3 days had no effect on the pharmacodynamics or pharmacokinetics of a single dose of warfarin. The same finding was reported in another similar study. In contrast, in a fourth study in 5 subjects, ranitidine 150 mg twice daily for a week reduced the clearance of a single dose of warfarin by almost 30%, but the half-life was not significantly changed and prothrombin times were not measured. Ranitidine 750 mg daily given to 2 subjects reduced the warfarin clearance by more than 50%. In an isolated case, a patient stabilised on ranitidine 150 mg twice daily and warfarin vomited blood one week after her ranitidine dose was doubled to 300 mg twice daily. Her prothrombin time had risen from 17.6 to 36.7 seconds. She was subsequently restabilised on ranitidine 150 mg twice daily and the original dose of warfarin with a prothrombin time between 19 and 20 seconds.

In one study in 10 patients stabilised on phenprocoumon, ranitidine 150 mg twice daily for 14 days had no effect on anticoagulation or on phenprocoumon plasma levels.

Mechanism

Cimetidine binds with the cytochrome P450 isoenzymes and inhibits oxidative metabolism in the liver. Although cimetidine is considered to be a general inhibitor, it exhibits a degree of specificity for certain isoenzymes such as CYP1A2 and CYP2C19. These isoenzymes are principally involved in the metabolism of R-warfarin and not S-warfarin (see ‘metabolism of the coumarins’, (p.358), for more detail). Thus, the interaction between warfarin and cimetidine has been found to be stereoselective (i.e. cimetidine interacts with the R-isomer but not with the S-isomer). Because R-warfarin is the less active isomer, and the pharmacokinetic interaction is not marked, the interaction is generally modest. Cimetidine also appears to interact with acenocoumarol, but not phenprocoumon. The other H₂-receptor antagonists normally do not act as enzyme inhibitors.

**Importance and management**

The interaction between warfarin and cimetidine is well documented, well established and potentially clinically important. Its effects are generally modest, but rarely, patients have shown a marked interaction. Because of this unpredictability, and to avoid bleeding, the response should be monitored well in every patient when cimetidine is first added, being alert for the need to reduce the warfarin dosage. The onset of the interaction appears rapid; effects have been seen within days, and even as early as 24 hours. The effect of low non-prescription doses of cimetidine on warfarin does not appear to have been studied. Acenocoumarol is reported to interact similarly, and there is one case of phenindione being affected. Expect other coumarins and indanediones to behave in the same way, with the possible exception of phenprocoumon, which was not affected in one study.

Famotidine, nizatidine, ranitidine and roxatidine normally appear not to interact with oral anticoagulants although note that, in rare cases, increases in prothrombin times and bleeding have been seen.

Heparin may prolong the prothrombin time, therefore a sufficient time interval should be allowed after the last heparin dose in a patient taking a coumarin to obtain a valid prothrombin time.

Clinical evidence, mechanism, importance and management

Heparin may prolong the one-stage prothrombin time. The US manufacturer notes that, if a valid prothrombin time is to be obtained in a patient starting warfarin or other coumarins, a period of at least 5 hours after the last intravenous heparin dose or 24 hours after the last subcutaneous dose should be left before measuring the prothrombin time. Note that it is usual clinical practice to start heparin and a coumarin anticoagulant at the same time. Further, it is clear that the concurrent use of warfarin and heparin will have an at least additive anticoagulant effect.

Many of the interactions of herbal medicines (health foods, dietary supplements) with warfarin in the published literature are solely hypothetical based on the postulated pharmacological effects of known chemical constituents of the plants. These mechanisms are discussed further below. Where specific clinical data on a herbal medicine interaction with warfarin are available, this is covered in a separate monograph.

All patients should be encouraged to report their use of herbal medicines and food supplements and cases of uneventful concurrent use should be published as well as cases of possible interactions to increase the clinical information available.

Clinical evidence and mechanism

(a) Antiplatelet effects

Antiplatelet doses of ‘aspirin’, (p.385), do not alter the anticoagulant efficacy of warfarin (INR); however, these doses of aspirin by themselves increase the risk of gastrointestinal bleeding, and the risk of this is higher in patients taking warfarin. On this basis, many herbs with antiplatelet activity in vitro are postulated to interact with warfarin, including ‘ginger’, (p.416) and ‘garlic’, (p.415). To establish the increased risk with antiplatelet doses of aspirin with warfarin, very large studies were needed because the absolute risks are small (about 1 in 100 in one study). Studies of this size are very unlikely to be conducted with herbs. One way might be to compare the in vivo antiplatelet activity of the herbal product with that of aspirin 75 mg, and then to extrapolate to the likely increased risk of bleeding.

(b) Coumarin constituents

There is a misconception that if a plant contains natural coumarins it will have anticoagulant properties. More than 3400 coumarins occur naturally throughout at least 160 plant families. Of these, just 13 have been tested for antithrombotic or anticoagulant activity, and only about half (7) were found to be active.7 There are no established interactions between warfarin and herbal medicines that have been attributed to the coumarin content of the herb. Even in the classic case of hemorrhagic death of livestock that occurred in a separate monograph.

(c) Hepatic cytochrome P450 metabolism

St John’s wort is the most well established example of a herb that can induce the metabolism of drugs, principally by the cytochrome P450 isoenzyme CYP3A4. This herb appears to have a modest effect on ‘warfarin’, (p.418), which might be clinically important. ‘Danshen’, (p.415) might interact by increasing the bioavailability of warfarin. No other herbs appear to have an established effect on the metabolism of warfarin.

(d) Vitamin K content

Vitamin K is found in highest levels in ‘green leafy vegetables’, (p.409), which, if ingested in sufficient quantities, can markedly reduce the effects of warfarin and related drugs. It would therefore not be surprising if many herbal medicines derived from dark green leaves contain vitamin K. However, whether enough of these herbs could be taken to cause an interaction seems less likely than with foods. Nevertheless, two case reports of altered coagulation status attributed to the vitamin K content of herbal preparations have been reported, see ‘vitamin K’, (p.418).

Importance and management

There are many reviews of the effect of various herbal medicines on warfarin. Most of these include interactions based on theoretical data, based on the knowledge that a plant has been shown to contain antiplatelet substances or coumarins. The problem with these lists is that a suggested interaction might never be clinically relevant if, for example, the coumarins present are found not to be anticoagulants, or the substances are found in such small quantities and the herb cannot be ingested in sufficient amounts to cause an interaction. With natural substances, there is also the problem of chemical variations between batches of product if they are not standardised. Moreover, even isolated reports of an interaction between a herbal medicine and warfarin cannot definitively establish that such an interaction exists (see also ‘anticoagulant interactions’, (p.358)).

Because of the potential for interactions, some consider that patients taking warfarin would be well advised to avoid all herbal medications. However, this approach may not be practical: there are many papers showing that patients taking warfarin do use a number of herbal medicines and dietary supplements (19.2% in a UK survey;2 26% in a Hong Kong survey). If patients have been told to avoid all herbal products, they may be less likely to admit to their use, and become less cautious in the future if they discover that the use of one product is uneventful. It may be better to advise patients to discuss the use of any products they wish to try, and to increase monitoring if it is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse use.

Coumarins + Herbal medicines; Boldo or Fenugreek

A report describes a woman taking warfarin whose INR rose modestly when she began to take boldo and fenugreek.

Clinical evidence, mechanism, importance and management

A woman taking warfarin for atrial fibrillation whose INR was normally within the range 2 to 3 had a modest rise in her INR to 3.4, apparently due to the use of 10 drops of boldo after meals and one capsule of fenugreek before meals. A week after stopping these two herbal medicines her INR had fallen to 2.6. When she restarted them, her INR rose to 3.1 after a week, and to 3.4 after 2 weeks. Her INR was later restabilised in her normal range in the presence of these two medicines by reducing the warfarin dosage by 15%.1 The mechanism of this apparent interaction remains unknown, and it is not known whether both herbs or just one was responsible for what happened. Boldo comes from Peumus boldus, and might have antiplatelet activity, and fenugreek comes from Trigonella foenum-graecum, which might contain coumarins (but see ‘Coumarins + Herbal medicines’, above). This patient had no undesirable reactions (e.g. bruising or bleeding), but this case serves to draw attention to the possibility of an interaction in other patients taking anticoagulants if these herbal medicines are also taken.

Coumarins + Herbal medicines; Chamomile

A single case report describes a woman stabilised on warfarin who developed a marked increase in her INR with bleeding complications five days after she started using two chamomile products.

Clinical evidence

A 70-year-old woman stabilised on warfarin with an INR of 3.6 started drinking 4 to 5 cups of chamomile tea daily for chest congestion, and using a chamomile-based skin lotion 4 to 5 times daily for foot oedema. About 5 days later she developed ecchymoses and was found to have an INR of 7.9, a retroperitoneal haematoma and other internal haemorrhages.1

Mechanism

Both species of chamomile used medicinally (Matricaria recutita also known as Matricaria chamomilla or Chamomilla recutita and Anthemis nobilis also known as Chamaemelum nobilis) are known to contain coumarins, but natural coumarins are not always anticoagulants, see ‘Coumarins + Herbal medicines’, above. There appear to be no reports of chamomile alone causing bleeding.
Importance and management

This paper discusses the first report of an interaction between warfarin and chamomile, and it may be that it was due to excessive use of two chamomile-based products. It serves to draw attention to the possibility of an interaction in other patients taking anticoagulants if chamomile is used concurrently. Further study is needed. However, note that there appear to be no reports of chamomile alone causing anticoagulation, which might suggest that the risk of an additive effect is small.

Coumarins + Herbal medicines; Curbicin

The INR of one patient taking warfarin modestly increased after he took Curbicin (saw palmetto, curbucita, and vitamin E). This product has also been associated with an increased INR in a patient not taking anticoagulants.

Clinical evidence, mechanism, importance and management

A 61-year-old man taking warfarin and simvastatin, with a stable INR of around 2.4, had an increase in his INR to 3.4 within 6 days of starting to take 5 tablets of Curbicin daily. Within a week of stopping the Curbicin, his INR had fallen to its previous value. Another elderly man who was not taking any anticoagulants and was taking 3 tablets of Curbicin daily was found to have an INR of 2.1 (normal 0.9 to 1.2). His INR improved (1.3 to 1.4) when he was given vitamin K, but did not normalise until a week after stopping the Curbicin. Curbicin is a herbal remedy used for micturition problems, and contains extracts from the fruit of Serenoa repens (saw palmetto) and the seed of Cucurbita pepo.¹

The authors of this report suggest that what happened was possibly due to the presence of vitamin E in the Curbicin preparation (each tablet contains 10 mg), but ‘vitamin E’, (p.401) does not normally affect INRs. The clinical significance of this interaction is unknown, but bear it in mind in the case of an unexpected response to treatment.

Coumarins and related drugs + Herbal medicines; Danshen (Salvia miltiorrhiza)

Two case reports and some animal data indicate that Danshen, a Chinese herbal remedy, can increase the effects of warfarin, resulting in bleeding.

Clinical evidence

A woman who had undergone venous mitral valve valvuloplasty and who was taking furosemide, digoxin and warfarin, began to take Danshen (the root of Salvia miltiorrhiza) every other day for intermittent influenza-like symptoms. After about a month she was hospitalised with malaise, breathlessness and fever and was found to be both very anaemic and over-anticoagulated (prothrombin time greater than 60 seconds, INR greater than 5.62). The anaemia was attributed to occult gastrointestinal bleeding and the over-anticoagulation to an interaction with the Danshen. She was later restabilised on the warfarin in the absence of the Danshen with an INR of 2.5, and within 4 months her haemoglobin levels were normal.¹

Another report describes a man taking warfarin, digoxin, captopril and furosemide with an INR of about 3, who developed chest pain and breathlessness about 2 weeks after starting to take Danshen. He was found to have a massive pleural effusion, which was later drained of blood, and an INR of more than 8.4. He was later discharged on his usual dose of warfarin with an INR stable at 3, in the absence of the Danshen.²

Mechanism

Not fully understood. Studies in rats show that Danshen can increase the bioavailability of both R- and S-warfarin thereby increasing its effects.³

It may affect haemostasis by inhibiting platelet aggregation and by interfering with extrinsic coagulation, and it also has antithrombin III-like activity and can promote fibrinolytic activity. The additive effects of these activities might be expected to result in bleeding complications.

Coumarins + Herbal medicines; Garlic

An isolated report described increases in the anticoagulant effects of warfarin in two patients taking garlic supplements. Garlic supplements alone have also rarely been associated with bleeding. However, in one study, aged garlic extract did not increase the INR or risk of bleeding in patients taking warfarin.

Clinical evidence

The INR of a patient stabilised on warfarin more than doubled in her prothrombin time and INR after taking dong quai for 4 weeks. The prothrombin time and INR were back to normal 4 weeks after stopping the dong quai. Another woman who had been taking warfarin for 10 years developed widespread bruising and an INR of 10, a month after starting to take dong quai.²

The reasons are not understood but dong quai is known to consist of natural coumarin derivatives, which may possibly have anticoagulant properties and inhibit platelet aggregation, but note that not all natural coumarins are anticoagulants, see ‘Coumarins + Herbal medicines’, p.414.

These seem to be only reports of this apparent interaction, but patients taking warfarin should be warned of the potential risks of also taking dong quai. For safety dong quai should be avoided unless the effects on anticoagulation can be monitored. More study is needed.

Coumarins + Herbal medicines; Dong quai (Angelica sinensis)

Two case reports describe a very marked increase in the anticoagulant effects of warfarin when dong quai was given.

Clinical evidence, mechanism, importance and management

A 46-year-old African-American woman with atrial fibrillation taking warfarin had a greater than twofold increase in her prothrombin time and INR after taking dong quai for 4 weeks. The prothrombin time and INR were back to normal 4 weeks after stopping the dong quai. Another woman who had been taking warfarin for 10 years developed widespread bruising and an INR of 10, a month after starting to take dong quai.²

The reasons are not understood but dong quai is known to consist of natural coumarin derivatives, which may possibly have anticoagulant properties and inhibit platelet aggregation, but note that not all natural coumarins are anticoagulants, see ‘Coumarins + Herbal medicines’, p.414.

These seem to be only reports of this apparent interaction, but patients taking warfarin should be warned of the potential risks of also taking dong quai. For safety dong quai should be avoided unless the effects on anticoagulation can be monitored. More study is needed.

Mechanism

Garlic has been associated with decreased platelet aggregation, which has on at least two documented occasions led to spontaneous bleeding in the absence of an anticoagulant. These effects might therefore increase the risk of bleeding with anticoagulants, see also ‘Coumarins + Herbal medicines’, p.414.

Importance and management

Information about an adverse interaction between warfarin and garlic seems to be limited to these two cases from one author. Bearing in mind the widespread use of garlic and garlic products, and the limited information from the review, and study with aged garlic extract, it seems most unlikely that garlic usually has any generally important interaction with anticoagulants. Nevertheless, bear the possibility in mind in the event of an unexpected response to treatment.

Evidence from pharmacological studies suggests that ginger does not increase the anticoagulant effect of warfarin, neither does it alter coagulation or platelet aggregation on its own. However, two case reports describe markedly raised INRs with phenprocoumon and warfarin, which were associated with eating dried ginger and drinking ginger tea.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in 12 healthy subjects, 3 ginger capsules three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single 25-mg dose of warfarin taken on day 7. The brand of ginger used was Blackmores Travel Calm Ginger, each capsule containing an extract equivalent to 400 mg of ginger rhizome powder. Moreover, ginger alone did not affect the INR or platelet aggregation.

However, a case report describes a rise in INR to greater than 10, with epistaxis, in a woman stabilised on phenprocoumon several weeks after she started to eat ginger regularly in the form of pieces of dried ginger and tea from ginger powder. She was eventually restabilised on the original dose of phenprocoumon, and was advised to stop taking ginger. Another very similar case has been described in a woman taking warfarin.

These appear to be the only reports of ginger as a probable cause of over-anticoagulation, despite the fact that prior to these Ginger (Zingiber officinale) has been sometimes listed as a herb that interacts with warfarin, on the basis that in vitro it inhibits platelet aggregation. However, this antipleatelet effect has not been demonstrated in clinical studies (which have been the subject of a review). See also ‘Coumarins + Herbal medicines’, p.414.

Evidence from pharmacological studies suggests that ginger does not increase the anticoagulant effect of warfarin, neither does it alter coagulation or platelet aggregation on its own. However, two case reports describe markedly raised INRs with phenprocoumon and warfarin, which were associated with ginger root and ginger tea. Bear the possibility in mind in the event of an unexpected response to treatment.

Evidence from pharmacological studies in patients and healthy subjects suggests that Ginkgo biloba extracts do not interact with warfarin. However, an isolated report describes intracerebral haemorrhage associated with the use of Ginkgo biloba and warfarin, and there are a few reports of bleeding associated with the use of ginkgo alone.

Clinical evidence

In a randomised, crossover study in 21 patients stabilised on warfarin, Ginkgo biloba extract 100 mg daily (Bio-Biloba) for 4 weeks did not alter the INR or the required dose of warfarin, when compared with placebo. Similarly, in another study in healthy subjects, Tavonin (containing standardised dry extract EGB 761 of Ginkgo biloba equivalent to 2 g of leaf) 2 tablets three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single dose of warfarin given on day 7. Moreover, a retrospective review of 21 clinical cases involving the concurrent use of ginkgo and warfarin also found no evidence of altered INRs.

Conversely, a report describes an intracerebral haemorrhage in an elderly woman within 2 months of starting Ginkgo biloba. Her prothrombin time was found to be 16.9 and her partial thromboplastin time was 35.5 seconds. She had been taking warfarin eventfully for 5 years. The author of the report speculated that Ginkgo biloba may have contributed towards the haemorrhage.

Mechanism

Uncertain. Isolated cases of bleeding have been reported with ginkgo alone (which have been the subject of a review). In pharmacological studies, Ginkgo biloba extract alone did not alter coagulation parameters or platelet aggregation. However, in animal studies it was found that the AUC of warfarin was decreased by 23.4% during EGB 761 administration, and the prothrombin time was also reduced by EGB 761, which would suggest that ginkgo should reduce the effects of warfarin. In healthy subjects, Ginkgo biloba extract had no effect on diclofenac or tolbutamide, which were used as marker substrates for the cytochrome P50 isoenzyme CYP2C9, suggesting that it will not alter the metabolism of S-warfarin.

Importance and management

There is good evidence from pharmacological studies in patients and healthy subjects that Ginkgo biloba extract would not be expected to interact with warfarin. However, there is one case report of over-anticoagulation, and a few reports of bleeding with ginkgo alone. This is insufficient evidence to justify telling patients taking warfarin to avoid Ginkgo biloba, but they should be told to monitor for early signs of bruising or bleeding and seek informed professional advice if any bleeding problems arise.

Coumarins + Herbal medicines; Ginkgo biloba

One pharmacological study found that American ginseng (Panax quinquefolius) modestly decreased the effect of warfarin, whereas another study found that Panax ginseng did not alter the effect of warfarin. Two case reports describe decreased warfarin effects, one with thrombosis, attributed to the use of ginseng (probably Panax ginseng).

Coumarins + Herbal medicines; Ginger

Evidence from pharmacological studies suggests that ginger does not increase the anticoagulant effect of warfarin, neither does it alter coagulation or platelet aggregation on its own. However, two case reports describe markedly raised INRs with phenprocoumon and warfarin, which were associated with eating dried ginger and drinking ginger tea.
Clinical evidence

In a placebo-controlled study, 20 healthy subjects were given warfarin 5 mg daily for 3 days alone then again on days 15 to 17 of a 3-week course of American ginseng 1 g twice daily. In the 12 subjects given ginseng, the peak INR was modestly reduced by 0.16, compared with a non-significant reduction of 0.02 in the 8 subjects given placebo. There was also a modest reduction in the AUC of warfarin. In this study, American ginseng (*Panax quinquefolius*) root was ground and capsulated.1

Evidence from two earlier case reports supports a reduction in warfarin effect. A man taking warfarin long-term, and also dietizem, glycercitrinitrate and salsalate, had a fall in his INR from 3.1 to 1.5 within 2 weeks of starting to take ginseng capsules (*Ginsana*) three times daily. This preparation contains 100 mg of standardised concentrated ginseng [probably *Panax ginseng*] in each capsule. Within 2 weeks of stopping the ginseng, his INR had risen again to 3.3.2 Another patient taking warfarin was found to have thrombosis of a prosthetic aortic valve, with a subtherapeutic INR of 1.4. Three months prior to this episode his INR had become persistently subtherapeutic, requiring a progressive increment in his warfarin dose. It was suggested that this might have been because he had begun using a ginseng product (not identified).3 In contrast, in a randomised, crossover study in 12 healthy subjects, ginseng capsules 1 g three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single 25-mg dose of warfarin taken on day 7. The brand of ginseng used was Golden Glow, each capsule containing an extract equivalent to 0.5 g of Panax ginseng root.4

Mechanism

Ginseng can come from the root of *Panax ginseng* (known in the US as Asian ginseng) or *Panax quinquefolius* (American ginseng), which differ in the concentrations and specific ginsenosides.5 The study showing a reduction in effect of warfarin used American ginseng, and the study showing no effect used *Panax ginseng*. A study in rats also failed to find any evidence of an interaction between warfarin and an extract from *Panax ginseng*.6 Nevertheless, the two case reports of reduced warfarin effect are probably *Panax ginseng*.

In contrast there have been handful of reports of spontaneous bleeding in patients using ginseng preparations (unspecified) in the absence of an anticoagulant,78 and, in *vitro*, Panax ginseng has been found to contain antiplatelet components.9 See also ‘Coumarins + Herbal medicines’, p.414.

Importance and management

The available evidence suggests that ginseng might decrease the effect of warfarin. It is possible that the effect is greater with, or specific to, American ginseng (*Panax quinquefolius*), since this interacted in one study whereas *Panax ginseng* did not. Although the ginseng dose was higher in the *Panax ginseng* study, the treatment duration was not as long, which may have obscured an effect. Moreover, the two case reports of decreased warfarin effects attributed to the use of ginseng were probably *Panax ginseng*.

Until further information becomes available it would seem prudent to be alert for decreased effects of coumarins in patients using ginseng, particularly American ginseng. However, the possibility of an increased risk of bleeding due to the antiplatelet component of Panax ginseng cannot entirely be ruled out, but see also ‘Coumarins + Herbal medicines’, p.414.

Coumarins + Herbal medicines; *Lycium barbarum*

There is an isolated report of a modest decrease in the anticoagulant effects of warfarin in a patient taking a herbal tea made from *Lycium barbarum*.

Clinical evidence, mechanism, importance and management

A 61-year-old Chinese woman stabilised on warfarin (INRs normally 2 to 3) had an unexpected rise in her INR to 4.1, which was identified during a routine monthly check. No bleeding was seen. She was also taking atenolol, benazepril, digoxin and fluvastatin. It was found that 4 days before visiting the clinic she had started to take one glass (about 170 mL) 3 or 4 times daily of a Chinese herbal tea made from the fruits of *Lycium barbarum* (also known as Chinese wolfberry, gou qi zi, Fructus Lycii Chinensis, or *Lycium chineense*) to treat blurred vision caused by a sore eye. When the herbal treatment was stopped, her INRs rapidly returned to normal. *Later in vitro* studies showed that an infusion of *Lycium barbarum* caused some inhibition of the cytochrome P450 isoenzyme CYP2C9, which is involved in the metabolism of warfarin, but this was apparently too weak to explain why this interaction occurred.1 So far this is an isolated case but it draws attention to the possibility of problems with this herbal remedy in other patients.

Coumarins + Herbal medicines; *Mellilotus officinalis*; *sweet clover*

Increased anticoagulation was seen in a patient taking acenocoumarol after using a mellilot-containing topical cream.

Clinical evidence

A 66-year-old taking acenocoumarol, levothyrozyne and prazepan had an increase in her INR after massaging a proprietary topical cream (*Cyclo 3*) containing mellilot (*Mellolitus officinalis*; *sweet clover*) and butcher’s broom (*Ruscus aculeatus*) on her legs three times daily. On the first occasion her INR rose from about 2 to 5.8 after 7 days of use, and on a later occasion it rose to 4.6 after 10 days of use.1

Mechanism

Mellilot (sweet clover) is known to contain natural coumarins, which can be turned into dicoumarol by moulds, see ‘Coumarins + Herbal medicines’, p.414. In another report, a woman with unexplained abnormal menstrual bleeding was found to have a prothrombin time of 53 seconds, and laboratory tests showed that her blood clotting factors were abnormally low. When given parenteral vitamin K her prothrombin time rapidly returned to normal (suggesting that she was taking a vitamin K antagonist of some kind). She strongly denied taking any anticoagulant drugs, but it was eventually discovered that she had been drinking large quantities of a herbal tea containing among other ingredients *tonka beans*, *mellilot* and *sweet woodruff*, all of which might contain natural coumarins, but see ‘Coumarins + Herbal medicines’, p.414.

Importance and management

This case is isolated, but it shows that herbal preparations of this kind might affect anticoagulation. Absorption through the skin appears to be enough to upset the anticoagulant control.1

Coumarins + Herbal medicines; *Quilinggao*

A single case report describes a man who had a marked increase in his INR with bleeding complications, nine days after he switched the brand of quilinggao he was using.
Clinical evidence

A 61-year-old man stabilised on warfarin with an INR in the range of 1.6 to 2.8 was found to have an INR greater than 6 and skin bruising, and complained of gum bleeding and epistaxis in the previous 3 days. For the past 3 years he had taken quillinggao, apparently without problems. However, 9 days previously he had started taking a different brand of quillinggao. He was eventually stabilised on the previous dose of warfarin with an INR of 2.5, but after discharge started taking a third brand of quillinggao, and 3 days later had an INR of 5.2.

Mechanism

Quillinggao is a Chinese herbal product made from a mixture of herbs. The first brand did not contain any herbs suspected to have anticoagulant effects except one with possible antiplatelet activity, but the second brand contained Chinese peony (Paeoniae rubra), Poncirus trifoliata and a couple of other herbs known to contain substances with anticoagulant or antiplatelet effects in vitro, but see also ‘Coumarins + Herbal medicines’, p.414.

Importance and management

This appears to be the only case of a possible interaction, and as such the interaction is not established. Quillinggao did not affect anticoagulant control in this patient for a number of years, and then did after switching brands. Bear the possibility of an interaction in mind.

Coumarins + Herbal medicines; St John’s wort (Hypericum perforatum)

St John’s wort can cause a moderate reduction in the anticoagulant effects of phenprocoumon and warfarin.

Clinical evidence

(a) Phenprocoumon

In a randomised, placebo-controlled crossover study in 10 healthy men,1 St John’s wort extract (LI 160, Lichtwer Pharma) 900 mg daily for 11 days reduced the AUC of a single 12-mg dose of phenprocoumon by a modest 17.4%. There is also a case report of a 75-year-old woman taking warfarin dosage increases of 6.6% and 15% when St John’s wort was added. The INRs of 4 of the patients returned to their former values when the St John’s wort was stopped.4

(b) Warfarin

In a randomised, crossover study in 12 healthy subjects, one tablet of St John’s wort three times daily for 3 weeks modestly decreased the AUC of both R- and S-warfarin by about 25% after a single 25-mg dose of warfarin taken on day 14. In this study, the brand of St John’s wort used was Bioglan tablets, each tablet containing an extract equivalent to 1 g of Hypericum perforatum flowering herb top containing 825 micrograms of hypericin and 12.5 mg of hyperforin.3

The Swedish Medical Products Agency received 7 case reports over the 1998 to 1999 period of patients stabilised on warfarin who showed decreased INRs when St John’s wort was added. Their INRs fell from the normal therapeutic range of about 2 to 4 to about 1.5. Two patients needed warfarin dosage increases of 6.6% and 15% when St John’s wort was added. The INRs of 4 of the patients returned to their former values when the St John’s wort was stopped.4

Mechanism

Uncertain, but it is suggested that the St John’s wort increases the metabolism and clearance of the anticoagulants3,4 possibly by induction of cytochrome P450 isoenzymes. It affected both R- and S-warfarin.5 Oral bioavailability was not altered.3

Importance and management

Information seems to be limited to these reports, but a modest pharmacokinetic interaction is established, which might be clinically important. It would be prudent to monitor the INRs of patients taking phenprocoumon, warfarin or any other coumarin if they start taking St John’s wort, being alert for the need to slightly raise the anticoagulant dosage. However, note that the advice of the CSM in the UK is that St John’s wort should not be used with warfarin. They note that the degree of induction of warfarin metabolism is likely to vary because levels of active ingredients may vary between St John’s wort preparations. If a patient is already taking the combination, they advise checking the INR, stopping St John’s wort and then monitoring the INR closely and adjusting the anticoagulant dosage as necessary.5

Coumarins + Herbal medicines; Vitamin K₁-rich

A man had a rise in his INR after stopping taking a herbal nutritional supplement (Nature’s Life Greens), which contained a number of plants known to be high in vitamin K₁. Another patient had a decrease in INR after starting to drink a plant extract juice (called Noni Juice).

Clinical evidence, mechanism, importance and management

(a) Nature’s Life Greens

A 72-year-old man stabilised on warfarin was found to have an INR of 4.43 at a routine clinic visit, which was increased from 3.07 six weeks previously. The patient had stopped taking a herbal product Nature’s Life Greens that month because he did not have enough money to buy it. He had been taking it for the past 7 years as a vitamin supplement because he had previously been instructed to limit his intake of green leafy vegetables. He was eventually restabilised on warfarin and the same nutritional product.

The product list detailed 25 vegetables without stating the amounts or concentrations, but at least 5 of the listed ingredients are known to contain high levels of vitamin K₁ including parsley, green tea leaves, spinach, broccoli, and cabbage (see also ‘foods; vitamin K–rich’, (p.409)). It is therefore likely it contained sufficient vitamin to antagonize the effect of the warfarin so that when it was stopped the warfarin requirements fell, and without an appropriate adjustment in dose, this resulted in an increased INR.

This case reinforces the view that all patients taking warfarin should seek advice when they want to stop or start any herbal medicine or nutritional supplement.

(b) Plant extracts juices

A 41-year-old woman stabilised on warfarin was found to have an INR of 1.6 at a routine clinic visit. The only possible cause identified was that the patient had begun to drink one to two small glasses daily of Noni Juice 4 Everything. This was identified as a brown liquid that contains extracts and derivateis from more than 115 components. The authors noted that many of the listed plants contained vitamin K and that vitamin K was listed as a separate component, indicating that the juice might be fortified with vitamin K. The patient was given heparin and then discharged on her previous dose of warfarin, and advised to stop taking this brand of juice.2

This case reinforces the view that all patients taking warfarin should seek advice when they want to stop or start any herbal medicine or nutritional supplement.

Coumarins + Herbicides

An isolated report describes a marked increase in the anticoagulant effects of acenocoumarol, with bleeding, caused by use of a herbicide containing thiocarbamates.

Clinical evidence, mechanism, importance and management

A 55-year-old patient with mitral and aortic prostheses, stabilised on acenocoumarol 2 mg daily and with an INR of 3.6 to 4.2 was hospitalised because of severe and uncontrollable gum bleeding. He responded when given a transfusion of fresh plasma. The cause of the marked increase in the anticoagulant effects of the acenocoumarol was eventually identified as almost certainly being due to the use of a herbicide (SATURN-S) containing thiobencarb and molinate (two thiocarbamates), which the patient was using to spray his rice crop. The thiobencarb can be absorbed through the skin and the molinate by inhalation. Just how these two compounds interact with acenocoumarol is not known but the authors of the report suggest that these herbicides may possibly have inhibited the metabolism of the anticoagulant, thereby increasing its effects. The patient was later restabilised on his former dose of acenocoumarol.1

This seems to be the first and only report of this interaction but it highlights one of the possible risks of using chemical sprays that have never been formally tested for their potential to interact with drugs. See also ‘Coumarins + Insecticides’, p.421.

Coumarins + Hormonal contraceptives

One small study found that the acenocoumarol dose requirements were about 20% lower during the use of a combined hormonal contraceptive. An isolated report describes a marked INR increase in the INR of a woman taking warfarin when she was given emergency contraception with levonorgestrel. In contrast, in small single-dose studies in healthy subjects, the anticoagulant effects of dicoumarol and phenprocoumon were slightly decreased by oral contraceptives.

Note that, in general, the indications for the use of oral anticoagulants are contraindications to the use of combined oral contraceptives.

Clinical evidence

(a) Acenocoumarol

The anticoagulant requirements of 12 patients taking acenocoumarol were about 20% lower while they were taking a combined hormonal contraceptive (average 19 months) than when they were not taking the contraceptive (average 12 months). Even then, they were anticoagulated to a higher degree while taking the contraceptive (prothrombin ratio of 1.67 compared with 1.5) than with the anticoagulant alone. The contraceptives used were Neogynona, Microgynon, Eugynon (ethinylestadiol with levonorgestrel) or Topasel (intramuscular estradiol enantate with algestone).1, 2

(b) Dicoumarol

A study in 4 healthy subjects given single 150- or 200-mg doses of dicoumarol on day 17 of a 20-day course of Enovid (noretynodrel and mestranol) found that the anticoagulant effects were decreased in 3 of the 4 subjects, although the dicoumarol half-life remained unaltered.2

(c) Phenprocoumon

In a controlled study in 14 healthy women, the clearance of a single 0.22-mg/kg dose of phenprocoumon was increased by 20% in the 7 subjects taking combined oral contraceptives, compared with that in the 7 not taking oral contraceptives.3

(d) Warfarin

A 39-year-old woman with familial type 1 antithrombin deficiency and a history of extensive deep vein thrombosis and pulmonary embolism, taking warfarin, was given levonorgestrel for emergency contraception. Within 3 days her INR had risen from 2.1 to 8.1. No bleeding occurred. Her INR returned to normal after stopping the warfarin for 2 days.4

Mechanism

Not understood. The oral contraceptives are well known to be associated with a small increased risk of venous thromboembolism in otherwise healthy women, and are therefore contraindicated in women who have had thrombosis. They can apparently increase the metabolism (glucuronidation) of phenprocoumon.3 The authors of the report about levonorgestrel suggest that it might have displaced the warfarin from its binding sites thereby increasing its activity,5 although this mechanism is now generally discounted.

Importance and management

Direct information seems to be limited to these reports. Oral contraceptives are normally contraindicated in those with thromboembolic disorders but if they must be used, be alert for any changes in the anticoagulant response if an oral contraceptive is started or stopped. The report about the apparent interaction between warfarin and postcoital levonorgestrel seems to be isolated and therefore its general importance is unknown.

Coumarins + related drugs + HRT or Tibolone

A retrospective analysis of women starting HRT found that only three needed warfarin dose increases, of about 10 to 30%. A case report describes a woman who needed 75% more acenocoumarol when she was given emergency contraception with levonorgestrel. When her HRT treatment with oral conjugated oestrogens was changed to transdermal estradiol.

Four women taking warfarin and one taking phenindione who started taking tibolone had modest to marked increases in INR and required 12% to 56% reductions in anticoagulant dose. Note that, because of the increased risk of developing venous thromboembolism with HRT, the use of HRT in women already on anticoagulant therapy requires careful consideration of the risks and benefits. Whether tibolone is associated with the same risk is unknown, therefore similar caution would seem prudent.

Clinical evidence

(a) Oestrogens for menopausal HRT

In a retrospective analysis, 18 women were identified who had started HRT while taking warfarin (n=16) or phenindione (n=2). A wide variety of HRT preparations were being used, including topical and oral preparations, oestrogens with or without progestogens, and progestogens alone. Half of the women taking warfarin had no change in their warfarin dose requirement after starting HRT. Five required a less than 10% increase or decrease in average warfarin dose, and 3 required a 12.8%, 22%, and 28% increase in average warfarin dose, the latter two of these being the only 2 women taking oestrogen-only oral HRT. Of the 2 women taking phenindione, one needed no change in dose, and the other a 4.6% increase in dose.4

In one case, a postmenopausal 53-year-old woman needed an increase in her daily dose of acenocoumarol from 2 to 3.5 mg when her HRT was changed from oral conjugated oestrogens 0.625 mg daily to transdermal estradiol 50 micrograms daily. When the oral HRT was restarted, her acenocoumarol requirements returned to their former levels.2

(b) Tibolone

In a retrospective analysis, five women were identified who had started tibolone while taking warfarin or phenindione, and one who discontinued tibolone while taking warfarin. All of the 5 patients had an increase in INR to a range of 4.6 to 9.5 after starting tibolone, and required reductions

Continued
in their anticoagulant dose (range of 12% to 53% reductions in warfarin dose, and 56% for phenindione). The woman who discontinued tibolone required an increase in her warfarin dose from 6 to 7.5 mg daily.1

Mechanism
Not understood. Menopausal HRT alone is now known to be associated with a small increased risk of venous thromboembolism. Tibolone alone increases fibrinolytic activity without altering prothrombin time,1 and might therefore be expected to increase the risk of bleeding with anticoagulants. However, this would not result in raised INRs, and it was suggested that the effect on the INR might be because of the androgenic effect of tibolone causing a reduction in factor VIIa.1

Importance and management
Published information on concurrent use of warfarin and HRT or tibolone appears to be very limited. The retrospective study suggests that usually HRT causes no or only minor changes in warfarin requirements, whereas tibolone causes more marked increases in INR and reduced warfarin requirements of up to about 50%.1 Because of this, increased monitoring of the INR on starting tibolone in patients stabilised on warfarin, other coumarins, or indanediones is required. Note that, because of the increased risk of developing venous thromboembolism with HRT, the use of HRT in women already taking an anticoagulant requires careful consideration of the risks and benefits. Whether tibolone is associated with the same risk is unknown,4 therefore similar caution would seem prudent.1

Effect on anticoagulant control
About 15 studies of the effect of influenza vaccine on the anticoagulant effect of coumarins have been published, and these are summarised in ‘Table 12.4’, (p.420). Most of these are non-controlled studies in small to moderate numbers of patients, and the majority were unable to demonstrate a significant change in prothrombin time or INR in patients taking coumarins, including the only randomised placebo-controlled study. Some studies found a slight change in anticoagulant effect (both slight increases and slight reductions), but they are probably of limited clinical relevance. However, in one larger case-control study, a clear increase in INR from 2.64 to 3.85 was seen in about half of the 90 patients, and 2 of these had bleeding episodes. The reasons for the clear difference between this study and the many others are not known.

There are also various brief case reports of a possible interaction. In one review paper, there is a very brief report of a patient receiving warfarin who had serious bleeding, which was almost fatal, after receiving a ‘flu shot’. No further details are given.1 An elderly man receiving warfarin developed bleeding (haematemesis and melaena) within 10 days of being given an influenza vaccination. His prothrombin time was found to be 36 seconds.2 Another patient taking warfarin had raised INRs in two successive years when an influenza vaccination was given.3

Route of injection of vaccine
In a randomised study in 26 patients stabilised on warfarin, there was no difference in injection site adverse events between intramuscular or subcutaneous injection of a standard trivalent influenza vaccine, and no patient had bruising or swelling. In addition, both routes of administration produced similar levels of antibody titres.4 In another study that specifically assessed the local reactions to intramuscular influenza vaccination, there were no detectable local complications after intramuscular injection, including no change in arm circumference.5

Mechanism
Not understood. In a placebo-controlled study in healthy subjects, influenza vaccine did not alter the half-life of either R- or S-warfarin.2 It has therefore been suggested that when an interaction occurs the synthesis of the blood clotting factors is altered.2

Importance and management
A well-investigated interaction, but with some contradictory data. The weight of evidence shows that influenza vaccination in those taking warfarin is normally safe and uneventful, nevertheless it would be prudent to be on the alert because very occasionally and unpredictably bleeding may occur. Acenocoumarol appears not to be affected. Limited evidence suggests that intramuscular administration is not associated with increased local complications, but also that subcutaneous administration is effective. Because of the theoretical risk of local muscle haematoma, it may be preferable to give influenza vaccines by deep subcutaneous injection in patients taking coumarins and related anticoagulants.

Clinical evidence

(a) Acenocoumarol

A farmer in Spain, normally well stabilised on acenocoumarol and amiodarone, had marked rises in his INR, from 3.5 up to 7.9, requiring a reduction in his anticoagulant dosage (from 12 to 8 mg weekly), which occurred during the summer months. No bleeding occurred. It was then discovered that he was using insecticides containing ivermectin and an organophosphate methidathion on his trees without any protective clothing.1

(b) Warfarin

A rancher in the USA, who was taking warfarin, had a very marked reduction in his anticoagulant response after dusting his sheep with an insecticide containing 5% toxaphene (camphechlor) and 1% lindane (gamma-benzene hexachloride). Over a 2-year period he had periods of considerable warfarin resistance, which were linked to the use of this insecticide. Normally warfarin 7.5 mg daily maintained his prothrombin time in the therapeutic range, but after exposure to the insecticide even 15 mg daily failed to have any effect at all.2 The dusting was done by putting the insecticide in a sack and hitting the sheep with it in an enclosed barn.2

Mechanism

The interaction between acenocoumarol and ivermectin with methidathion is not understood. When used on its own, ivermectin used for onchocerciasis normally has no effect on prothrombin times,3,4 but two unexplained cases of prolonged prothrombin times associated with the development of haematomas have been reported.5 Methidathion is an organophosphate. Lindane and other chlorinated hydrocarbon insecticides are known liver enzyme inducers,6 which increase the metabolism and clearance of the warfarin, thereby reducing or even abolishing its effects.

Importance and management

Information about these interactions appears to be limited to these isolated case reports. Neither interaction is well established and neither would appear to be of general clinical importance. The chlorinated hydrocarbon insecticides have been withdrawn from general use in most countries so that the possibility of an interaction with any anticoagulant is now very small. No other cases of an interaction between an anticoagulant and ivermectin, whether used as an insecticide or for the treatment of onchocerciasis, appear to have been reported.

As a general rule, farm workers and others should use proper protection (gloves, masks, protective clothing) if they are exposed to substantial amounts of any insecticide, because these can be both directly toxic and can also apparently interact with some prescribed drugs, including the anticoagulants, even if only very rarely.

Coumarins + Ispaghula (Psyllium)

Ispaghula (psyllium) did not affect either the absorption or the anticoagulant effects of warfarin in one study. A cohort study also found no evidence of an interaction in patients taking acenocoumarol or phenprocoumon.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects, ispaghula (given as a 14-g dose of colloidal (Metamucil) in a small amount of water with a single 40-mg dose of warfarin, and three further doses of ispaghula every 2 hours thereafter) did not affect either the absorption or the anticoagulant effects of the warfarin.1 Similarly, in a population-based cohort study in patients taking acenocoumarol or phenprocoumon, there was no increased risk of over-anticoagulation (INR greater than 6) associated with the use of ispaghula (psyllium seeds), although the number of people treated was small.1,2 No alteration of the anticoagulant response would therefore be expected on concurrent use.

Coumarins + Lanthanum

Lanthanum did not alter the pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study in healthy subjects, lanthanum (3 doses of 1 g the day before warfarin, then 1 g thirty minutes before warfarin) had no effect on the pharmacokinetics of a single dose of warfarin.1 Lanthanum is a phosphate-binding drug, and does not appear to alter warfarin absorption. This suggests that no warfarin dose adjustments are expected to be needed on concurrent use. However, note that the pharmacodynamics of warfarin (e.g. the effects on INR) were not assessed in this study.

Coumarins + Interferons

Isolated case reports indicate that the effects of acenocoumarol and warfarin may be increased by interferons.

Clinical evidence

A woman stabilised on long-term warfarin 2.5 to 3.5 mg daily had a prothrombin time rise from 16.7 to 20.4 seconds after receiving 6 million units of interferon-alpha daily for 10 days, then three times a week. Her serum warfarin levels rose from about 0.8 to 5.2 micrograms/mL. She responded to a reduction in the warfarin dosage to 2 mg daily. The authors of the report also say that they have seen 4 other patients taking warfarin who needed a dosage reduction when given interferon, two of them while taking interferon beta and the other two while taking interferon alfa-2b.1 A woman taking acenocoumarol 1 and 2 mg on alternate days had gingival bleeding and a thrombotest change from 35% to 19% (indicating an increased anticoagulant effect) within 6 weeks of starting treatment with 3 million units of interferon-alpha 2b three times weekly. Her thrombotest percentages stabilised between 25 and 40% when the acenocoumarol dosage was reduced to 1 mg daily. A later reduction in the interferon dosage caused a decrease in the anticoagulant effects of acenocoumarol.2

Mechanism

Not understood. The authors of both reports suggest that interferon reduces the metabolism of the anticoagulants by the liver, thereby reducing their clearance and increasing their effects.1,2

Importance and management

These reports seem to be the only ones to describe this interaction so the interaction is not yet established. However it would seem prudent to monitor the effects if interferon is given to patients taking coumarins, reducing the dosage if necessary. For a case of decreased warfarin effects in a patient given interferon alfa-2b and ribavirin, see ‘Coumarins + Ribavirin’, p.447.

Coumarins + Lanthanum

Lanthanum did not alter the pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study in healthy subjects, lanthanum (3 doses of 1 g the day before warfarin, then 1 g thirty minutes before warfarin) had no effect on the pharmacokinetics of a single dose of warfarin.1 Lanthanum is a phosphate-binding drug, and does not appear to alter warfarin absorption. This suggests that no warfarin dose adjustments are expected to be needed on concurrent use. However, note that the pharmacodynamics of warfarin (e.g. the effects on INR) were not assessed in this study.

In a study, lasofoxifene caused a minor 16% decrease in prothrombin time without changing warfarin pharmacokinetics.

Clinical evidence, mechanism, importance and management
In 12 healthy postmenopausal women, lasofoxifene 4 mg on day one then 500 micrograms daily for 13 days had no effect on the pharmacokinetics of \( R \)- or \( S \)-warfarin when a single 20-mg dose of warfarin was given on day 8. Conversely, the maximum prothrombin time was decreased by 16%, with a similar decrease in maximum INR from 1.9 to 1.6.1

Because this slight decrease in warfarin effects has been seen with ‘raloxifene’, (p.446), the authors suggested that it might be because oestrogenic compounds increase plasma concentrations of vitamin K-dependent clotting factors.1

The authors suggest that the small decrease in warfarin effect with lasofoxifene may not be clinically relevant. Nevertheless, they say that until more data are available on longer-term concurrent use, it is recommended that prothrombin time should be monitored when starting or stopping lasofoxifene.1 This seems a sensible precaution.

In one cohort study, the long-term use of lactulose appeared to be associated with an increased risk of overanticoagulation. Limited evidence suggested no interaction occurred with liquid paraffin or colocynt.

Clinical evidence
In a population-based cohort study in patients taking acenocoumarol or phenprocoumon, lactulose significantly increased the risk of over-anticoagulation (INR greater than 6) (relative risk of 3.4, range 2.2 to 5.3). When analysed by duration of use, less than 27 days use of lactulose actually decreased the risk of over-anticoagulation, whereas longer use was associated with an increased risk. In this study, neither liquid paraffin nor colocynt preparations were associated with an increased risk of over-anticoagulation, but numbers of patients treated with these drugs was small.1

Mechanism
In theory, drugs that shorten gastrointestinal transit time such as laxatives and liquid paraffin (mineral oil) might be expected to decrease the absorption of both vitamin K and the oral anticoagulants. Decreasing the absorption of vitamin K would be expected to increase the effect of oral anticoagulants, which could be offset by the decrease in absorption of oral anticoagulants. In the case of short-term lactulose use, it was suggested that decreasing the colonic pH might have increased the absorption of vitamin K, thereby reducing the effect of the anticoagulant. On longer term use, it was postulated that lactulose might reduce faecal flora that produce vitamin K, so increasing the risk of over-anticoagulation.1 Liquid paraffin might also be expected to impair the absorption of vitamin K.

Importance and management
The cohort study cited appears to be the first and only evidence of a possible interaction with laxatives, and it suggests that long-term use of lactulose may increase the effect of coumarins. This finding requires confirmation in a controlled pharmacological study. Until further data are available, it may be prudent to consider the possibility of an interaction in anybody taking lactulose long-term. Limited evidence suggested no interaction occurred with liquid paraffin or colocynt. Clinical evidence for an interaction with other laxatives is lacking, despite the theoretical considerations.

There are a few reports of increased INRs, some with bleeding complications, in patients taking warfarin with leflunomide.

Clinical evidence, mechanism, importance and management
A short report describes a patient taking warfarin whose INR rose from 2.5 to over 6, resulting in a hospital admission, shortly after she started taking leflunomide (3 days of 100 mg daily).1

Another report describes a patient taking warfarin who developed haematuria after taking leflunomide 100 mg daily for 2 days. His INR was found to have risen from 3.4 to over 11, and warfarin was discontinued. The haematuria spontaneously resolved, but as the INR remained elevated for the next 2 days he was given 1 mg of vitamin K, which brought his INR down to 1.9. He was later stabilised on warfarin 1 mg daily with a leflunomide maintenance dose of 20 mg daily.2 The authors of this report stated that at that time (2002) the CSM in the UK had received over 300 reports of leflunomide raising the INRs of patients taking warfarin; however, this was an error, and it should have read that of 300 reports of raised INRs with warfarin and another drug, four reports related to leflunomide.3 An additional case describes a patient who required a 22% decrease in her weekly warfarin dose after starting leflunomide.4

The manufacturers of leflunomide note that in vitro, the active metabolite of leflunomide inhibits the cytochrome P450 isozyme CYP2C9. They therefore advise caution if leflunomide is given with drugs metabolised by CYP2C9, of which they give warfarin and phenprocoumon as examples.5 On the basis of the cases seen, it would seem prudent to monitor the INR of any patient taking a coumarin anticoagulant who is started on leflunomide.

Zafirlukast increases the anticoagulant effects of warfarin and bleeding has been seen. Pranlukast is predicted to interact similarly. In contrast, montelukast did not alter the pharmacokinetics or anticoagulant effects of single-dose warfarin.

Clinical evidence
(a) Montelukast
In a double-blind, placebo-controlled, randomised study, 12 healthy subjects were given oral montelukast 10 mg daily for 12 days and a single 30-mg dose of warfarin on day 7. It was found that the pharmacokinetics of the warfarin were virtually unchanged by the montelukast, and prothrombin times and INRs were not significantly altered.1

(b) Zafirlukast
In a placebo-controlled study, 16 healthy subjects taking zafirlukast 80 mg twice daily for 10 days were given a single 25-mg dose of warfarin on day 5. The mean AUC of \( S \)-warfarin was increased by 63% and the half-life by 36%, but the pharmacokinetics of \( R \)-warfarin were not significantly changed. The mean prothrombin time increased by 35%.2

An 85-year-old woman taking warfarin, salbutamol (albuterol), diltiazem, digoxin, furosemide and potassium was admitted to hospital with various cardiac-related problems and bleeding (epistaxis, melena, multiple bruising), which was attributed to the use of zafirlukast 20 mg twice daily. Her INR had risen from 1.1 (measured 6 months previously) to 4.5. The report does not say how long she had been taking the both drugs together.3

Mechanism

The reason for the interaction is thought to be that the zafirlukast inhibits the cytochrome P450 isoenzyme CYP2C9, which metabolises S-warfarin. In vitro studies suggest that pranlukast has a similar effect.

Importance and management

Information appears to be limited to these reports but the interaction with zafirlukast would seem to be established. If zafirlukast is given to patients stabilised on warfarin, monitor prothrombin times well and be alert for the need to reduce the warfarin dosage to avoid over-anticoagulation. Other coumarins might be expected to be affected similarly. Pranlukast is also predicted to interact, as it is also an inhibitor of CYP2C9. In contrast, montelukast does not appear to interact with warfarin, and no warfarin dose adjustments are predicted to be needed on concurrent use.

Coumarins + Levitracetam

In a controlled study, levetiracetam did not alter the pharmacokinetics or pharmacodynamics of warfarin.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, placebo-controlled study in 42 healthy subjects stabilised on warfarin, levetiracetam 1 g twice daily for 7 days had no significant effect on the pharmacokinetics of R- or S-warfarin and the INRs were not significantly altered. No warfarin dose adjustments would therefore be expected to be needed on concurrent use.

Coumarins + MAOIs or RIMAs

Although some animal data show that the non-selective MAOIs increase the effects of some oral anticoagulants, there appears to be no clinical evidence of an interaction. Moclobemide did not interact with phenprocoumon in a pharmacological study.

Clinical evidence, mechanism, importance and management

A number of studies in animals have shown that some of the non-selective MAOIs can increase the effects of some oral anticoagulants. However, there appear to be no clinical studies or case reports of this interaction, and therefore no special precautions seem to be necessary. A study in healthy subjects found that moclobemide 200 mg three times daily for 7 days did not alter the anticoagulant effects of steady-state phenprocoumon.

Coumarins + Medroxyprogesterone acetate or Megestrol

High-dose medroxyprogesterone acetate and megestrol prolonged the half-life of single-dose warfarin in one small study in patients with advanced breast cancer. There is also a case of increased bleeding times when megestrol was given with unnamed anticoagulants.

Clinical evidence, mechanism, importance and management

In a study in patients with advanced breast cancer, a single 0.3-mg/kg dose of warfarin were given to 2 patients before and after oral medroxyprogesterone acetate 500 mg twice daily for 5 weeks and to 2 patients before and after megestrol 160 mg daily for 5 weeks. The half-life of warfarin was increased by 71% and the clearance decreased by 35%. A bulletin includes a brief mention of increased bleeding times in a patient taking unnamed anticoagulants and given megestrol (dose not stated).

Although the evidence is limited, what is known suggests that it would be prudent to monitor prothrombin times in patients taking warfarin who are high-dose medroxyprogesterone acetate or megestrol, being alert for any increased warfarin effects.

Coumarins + Mefloquine

The effects of warfarin and an unnamed coumarin were increased in two patients who took mefloquine.

Clinical evidence, mechanism, importance and management

A 66-year-old man taking warfarin and various other drugs presented to an emergency department unwell with a distended abdomen while travelling in Kenya. His prothrombin time was grossly prolonged and the distension was found to be due to bleeding. One week before travel he had started mefloquine 250 mg weekly without a check of his prothrombin time. He was given subcutaneous enoxaparin instead of warfarin while continuing the mefloquine. Another patient taking a coumarin and oral antidiabetics presented with hypoglycaemia and a large haematoma of the right leg after taking 3 doses of mefloquine 250 mg weekly. His INR was 6.4.

The author considered that mefloquine may have caused the increased anticoagulation in these two cases, and suggested that mefloquine should be started several weeks before travel to allow for monitoring of any changes in anticoagulant effects. The manufacturers of mefloquine also recommend that, before departure, travellers also taking anticoagulants should be checked for any alteration in their effect. This is probably prudent, although patients should be advised that many other factors to do with travel such as altered diet could contribute to a change in anticoagulant control.

Coumarins + Menthol lozenges

A man had a reduction in the effects of warfarin, which were attributed to the use of menthol cough lozenges during a flu-like illness.

Clinical evidence, mechanism, importance and management

A 57-year-old man taking warfarin 49 mg weekly with an INR in the range of 2.28 to 2.68 for the previous 3 weeks was found to have an INR of 1.45. He had been unwell with a flu-like illness over the past week, for which he had been taking about 6 Halls menthol cough lozenges (cough
drops) per day for 4 days. He said he had not changed his diet or missed any warfarin doses. The warfarin dose was increased to 53 mg weekly for a week with an INR rise to 2.2, then the warfarin dose was decreased to 52 mg weekly with an INR of 3.06, so the previous dose of 49 mg weekly was resumed with an INR of 2.92.1 Whether this case represents an interaction with the menthol lozenges is uncertain. Further study is needed.

### Coumarins + Meprobamate

The anticoagulant effects of warfarin are not altered to a clinically relevant extent by meprobamate.

Meprobamate 400 mg four times daily for 2 weeks was given to 9 patients stabilised on warfarin. Three of them showed a small increase in prothrombin times, five a small decrease and one remained unaffected: all the changes were considered to fall within the range of variations normally seen in clinical practice.1 Moreover, in a later placebo-controlled study in 17 patients taking warfarin, the 8 patients who were also given meprobamate 2.4 g daily for 4 weeks showed only a small clinically unimportant reduction in prothrombin times.2 Similar results were found in another study.3 No warfarin dose adjustments would therefore seem to be needed if meprobamate is added to established treatment with warfarin.

### Coumarins + Mesalazine (Mesalamine) or Sulfasalazine

A single case report describes reduced warfarin effects in a patient given mesalazine. Another single case report describes a marked reduction in the response to warfarin when mesalazine was switched to sulfasalazine.

#### Clinical evidence

**Mesalazine**

A woman stabilised on warfarin 5 mg daily, with INRs between 2 and 3, started taking mesalazine 800 mg three times daily for the treatment of a caecal ulcer. Four weeks later she presented to hospital with left leg pain, which was diagnosed as an acute popliteal vein thrombosis, and at the same time it was found that her prothrombin time and INR had fallen to 11.3 seconds and 0.9, respectively. The patient was treated with intravenous heparin. Over the next 10 days INRs of up to 1.7 were achieved by increasing the doses of warfarin up to 10 mg daily, but a satisfactory INR of 2.1 was only reached when the mesalazine was stopped. The report says that serum warfarin levels were not detectable during the use of mesalazine.1 For discussion of a patient who had a reduction in the response to warfarin when switched from mesalazine to sulfasalazine, see below.

**Sulfasalazine**

A 37-year-old woman taking warfarin 30 mg weekly with stable INRs between 2 and 3 in the previous 2 years (and also taking beclometasone, salbutamol, aspirin, azathioprine, ethylniostroadiol/norgestrel), had her treatment for arthritis and ulcerative colitis changed from mesalazine to sulfasalazine 1 g four times daily. The day after the change her INR was found to be subtherapeutic (1.5) and she needed numerous increases in the warfarin doses over the next 6 weeks, eventually needing warfarin 75 mg weekly before acceptable INRs were achieved. During this period she developed a new deep vein thrombosis. When the sulfasalazine was later stopped and the mesalazine restarted, her warfarin dosage requirements dropped to 45 mg weekly.2

### Mechanism

Not understood. Sulfasalazine is broken down in the colon to a sulfonamide, sulfapyridine, and 5-aminosalicylic acid (mesalazine). Some ‘sulfonamides’, (p.376) are known inhibitors of warfarin metabolism, and increase the effects of warfarin. In contrast, in the case with sulfasalazine a marked decrease was noted.

### Importance and management

Not established. The case of a reduction in effect of warfarin on starting mesalazine appears to be the first and only report of an interaction, which suggests that it is unlikely to be of general importance. Similarly, the case when mesalazine was switched to sulfasalazine is an unexplained and isolated case, and its validity has been debated.3,4 There are no other reports in the literature and this possible interaction also seems unlikely to be of general importance. Consider these cases in the event of an unexpected response to treatment.

### Coumarins + Methaqualone

Methaqualone may cause a very small and clinically unimportant reduction in the anticoagulant effects of warfarin.

#### Clinical evidence, mechanism, importance and management

The average prothrombin time of 10 patients stabilised on warfarin was 20.9 seconds before, 20.4 seconds during, and 19.6 seconds after taking methaqualone 300 mg at bedtime for 4 weeks.1 The plasma warfarin levels of another patient were unaffected by methaqualone, although there was some evidence that enzyme induction had occurred.2 Methaqualone has some enzyme-inducing effects so that any small changes in prothrombin times reflect a limited increase in the metabolism and clearance of warfarin, but these appear to be too small to be of clinical significance.2,3 No special precautions seem to be necessary.

### Coumarins + Methylphenidate

Methylphenidate appears not to interact with ethyl biscoumacetate.

#### Clinical evidence, mechanism, importance and management

In one study in 4 healthy subjects, the half-life of a single dose of ethyl biscoumacetate was approximately doubled after they took methylphenidate 20 mg daily for 3 to 5 days.1 However, a later double-blind, placebo-controlled study failed to confirm this interaction: the half-life of ethyl biscoumacetate was not altered by methylphenidate 20 mg daily for 4 days in 4 healthy subjects, and was not different to that seen in 4 subjects given placebo.2 The first authors suggested that methylphenidate inhibits the metabolism of the oral anticoagulant, but this seems unlikely given the findings of the second study.

Although the findings of these 2 studies are at odds with each other, the better-controlled study and the lack of reports of problems in the literature suggest that an interaction is unlikely. There does not seem to be any information about other anticoagulants. Nevertheless the manufacturers recommend caution and suggest that patients taking coumarins should have their INR monitored if methylphenidate is started or stopped.3

Metoclopramide caused a small decrease in the AUC of phenprocoumon, without altering its anticoagulant effects seemed to occur.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, metoclopramide 30 mg daily for 10 days slightly reduced the AUC of a single dose of phenprocoumon given on day 4 by 16%, but no significant changes were seen in the anticoagulant effects.1 This suggests that no phenprocoumon dose adjustment would be expected to be necessary if these two drugs are given together. There seems to be no information about any other anticoagulant.

Coumarins + Metrifonate

Metrifonate did not interact with single-dose warfarin in one study.

Clinical evidence, mechanism, importance and management

A double-blind, placebo-controlled, crossover study in 14 healthy subjects found that metrifonate 50 mg daily for 8 days did not change the pharmacokinetics and pharmacodynamics of a single 25-mg dose of warfarin given on day 4. Plasma warfarin levels and prothrombin times remained unchanged.1 This suggests that no warfarin dose adjustments are needed if these two drugs are used concurrently. Information about other anticoagulants is lacking.

Coumarins + Misoprostol

A reduction in the anticoagulant effects of acenocoumarol has been attributed to the use of misoprostol in one patient.

Clinical evidence, mechanism, importance and management

A 39-year-old woman taking acenocoumarol, celiprolol, triostramene, clozthiazide, pravastatin and diosmin had a rise in her prothrombin levels from 0.3 to 1 within 8 days of starting to take diclofenac and misoprostol 400 micrograms daily. A day after these two drugs had been withdrawn, her prothrombin level had fallen to 0.67, and after another 3 days to 0.32.1 The reasons for this reaction are not known, but suspicion falls on the misoprostol. This suggests that no misoprostol should cause these changes is not clear.

This is an isolated case, complicated by the presence of a number of other drugs, which suggests that it is unlikely to be of general importance. More study is needed.

Coumarins + Moracizine

Moracizine did not alter the pharmacodynamics of single-dose warfarin, and the only pharmacokinetic change was a slight decrease in half-life. An isolated report describes bleeding in a patient taking warfarin with moracizine.

Clinical evidence

In a study in 12 healthy subjects, moracizine 250 mg every 8 hours for 21 days caused little or no change in the pharmacokinetics of a single 25-mg dose of warfarin given on day 14. There was only a slight decrease in the warfarin elimination half-life, from 37.6 to 34.2 hours, and no change in prothrombin times.1,2 The manufacturer also noted that clinical experience in 34 patients showed that no significant changes in warfarin dosage requirements were needed after moracizine was started.1

However, in one case report the prothrombin time of a woman taking warfarin, digoxin, captopril and prednisone rose from a range of 15 to 20 seconds up to 41 seconds within 4 days of starting moracizine 300 mg three times daily. She bled (haematemesis, haematuria), but responded rapidly to withdrawal of the warfarin and moracizine, and the administration of phytonadione.3

Mechanism

Not understood.

Importance and management

Information appears to be limited to these reports. The study and early clinical experience suggest that no interaction occurs. The case of an increased effect seems to be an isolated report, and therefore unlikely to be of general importance.

Mechanism

Unknown.

Importance and management

The incidence of this interaction is unknown. All the evidence suggests that some patients require a moderate increase in warfarin dose when starting trazodone. Be aware of this interaction in all patients taking warfarin if trazodone is started or stopped, and adjust the dosage if necessary. The interaction can occur within a few days. The clinical relevance of the 12% decrease in S-warfarin levels see with nefazodone is likely to be minor. The authors of the study concluded that no change in warfarin dose is likely to be required on concurrent use.1

Coumarins + Nevirapine

One report of 3 cases suggests that warfarin requirements are markedly increased by nevirapine.

Clinical evidence, mechanism, importance and management

A man taking warfarin 2.5 mg daily (INR 2.1 to 2.4) needed a doubled warfarin dose when his treatment with zidovudine and didanosine was replaced by stavudine, lamivudine and nevirapine. A few days later when his treatment was again changed (to stavudine, lamivudine and saquinavir) his original warfarin dosage was found to be adequate. Another patient was resistant to doses of warfarin of up to 17 mg daily while taking zidovudine, lamivudine and nevirapine, but he responded to warfarin 5 mg daily when the nevirapine was withdrawn. The warfarin dosage had to be raised to 12 mg daily when nevirapine was restarted. Yet another patient showed resistance to warfarin while taking nevirapine.1

Nevirapine is a known enzyme inducer, and therefore possibly induces the enzymes concerned with the metabolism of the warfarin. Information seems to be limited to these three cases, but it would be prudent to monitor prothrombin times and INRs in any patient if warfarin and nevirapine are used concurrently, being alert for the need to increase the warfarin dosage (possibly twofold). Information about other oral anticoagulants seems to be lacking, but if the suggested mechanism is correct, all coumarins would be expected to interact to some extent.2

Coumarins and related drugs + NSAIDs

Combined use of NSAIDs and coumarin anticoagulants increases the risk of gastrointestinal haemorrhage. Care is needed with the combination. Some individual NSAIDs also alter the pharmacokinetics of warfarin, and these effects are covered in specific monographs that follow.

Clinical evidence

(a) Gastrointestinal bleeding

In a retrospective cohort study of patients hospitalised for peptic ulcer disease, combined current use of both oral anticoagulants and NSAIDs was associated with a marked increase in the risk of haemorrhagic peptic ulcer disease of 12.7 (95% confidence interval 6.3 to 25.7). This was much higher than the risk associated with NSAIDs alone or oral anticoagulants alone (both about a fourfold increased risk). In this study, about 10% of the hospitalisations for haemorrhagic peptic ulcer disease in patients taking anticoagulants were attributed to the concurrent use of NSAIDs. The oral anticoagulants used were the coumarins warfarin, phenprocoumon and acenocoumarol, and the indanediones phenindione and anisindione. The NSAIDs used were nonacetylated salicylates, ibuprofen, indometacin, sulindac, naproxen, fenoprofen, piroxicam, tolmelin, and meclofenamate.3

In a case-control study, patients taking warfarin who were admitted to hospital with upper gastrointestinal haemorrhage were significantly more likely to be taking non-selective NSAIDs (odds ratio 1.9). A similar increased risk was seen with the ‘coxibs’, (p.428), celecoxib and rofecoxib.2 Similarly, in a questionnaire-based study, 12.2% of patients taking acenocoumarol or phenprocoumon who had a bleeding complication were found to have used an NSAID in the previous month compared with only 2.5% of coumarin users who did not have a bleed (an increased relative risk of bleeding of 5.8). The NSAIDs used in the patients with bleeding complications were diclofenac (more than 50% patients), ibuprofen, indometacin, naproxen (all 10 to 12%), ketoprofen, piroxicam, and tiaprofenic acid (all 1 to 6%). The specific NSAIDs and the frequency of their use were similar in the patients without bleeds.3

(b) Pharmacokinetic interactions

‘Phenylbutazone’ (p.434) and related drugs are well known to inhibit the metabolism of warfarin by the cytochrome P450 isozyme CYP2C9. Few other NSAIDs are known CYP2C9 inhibitors; however; many are CYP2C9 substrates. In one cohort study in patients taking acenocoumarol or phenprocoumon, use of NSAIDs that are known substrates of CYP2C9 (celecoxib, diclofenac, flurbiprofen, ibuprofen, indometacin, ketoprofen, meloxicam, naproxen and piroxicam) slightly increased the risk of over-anticoagulation (INR greater than 6) in patients with wild-type CYP2C9 (relative risk 1.69). However, the risk was greater in patients with variant CYP2C9 (relative risk 2.28), and particularly high in those with *3 variant alleles (relative risk 10.8).4 In another smaller retrospective cohort study, starting the CYP2C9 substrates diclofenac, naproxen, or ibuprofen increased the INR above the therapeutic range in 52 of 112 patients taking acenocoumarol. However, in this study CYP2C9 genotype did not influence the interaction between acenocoumarol and diclofenac, naproxen, and ibuprofen.5 For more general information, see ‘Genetic factors in drug metabolism’, (p.4).

Mechanism

NSAIDs, to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Many also have antiplatelet activity, which can affect bleeding times.

Some NSAIDs are inhibitors of the cytochrome P450 isozyme CYP2C9, and inhibit the metabolism of warfarin via this isoenzyme. There is also possibly a pharmacokinetic interaction with NSAIDs that are substrates for CYP2C9. People with variant CYP2C9 (about 5 to 11% of Caucasians) have a lower metabolising capacity for warfarin, and require much lower maintenance doses. It is possible that use of an NSAID that is a CYP2C9 substrate may result in reduced warfarin metabolism, although this requires confirmation in controlled studies.

Importance and management

The available data indicate that the risk of bleeding is increased if NSAIDs are used in patients taking coumarin or indanedione anticoagulants. For this reason, it would be prudent to avoid the unnecessary concurrent use of NSAIDs when simple analgesics will do. When concurrent use is necessary, extra caution may be appropriate. Further study is required to ascertain whether people with CYP2C9 poor metabolising capacity are at increased risk of an interaction when given NSAIDs that are CYP2C9 substrates.

**Coumarins + NSAIDs; Benzydamine**

Oral benzydamine did not alter the anticoagulant effects of phenprocoumon. Topical formulations (mouthwash and spray) would not be expected to interact.

**Clinical evidence, mechanism, importance and management**

In 10 patients stabilised on phenprocoumon, the anticoagulant response was not significantly changed by benzydamine 50 mg three times daily for 2 weeks, although there was some evidence of an increase in blood levels of the anticoagulant. This suggests that no phenprocoumon dosage adjustments are likely to be needed on concurrent use. Note that benzydamine tends to be used as a topical mouthwash or spray. Neither of these topical formulations would be expected to interact.

**Coumarins + NSAIDs; Clonixin**

Clonixin lysine did not alter the anticoagulant effects of phenprocoumon in a pharmacological study. However, note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

**Clinical evidence, mechanism, importance and management**

In a randomised, crossover study in 12 healthy men, the pharmacokinetics and the anticoagulant activity of a single 18-mg dose of phenprocoumon were unchanged by clonixin lysine 125 mg five times daily, given for 3 days before and for 13 days after the phenprocoumon. On the basis of this study, no adjustment in coumarin dose would be expected to be needed when clonixin is used. However, care is still needed with every NSAID, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information, see ‘NSAIDs’, (p.427).

**Coumarins and related drugs + NSAIDs; Coxibs**

Etoricoxib, lumiracoxib and rofecoxib caused a slight 8% to 15% increase in the INR in response to warfarin, whereas celecoxib and parecoxib had no effect. However, raised INRs accompanied by bleeding, particularly in the elderly, have been attributed to the use of warfarin and celecoxib or rofecoxib in other reports. In addition, in a case-control study in patients taking warfarin, the use of celecoxib or rocoxib was associated with an increased risk of hospitalisation for upper gastrointestinal haemorrhage, which was of a similar magnitude to that seen with non-selective NSAIDs.

**Clinical evidence**

(a) Celecoxib

In a placebo-controlled study, warfarin 2 to 5 mg daily was given to 24 healthy subjects to maintain a stable prothrombin time of 1.2 to 1.7 times their pretreatment values for at least 3 consecutive days. They were then given placebo or celecoxib 200 mg twice daily for a week. It was found that the steady-state pharmacokinetics of both S- and R-warfarin and the prothrombin times were unchanged by the presence of the celecoxib. However, in 16 patients stabilised on warfarin and given celecoxib 200 mg daily for 3 weeks, the INR increased by 13%, 6% and 5% at week 1, 2 and 3, respectively, the change at week 1 being statistically significant. In another analysis, 28 patients taking warfarin who were prescribed either celecoxib or rocoxib, 13 had increases in their INR, of which 7 (5 taking celecoxib) had no other explanation for the INR increase other than the coxib. The average increase in INR in these 7 patients was 1.5, and 1 patient had bruising and epistaxis and required treatment with phytonenadione.

Case reports of an interaction have also been published. In one report, an 88-year-old woman stabilised on warfarin had a rise in her INR from 3.1 to 5.8 when celecoxib 200 mg daily was substituted for diclofenac. After several warfarin dosage adjustments she was later stabilised on a 25% lower warfarin dose. There is a similar case report of a 77-year-old patient who required a 10% decrease in warfarin dosage to maintain her target INR when celecoxib 100 mg twice daily was also given. In another case, the patient was shown to have a variant of CYPT2C9, with lower metabolising capacity, which was thought to explain the interaction, see also ‘Mechanism’, below. The manufacturers also noted that bleeding events have been reported with this combination, predominantly in the elderly, which led to a change in the product labelling. A 2001 report from the Australian Adverse Drug Reactions Advisory Committee noted they had received 21 reports of increases in the INR in patients taking warfarin with celecoxib since the introduction of celecoxib in October 1999. Six of these cases reported bleeding complications. In addition, they had 11 cases of bleeding in patients taking the combined, with no reference to INR, or with an unchanged INR in one case. A review of adverse effects of coxibs mentioned 2 patients taking warfarin who had increases in their INR while taking celecoxib.

Moreover, in a case-control study, patients taking warfarin and admitted to hospital with upper gastrointestinal haemorrhage were significantly more likely to be also taking celecoxib (odds ratio 1.7). A similar increased risk was seen with rofecoxib and non-selective ‘NSAIDs’, (p.427). In a retrospective analysis, the relative risk of all bleeding complications was slightly increased (1.34) in 123 patients taking celecoxib with warfarin when compared with 1022 control patients taking warfarin alone.

(b) Etoricoxib

The manufacturer notes that in healthy subjects stabilised on warfarin, etoricoxib 120 mg daily increased the INR by about 13%.

(c) Lumiracoxib

The manufacturer notes that in healthy subjects stabilised on warfarin, lumiracoxib 400 mg daily increased the INR by about 15%.

(d) Parecoxib

In a randomised study in healthy subjects given warfarin, the use of intravenous parecoxib 10 mg twice daily for 7 days had no significant effects on prothrombin times when compared with placebo. Parecoxib did not affect the pharmacokinetics of S- or R-warfarin.

(e) Rofecoxib

In a study in 12 healthy subjects, rofecoxib 50 mg daily for 12 days increased the maximum INR after a single 30-mg dose of warfarin given on day 7 by about 14%. In a steady-state study, 15 healthy subjects were given warfarin 5 mg daily to produce a stable prothrombin time of 1.4 to 1.7 for at least 3 consecutive days. They were then additionally given rofecoxib 25 mg or placebo daily for 3 weeks. It was found that the 24-hour average INR was increased by 8.6% by rofecoxib. Rofecoxib had no effect on the pharmacokinetics of the more potent S-warfarin enantiomer, but the AUC of R-warfarin was increased by about 40% in both the single dose and steady-state studies. Moreover, in 16 patients stabilised on warfarin and given rofecoxib 25 mg daily for 3 weeks, the INR increased by 5%, 9%, and 5% at week 1, 2, and 3, respectively, the change at week 2 being statistically significant. In one case report, an increase in INR was seen in two elderly patients taking warfarin and rocoxib. The INRs were raised, in one case from less than 3 to 4.1 within a month of starting rofecoxib 12.5 mg daily, and in the other case from 3.2 to 4.6 within 2 days of starting rocoxib. The INRs decreased when the warfarin dosage was reduced. In another case, this time in a patient taking acenocoumarol, the INR rose from the range of 2 to 3 up to over 8 weeks after starting rocoxib 50 mg daily. A 2002 report from the Australian Adverse Drug Reactions Advisory Committee noted that they had received 8 reports of increases in the INR of patients taking warfarin with rofecoxib since the introduction of rofecoxib in late 2000. Two of these cases reported bleeding complications. A further patient died of a cerebral haemorrhage, although the INR was stable. A review of the adverse effects of coxibs included 5 patients taking warfarin who had increases in their INR while taking rofecoxib and warfarin.
Moreover, in a case-control study, patients taking warfarin and admitted to hospital with an upper gastrointestinal haemorrhage were significantly more likely to be also taking rofecoxib (odds ratio 2.4). 13 Note that rofecoxib has generally been withdrawn because of adverse cardiovascular effects.

Mechanism

Non-selective ‘NSAIDs’, p.427, inhibit platelet aggregation and cause gastrointestinal toxicity, which can result in bleeding, the risk of which is increased in patients taking anticoagulants. Although coxibs are generally considered to be associated with a lower risk of gastrointestinal haemorrhage than non-selective NSAIDs, the only available comparative epidemiological study found a similar increased risk of bleeding when coxibs were given with warfarin.

There is also possible a pharmacokinetic interaction. Both warfarin and celecoxib are substrates of the cytochrome P450 isoenzyme CYP2C9, and it is possible that people with variants of CYP2C9 with lower metabolising capacity may develop an interaction if given the combination. For more general information, see ‘Genetic factors in drug metabolism’, p.4).

Rofecoxib possibly inhibits the metabolism of the less active R-warfarin via inhibition of CYP1A2, 19 and the active R-celecoxib by the same isoenzyme and CYP2C9. 19

Importance and management

The interaction of coumarin anticoaguants with these coxibs can be clinically significant, but is apparently rare. For example, of the 4 million prescriptions for celecoxib dispensed over the 18-month period from December 1998, about 1% were estimated to be for patients who would have been taking warfarin, 10 and only a handful of cases of an interaction had been reported. However, the manufacturers recommend that anticoagulant activity should be monitored in patients taking warfarin, other coumarins, or indanediones, particularly in the first few days after initiating or changing the dose of a coxib. Others recommend increased monitoring for 3 weeks. 2 Some increased monitoring is certainly appropriate because all NSAIDs, including coxibs, can irritate the gastrointestinal tract and cause bleeding, the risk of which is increased with anticoagulants.

Coumarins + NSAIDs; Diclofenac

Studies suggest that diclofenac does not alter the anticoagulant effect of acenocoumarol, phenprocoumon or warfarin, suggesting dose adjustments are unlikely to be needed. Isolated cases of raised INRs have been described. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

In a crossover study in 29 patients stabilised on acenocoumarol, diclofenac 25 mg four times daily for one week did not alter the anticoagulant effect (prothrombin value) of acenocoumarol, when compared with placebo. 1 Other studies similarly confirm that diclofenac does not alter the anticoagulant effect of either phenprocoumon 2 or warfarin. 3

However, a patient taking acenocoumarol developed a pulmonary haemorrhage associated with a very prolonged prothrombin time within 10 days of starting to take diclofenac. 2 Another report mentions a Chinese patient taking warfarin who developed an INR of 4 within 4 days of using a 1% diclofenac topical gel for joint pain. 5

For studies, including the one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding when used with warfarin, see ‘Coumarins and related drugs + NSAIDs’, p.427.

Mechanism

See ‘Coumarins and related drugs + NSAIDs’, p.427.

Importance and management

On the basis of the pharmacological studies, no adjustment in coumarin dose would be anticipated to be needed when diclofenac is used. The isolated cases of raised INRs are unexplained. However, care is still needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see ‘Coumarins and related drugs + NSAIDs’, p.427.

Coumarins + NSAIDs; Diflunisol

There is limited evidence to suggest that diflunisol might increase the anticoagulant effects of acenocoumarol and possibly warfarin, but probably not phenprocoumon. All NSAIDs increase the risk of gastrointestinal bleeding, and should be used with care in patients taking oral anticoagulants.

Clinical evidence

The total plasma warfarin levels of 5 healthy subjects fell by about one-third (from 741 to 533 nanograms/mL) when they were given diflunisol 500 mg twice daily for 2 weeks. Also, unbound warfarin increased from 1.02 to 1.34%, but the anticoagulant response was unaffected. When the diflunisol was withdrawn the anticoagulant response was reduced. 1 Another report very briefly describes an increased INR when a patient taking warfarin was given diflunisol. 2

A brief report states that 3 out of 6 subjects taking acenocoumarol had significant increases in prothrombin times, but no interaction was seen in 2 subjects on phenprocoumon, when they were given diflunisol 750 mg daily. 3
Mechanism

Uncertain. Diflunisal can displace warfarin from its plasma protein binding sites but this on its own is almost certainly not the full explanation.\(^1\) The fall in anticoagulant response when diflunisal was stopped is possibly linked to a difference in the rates that total and unbound plasma warfarin returned to their original levels.\(^1\)

Importance and management

This interaction is neither well defined nor well documented. Its importance is uncertain. However, the reports cited and the manufacturers suggest that an increased anticoagulant effect should be looked for if diflunisal is added to established treatment with any anticoagulant. A decreased effect might be expected if diflunisal is withdrawn. Note that care is needed with every ‘NSAID’, (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + NSAIDs; Etodolac

In a pharmacological study, etodolac did not interact significantly with warfarin, suggesting dose adjustments are unlikely to be needed. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

In a three-period, crossover study, each period lasting 2.5 days 18 healthy subjects were given warfarin 20 mg on day 1, 10 mg on days 2 and 3 and etodolac 200 mg every 12 hours. Although the median peak serum levels of the warfarin fell by 19% and the median total clearance rose by 13% in the presence of etodolac, the prothrombin time response remained unchanged.\(^1,2\) On the basis of this study, no adjustment in coumarin dose would be expected to be needed when etodolac is used. However, care is still needed with every ‘NSAID’, (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

1. Ermer JC, Hicks DR, Wheeler SC, Kraml M, Jusko WJ. Concomitant etodolac affects neither
b) Gafenine

In a double-blind study in 20 patients stabilised on phenprocoumon and given either glafenine 200 mg or placebo three times daily it was noted that within a week of starting glafenine there was a significant increase in thrombotest times.\(^4\) In another report, 5 out of 7 patients needed a phenprocoumon dose reduction while taking glafenine.\(^5\) Conversely, in another study, 10 patients taking acenocoumarol, ethyl biscoumacetate or ‘indanedione’ had no changes in their anticoagulant response when given glafenine 800 mg daily over a 4-week period.\(^6\)

(c) Mefenamic acid

After taking sodium meclofenamate 200 to 300 mg daily for 7 days, the average dose of warfarin required by 7 patients fell from 6.5 to 4.25 mg daily, and by the end of 4 weeks it was 5.5 mg (a 16% reduction with a 0 to 25% range).\(^7\)

(d) Mefenamic acid

After taking mefenamic acid 500 mg four times daily for a week the mean prothrombin concentrations of 12 healthy subjects stabilised on warfarin fell by about 3.5%. Microscopic haematuria was seen in 3 of them, but no overt haemorrhage. Their prothrombin concentrations were 15 to 25% of normal, well within the accepted anticoagulant range.\(^8\)

Mechanism

Uncertain. Mefenamic acid can displace warfarin from its plasma protein binding sites,\(^7,9\) and in vitro studies have shown that therapeutic concentrations (equivalent to 4 g daily) can increase the unbound and active warfarin concentrations by 140 to 340%,\(^7,8\) but this interaction mechanism alone is only likely to have a transient effect. See also ‘Coumarins and related drugs + NSAIDs’, p.427.

Importance and management

The pharmacological studies cited suggest that all the fenamates can cause a small to modest increase in the effects of coumarin anticoagulants. If both drugs are given, increase monitoring and anticipate the need for a small reduction in coumarin dosage. Although there are no data on combined use with the fenamate tolfenamic acid, the manufacturer similarly recommends close monitoring of coagulation.\(^10\) Also note that, all ‘NSAIDs’, (p.427), to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Fenamates

In pharmacological studies, the anticoagulant effect of acenocoumarol was modestly increased by floctafenine, that of phenprocoumon was increased by floctafenine and glafenine, and that of warfarin was increased to some extent by meclofenamic acid and mefenamic acid. Tolfenamic acid might be expected to interact similarly. However, limited evidence from one small study found glafenine did not alter the response to acenocoumarol, or ethyl biscoumacetate. Note also that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

(a) Floctafenine

In a double-blind study in 20 patients stabilised on acenocoumarol or phenprocoumon and given either floctafenine 200 mg or placebo four times daily for 3 weeks, floctafenine prolonged their thrombotest times by an average of about one-third, even though the anticoagulant dosage of some of the patients was reduced.\(^1\)
Clinical evidence

(a) Fenbufen
In a study in 10 healthy subjects who were stabilised on warfarin then given either fenbufen 400 mg twice daily or placebo for a week, the prothrombin times were increased by 1.9 seconds within 2 days in the fenbufen recipients, and the serum warfarin levels fell by 14%.1

(b) Flurbiprofen
A small but significant fall in Quick value (from 23.84 and 25.05% to 20.68 and 20.29%) occurred in 19 patients stabilised on phenprocoumon when they were given flurbiprofen 50 mg three times daily for 2 weeks. Two patients bled (haematuria, epistaxis, haemorrhoidal bleeding) and the prothrombin times of 3 patients fell below the therapeutic range.2

A case report describes two patients taking acenocoumarol who had a rise in thrombostest times and bled (haematuria, melaena, haematomas) within 2 to 3 days of starting to flurbiprofen 150 to 300 mg daily.3

(c) Ibuprofen
Ibuprofen 600 mg to 2.4 g daily for 7 to 14 days did not alter the effects of coumarins in studies in: patients stabilised on phenprocoumon,4,6 healthy subjects5 or patients stabilised on warfarin, or patients stabilised on dicumarol.7 However, in one study in 20 patients taking warfarin, ibuprofen 600 mg three times daily for 1 week had no effect on prothrombin time; however, it did prolong bleeding time (4 cases above the normal range) and microscopic haematuria and haematoma were seen.8 Note that, this finding is probably more of a function of the effect of ibuprofen than an interaction per se,9 although it does explain why the combination of an anticoagulants and an ‘NSAID’, (p.427), has an increased risk of haemorrhage.

A raised INR occurred in one patient on warfarin who used topical ibuprofen,10 and subclinical bleeding with a raised INR occurred in a 74-year-old woman with multiple medical problems taking warfarin who was given ibuprofen.11 For studies, including one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding, see ‘Coumarins and related drugs + NSAIDs’, p.427.

(d) Indoprofen
In a placebo-controlled study in 18 patients stabilised on warfarin and given indoprofen 600 mg daily for 7 days, no changes occurred in any of the blood coagulation measurements made.12

(e) Ketoprofen
In a study in 15 healthy subjects stabilised on warfarin, ketoprofen 100 mg twice daily for 7 days had no effect on prothrombin times or coagulation cascade parameters, and there was no evidence of bleeding.13 This contrasts with an isolated case of bleeding in a patient taking warfarin (prothrombin time increased from 18 to 41 seconds) a week after starting ketoprofen 25 mg three times daily.14

(f) Naproxen
In a study in 10 healthy subjects, naproxen 375 mg twice daily for 17 days did not alter the pharmacokinetics of a single dose of warfarin given on day 10, or its anticoagulant effects.15 Similar results were found in a study of warfarin at steady state.16 A further study in patients taking phenprocoumon showed that naproxen 250 mg twice daily transiently increased the anticoagulant effects and caused an unimportant change in primary bleeding time.17 For studies, including one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding, see ‘Coumarins and related drugs + NSAIDs’, p.427.

(g) Oxaprozin
In a study in 10 healthy subjects stabilised on warfarin for an average of 15 days, oxaprozin 1.2 g daily for 7 days did not significantly alter prothrombin times.18

(h) Tiaprofenic acid
In a study in 6 healthy subjects, the anticoagulant effects and the pharmacokinetic profile of phenprocoumon remained unchanged when they took tiaprofenic acid daily for 2 days.19 This study is also published elsewhere.20 No significant interaction occurred in 9 patients stabilised on acenocoumarol and given tiaprofenic acid 200 mg three times daily for 2 weeks, but in 4 patients a ‘rebound’ rise in prothrombin percentages occurred following withdrawal of the NSAID.21 However, an elderly man taking acenocoumarol had severe epistaxis and bruising 4 to 6 weeks after starting to take tiaprofenic acid 300 mg twice daily. His prothrombin time had risen to 129 seconds.22

Mechanism
When given alone, ibuprofen and related drugs can prolong bleeding times because of their antiplatelet effects.11 They may also cause gastrointestinal toxicity. Because of these effects, in patients on anticoagulants, the risk of bleeding is increased by ‘NSAIDs’, (p.427). Most of the propionic acid derivatives can displace the anticoagulants from plasma protein binding sites to some extent, but this mechanism on its own is rarely, if ever, responsible for clinically important drug interactions.

Importance and management
It is well established that ibuprofen does not alter the anticoagulant effect of warfarin or other coumarins, (although isolated and unexplained cases of bleeding or raised INRs have occurred but only very rarely). On the basis of these studies, no adjustment in coumarin dose would be anticipated to be needed when ibuprofen is used. Pharmacological studies also show no interaction for related propionic acid derivatives including indoprofen, ketoprofen, naproxen and oxaprozin, although the documentation is more limited. A slight increase in anticoagulant effects has been seen with fenbufen, flurbiprofen, and possibly tiaprofenic acid, although this is probably of limited clinical relevance. However, note that some care is still needed with every NSAID, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see ‘Coumarins and related drugs + NSAIDs’, p.427.

References
Coumarins + NSAIDs; Indomethacin and related drugs

In pharmacological studies, the anticoagulant effects of acenocoumarol, phenprocoumon and warfarin were not affected by indomethacin, or phenprocoumon by acemetacin. However, isolated cases of a possible interaction with a raised INR and bleeding complications have been reported. Also, note that, like all NSAIDs, indomethacin can irritate the gut thereby increasing the risk of gastrointestinal bleeding, the risk of which is further increased in patients taking anticoagulants.

Clinical evidence

(a) Acemetacin

In a placebo-controlled study in 20 patients stabilised on phenprocoumon, acemetacin 60 mg three times daily for 3 weeks did not alter the thromboplastin value.1

(b) Indomethacin

In a placebo-controlled, double-blind study, indomethacin 100 mg daily for 5 days had no effect on the anticoagulant effects of steady-state warfarin in 8 healthy subjects. 2 Similarly, when 19 healthy subjects took either indomethacin 25 mg four times daily or placebo for 11 days, neither the anticoagulant effects nor the half-life of single doses of warfarin were affected. 2

Other studies in healthy subjects and patients anticoagulated with acenocoumarol or phenprocoumon similarly showed that the anticoagulant effects were not changed by indomethacin.

However, isolated cases of possible interactions in patients taking warfarin have been reported.3–10 One patient had a rise in INR from 2 to 3.3,8 and another had a rise from 2.75 to 3.42, then to 3.6 despite a reduction in warfarin dose.10 However, there are other possible interpretations of this case.11 In another report a patient taking indomethacin appeared to have an enhanced response to warfarin, which subsequently improved when ibuprofen was substituted for indomethacin.7 The preliminary report of an analysis of possible drug interactions with warfarin stated that indomethacin was found to have a clinically relevant effect on the anticoagulant action of warfarin.12 One patient taking warfarin and indomethacin died from acute peptic ulceration.13 Another report includes the interaction in a list, with no details. 7 In a recent report, a patient who was very sensitive to acenocoumarol was found to have melaena and an INR of greater than 10 a week after starting indometacin and tetrazepam. He was found to have poor metaboliser phenotype of isoenzyme CYP2C9 (variant *3).14 For studies, including the one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding, see ‘Coumarins and related drugs + NSAIDs’, p.427.

Mechanism

None. Indomethacin reduces platelet aggregation and thereby prolongs bleeding when it occurs. Acemetacin would act similarly since it is a glycolic acid ester of indomethacin and indomethacin is the major metabolite.

Importance and management

In pharmacological studies it is well established that indomethacin does not normally alter the anticoagulant effects of acenocoumarol, phenprocoumon or warfarin. No coumarin dose adjustments would therefore expected to be needed during concurrent use. However, caution is still appropriate, because indomethacin, like other NSAIDs, can cause gastrointestinal irritation, ulceration and bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see ‘Coumarins and related drugs + NSAIDs’, p.427.

Coumarins and related drugs + NSAIDs; Ketorolac

Ketorolac did not alter the pharmacokinetics of, or prothrombin time response to, warfarin. However, ketorolac has been associated with serious gastrointestinal bleeding.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study1 in 10 healthy subjects, ketorolac 10 mg four times daily for 12 days caused no major changes in the pharmacokinetics of R- or S-warfarin, nor in the prothrombin time after a single 25-mg dose of warfarin given on day 6. This suggests that ketorolac is normally unlikely to affect the anticoagulant response of patients taking warfarin chronically, and that no warfarin dose adjustments would be anticipated to be necessary on concurrent use. However, in 1993 the CSM in the UK reported on an analysis of adverse reactions associated with ketorolac: they had received 5 reports of postoperative haemorrhage and four reports of gastrointestinal haemorrhage (one fatal) in patients taking ketorolac. 2 As result of this analysis, the use of ketorolac with anticoagulants was contraindicated in the UK.2,3 In the US, the manufacturers state that patients taking anticoagulants have an increased risk of bleeding complications if they are also given ketorolac, and therefore they should be used together extremely cautiously. They note that, in particular, there is an increased risk of intramuscular haematoma from intramuscular ketorolac in patients taking anticoagulants. 2 See also ‘Coumarins and related drugs + NSAIDs’, p.427.

Coumarins + NSAIDs; Metamizole sodium (Dipyrone)

One report claims that metamizole sodium does not interact with phenprocoumon or ethyl biscoumacetate, whereas another describes a rapid but transient increase in the effects of ethyl biscoumacetate. All NSAIDs increase the risk of gastrointestinal bleeding; and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

A single 1-g dose of metamizole sodium did not alter the steady-state anticoagulant effects of either phenprocoumon (5 subjects) or ethyl biscoumacetate (6 subjects).1 Conversely, another report describes a short-lived but rapid increase (within 4 hours) in the effects of ethyl biscoumacetate caused by single 1-g dose metamizole sodium. 2 The reasons are not understood. However, care is still needed with every ‘NSAID’, (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which
In pharmacological studies, nabumetone did not alter the anticoagulant effects of acenocoumarol or warfarin. An isolated report describes a raised INR and haemarthrosis in one patient taking warfarin attributed to an interaction with nabumetone. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

Nabumetone 2 g daily for 2 weeks did not significantly alter the anticoagulant effects of steady-state warfarin in healthy subjects. Similarly, nabumetone 1 to 2 g daily for 6 weeks had no effect on the INR in 58 patients stabilised on warfarin. Another clinical study in osteoarthritis patients also found that there was no difference in the proportion of patients with no INR change and no change in acenocoumarol dose in 27 patients given nabumetone 1 to 2 g daily for 4 weeks and 29 patients given placebo. Moreover, nabumetone also appears not to affect bleeding time, platelet aggregation or prothrombin times in the absence of an anticoagulant. However, an isolated and unexplained report describes an increase in INR from 2 to 3.7 and haemarthrosis in a patient taking warfarin a week after nabumetone 750 mg twice daily was added.

On the basis of the above studies, no coumarin dose adjustment would be expected to be needed with nabumetone. However, care is still needed with every ‘NSAID’, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Piroxicam increased plasma levels of R-acenocoumarol, and a few cases of raised INRs and bleeding have been reported when it was given with acenocoumarol or warfarin. In pharmacological studies, lornoxicam modestly increased the anticoagulant effects of warfarin, and possibly decreased the effect of phenprocoumon, but it did not interact with acenocoumarol. Studies have indicated that meloxicam does not interact with warfarin, and that tenoxicam does not interact with warfarin or phenprocoumon. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

(a) Lornoxicam

In an open, crossover study in 6 healthy subjects, lornoxicam 8 mg twice daily for 7 days had no effect on the pharmacokinetics or the anticoagulant activity of a single 10-mg dose of acenocoumarol given on day 4.

In an open, crossover study in 6 healthy subjects, lornoxicam 8 mg twice daily for 21 days increased the bioavailabilities of S- and R-phenprocoumon by 14% and 6%, respectively, and decreased their clearances by 15% and 6%, respectively, after a single 9-mg dose of phenprocoumon given on day 4. Despite the minor pharmacokinetic changes, statistically significant reductions in the activities of factors II and VII were seen.

Lornoxicam 4 mg twice daily was given to 12 healthy subjects for 5 days, and warfarin was added with a stable prothrombin time, averaging about 23.6 seconds, was achieved. The period to achieve this varied from 9 to 24 days, depending on the subject. The warfarin was then continued and the lornoxicam withdrawn, whereupon the mean prothrombin time fell to 19.5 seconds, the INR fell from 1.48 to 1.23 and the serum warfarin levels fell by 25%.

(b) Meloxicam

Meloxicam 15 mg daily for 7 days did not significantly affect the pharmacokinetics of warfarin or INR values in a group of 13 healthy subjects stabilised with INRs of 1.2 to 1.8.

(c) Piroxicam

1. Acenocoumarol. In a single-dose study in healthy subjects, when piroxicam 40 mg was given with acenocoumarol 4 mg the AUC of the more active R-isomer was increased by 47% and its maximum plasma level was increased by 28%. In patients stabilised on acenocoumarol, piroxicam 20 mg daily for 2 weeks increased the effects of acenocoumarol in 4 out of 11 patients: the effect was considered mild in 3 patients, and significant in the fourth, although no specific values were given. An increased prothrombin ratio has been seen in another patient. A further patient taking acenocoumarol developed gastrointestinal bleeding 3 days after starting to take piroxicam 20 mg daily. His INR rose from 2.2 to 6.5.

2. Warfarin. A man stabilised on warfarin had a fall in his prothrombin time from a range of 1.7 to 1.9 times his control value to 1.3 when he stopped taking piroxicam 20 mg daily. The prothrombin times rose and fell when he re-started and then stopped the piroxicam. Another patient taking warfarin had an increase in her prothrombin time (from a range of 16.5 to 18.1 seconds to 24.9 seconds) when piroxicam 20 mg daily was started, and a decrease when it was then stopped. The INR of 2 Chinese patients rose to 4.5 and 4.2 after they were treated with piroxicam 20 mg daily and 0.5% topical piroxicam gel. One of them had bruises over the legs within 3 days.

A woman who spread warfarin rat poison with her bare hands developed intracerebral bleeding, possibly exacerbated by piroxicam, which she took occasionally.

(d) Tenoxicam

In single-dose and steady-state studies in a total of 16 healthy subjects, tenoxicam 20 mg daily for 14 days had no significant effect on the anticoagulant effects of warfarin or on bleeding times. This report also mentions tenoxicam treatment cases in a small number of patients and healthy subjects, which similarly found that tenoxicam had no significant effect on the anticoagulant effects of phenprocoumon.
Mechanism

Piroxicam inhibits the metabolism of the active R-acenocoumarol, but its effect on the metabolism of warfarin is unknown. Lornoxicam inhibited the metabolism of warfarin, but not acenocoumarol, in vitro. In addition NSAIDs have antiplatelet effects, which can prolong bleeding if it occurs. They may also cause gastrointestinal toxicity. Because of these effects, in patients taking anticoagulants, the risk of bleeding is increased by ‘NSAIDs’, (p.427).

Importance and management

The interaction of piroxicam with acenocoumarol would appear to be established, and case reports suggest that warfarin might be similarly affected. Concurrent use need not be avoided, but monitor the outcome well and anticipate the need to reduce the anticoagulant dosage. Lornoxicam appears to have a similar effect with warfarin, although no cases of an interaction have been reported. Meloxicam and tenoxicam appear not to interact. However, care is still needed with every ‘NSAID’, (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anti-coagulated patients.

Cumarins and related drugs + NSAIDs; Phenybutazone and related drugs

The anticoagulant effects of warfarin are markedly increased by azapropazone, oxypHENbutazone and phenylbutazone. Concurrent use should be avoided because serious bleeding can occur. Feprazone appears to interact similarly. Bleeding has also been seen in patients taking phenindione or phenprocoumon when given phenylbutazone, but successful concurrent use has been achieved with both phenprocoumon and acenocoumarol, apparently because the anticoagulant dosage was carefully reduced. Note also that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

(a) Azapropazone

A woman taking digoxin, furosemide, spironolactone, allopurinol, and warfarin (prothrombin ratio 2.8) developed haematemesis within 4 days of starting to take azapropazone 300 mg four times a day. Her prothrombin ratio was found to have risen to 15.7. Subsequent gastroscopic examination revealed a benign ulcer, the presumed site of the bleeding. At least 12 other patients are reported to have developed this interaction. Brusing or bleeding (melaena, epistaxis, haematuria) and prolonged prothrombin times have occurred within a few days of starting azapropazone. Three patients died. Another patient taking warfarin and azapropazone, diclofenac and co-proxamol had an increase in prothrombin time.

(b) Feprazone

Five patients stabilised on warfarin had a mean prothrombin time rise from 29 to 38 seconds after taking feprazone 200 mg twice daily for 5 days, despite a 40% reduction in the warfarin dosage (from 5 to 3 mg daily). Four days after feprazone was stopped, their prothrombin times were almost back to usual. The interaction with feprazone was less marked than that with phenylbutazone.

(c) OxypHENbutazone

A man stabilised on warfarin developed gross haematuria within 9 days of starting to take oxypHenbutazone 400 mg daily. His prothrombin time had increased to 68 seconds. Two similar cases have been described elsewhere. A clinical study has also shown that oxypHenbutazone slows the clearance of dicoumarol.

(d) Phenybutazone

In a study in 3 subjects and one patient, phenylbutazone 200 mg three times daily and twice daily, respectively, given for 11 to 19 days before and 11 days after a single dose of warfarin, markedly increased the prothrombin time, but decreased the half-life of warfarin, and the warfarin AUC. In another study that gave the enantiomers of warfarin separately, it was found that phenylbutazone inhibited the clearance of S-warfarin, but increased the clearance of R-warfarin. This was confirmed in other studies, where the AUC of R-warfarin was decreased by 41% and the AUC of S-warfarin increased by 18%. A number of other studies have shown a markedly increased prothrombin times in patients9,17 or healthy subjects18 taking warfarin and given phenylbutazone. Moreover, there are a number of case reports demonstrating the clinical importance of this interaction. In one, a man stabilised on warfarin following mitral valve replacement was later given phenylbutazone for back pain by his general practitioner. On admission to hospital a week later he had epistaxis, and his face, legs and arms had begun to swell. He showed extensive bruising of the jaw, elbow and calves, some evidence of gastrointestinal bleeding, and a prothrombin time of 89 seconds. Two similar cases were also reported. A similar interaction occurs between phenylbutazone and phenprocoumon. In one study in

The anticoagulant effects of warfarin are reduced by phenylbutazone.

Clinical evidence

The plasma warfarin concentrations were halved (from 2.93 to 1.41 micrograms/mL) and the anticoagulant effects accordingly reduced after 5 patients took phenprocoumon 600 mg daily for 50 days. The thrombotest percentage of one patient rose from 5 to 50%. In an associated study it was found that phenoxazone 600 mg daily for 30 days caused a reduction in the warfarin half-life from 47 to 27 hours and from 69 to 39 hours, respectively, in 2 patients.1,2

Mechanism

Phenazone is an enzyme inducer, which increases the metabolism and clearance of warfarin, thereby reducing its effects.1,2

Importance and management

An established interaction. The effects of concurrent use should be monitored and the dosage of warfarin increased appropriately. However, note that phenazone is little used clinically, and an alternative ‘NSAID’, (p.427), that does not alter the metabolism of coumarins would be more appropriate. Other coumarins might be expected to behave similarly.

healthy subjects, phenylbutazone 300 mg daily for 14 days markedly increased the prothrombin time response to a single dose of phenprocoumon given on day 4 by twofold, while decreasing the phenprocoumon AUC by 31%. Cases of a clinically important interaction have also been reported for phenprocoumon. In one early report, the required dose ofacenocoumarol was 25% lower in patients taking phenylbutazone. A single unconfirmed report describes this interaction in two patients taking phenindione.

**Mechanism**

Phenylbutazone very effectively displaces the anticoagulants from their plasma protein binding sites, thereby increasing the concentrations of free anticoagulant (an effect easily demonstrated in vitro). By itself, the importance of this mechanism is usually small, since any displaced drug is then available to be cleared, so any effect is usually transient (see ‘Protein-binding interactions’, p.3). However, phenylbutazone also inhibits the metabolism of S-warfarin (the more potent of the two warfarin enantiomers) so its effects are increased and prolonged. In contrast, the unbound clearance of R-warfarin is not altered, so the total clearance of R-warfarin is increased due to displacement. Thus, overall it appears that phenylbutazone decreases total plasma warfarin levels, while increasing its effect.

Azapropazone and oxyphenbutazone (the major metabolite of phenylbutazone) probably act similarly.

**Importance and management**

The pharmacokinetic interaction between warfarin and azapropazone or phenylbutazone is very well established and clinically important. Serious bleeding can result and concurrent use should be avoided. Feprazone and oxyphenbutazone appear to interact similarly. Much less is known about phenindione. Single unconfirmed reports describe this interaction in two patients taking anticoagulants.

Phenylbutazone very effectively displaces the anticoagulants from their plasma protein binding sites, thereby increasing the concentrations of free anticoagulant (an effect easily demonstrated in vitro). By itself, the importance of this mechanism is usually small, since any displaced drug is then available to be cleared, so any effect is usually transient (see ‘Protein-binding interactions’, p.3). However, phenylbutazone also inhibits the metabolism of S-warfarin (the more potent of the two warfarin enantiomers) so its effects are increased and prolonged. In contrast, the unbound clearance of R-warfarin is not altered, so the total clearance of R-warfarin is increased due to displacement. Thus, overall it appears that phenylbutazone decreases total plasma warfarin levels, while increasing its effect.

Azapropazone and oxyphenbutazone (the major metabolite of phenylbutazone) probably act similarly.

**Coumarins + NSAIDs; Sulindac**

In pharmacological studies, sulindac did not significantly alter the anticoagulant effect of warfarin or phenprocoumon. Isolated cases of a modest to marked increase in the anticoagulant effects of warfarin have been reported with sulindac. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

**Clinical evidence**

In a study in healthy subjects stabilised on warfarin, sulindac 200 mg twice daily for 7 days did not significantly alter the prothrombin time, when compared with placebo, although prothrombin time was slightly higher in the sulindac group. Similarly, in 20 patients stabilised on phenprocoumon, sulindac 200 to 400 mg daily for 4 weeks did not alter measures of coagulation or bleeding time.

However, a patient stabilised on warfarin, ferrous sulfate, phenobarbital and sulfasalazine had a marked increase in his prothrombin time ratio from about 3.2 to 10 after taking sulindac 100 mg twice daily for 5 days. There are 4 similar cases of this interaction on record. One of the patients had a gastrointestinal bleed after taking only three 100-mg doses of sulindac, although this patient was also taking flurbiprofen. Another patient was stabilised on about 40% lower dose of warfarin with continuation of the sulindac. Another patient had a potassium-losing renal tubular defect, which was thought to contribute to the interaction.

**Mechanism**

Not understood. In one patient, renal impairment may have caused sulindac accumulation, which in turn may have affected warfarin pharmacokinetics. See also ‘Coumarins and related drugs + NSAIDs’, p.427.

**Importance and management**

The pharmacological studies cited suggest that usually no coumarin dose adjustment would be needed in patients given sulindac. However, the isolated cases of an interaction suggest that, rarely, some patients may be affected. Also noted that all ‘NSAIDs’, (p.427) can irritate the gastric mucosa, affect platelet activity and cause gastrointestinal bleeding, which will be more severe in anticoagulated patients.

11. Fox SL. Potentiation of anticoagulants caused by pyrazole compounds. JAMA (1964) 188, 320–1.
In pharmacological studies, tolmetin did not alter the anticoagulant effect of phenprocoumon or warfarin. Isolated cases of raised INRs have been described. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

In a placebo-controlled study, no changes in prothrombin times occurred in 15 healthy subjects stabilised on warfarin when they took tolmetin 400 mg three times daily for 14 days. Similarly, no changes in prothrombin times occurred in 15 patients taking phenprocoumon when they were given tolmetin 200 mg four times daily for 10 days. Bleeding times were reported to be slightly prolonged though not to a clinically relevant extent. Bleeding times were not significantly altered in healthy subjects given acenocoumarol and tolmetin 400 mg twice daily, or patients taking acenocoumarol and tolmetin.

However, there is a single published case report of a diabetic patient stabilised on warfarin, insulin, digoxin, theophylline, ferrous sulfate, furosemide and sodium polystyrene sulfonate who had a nosebleed after taking three 400-mg doses of tolmetin. His prothrombin time had risen from a range of 15 to 22 seconds up to 70 seconds. The manufacturers of tolmetin and the FDA in the US also have 10 other cases on record, received over a 10-year period.

Mechanism

See ‘Coumarins and related drugs + NSAIDs’, p.427.

Importance and management

The pharmacological studies cited suggest that usually no coumarin dose adjustment would be needed in patients given tolmetin. The isolated cases of an interaction are unexplained.

However, care is needed with every ‘NSAID’, (p.427) because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

4. Rüst O, Biland L, Thilo D, Nyman D, Duckert F. Effekten of the drug, and the adverse effects of the olanzapine and the anticoagulant ef-

A double-blind study in 23 patients anticoagulated with un-named coumarol derivatives and given dextropropoxyphene 450 mg daily for 15 days or ibuprofen did not show any change in prothrombin times with either drug.

Mechanism

Not understood. The effect dextropropoxyphene has on the metabolism of the warfarin enantiomers does not appear to have been studied. Dextropropoxyphene does not interact with other cytochrome P450 isoenzyme CYP2C9 substrates such as ‘tolbutamide’, (p.486), although it does interact with the CYP3A4 substrate ‘carbamazepine’, (p.527). There is also the possibility that the paracetamol component had some part to play (see also ‘Coumarins + Paracetamol (Acetaminophen)’, p.438). Alternatively, these cases may just represent idiosyncratic reactions.

Coumarins + Opioids; Dextropropoxyphene (Propoxyphene)

In one study, dextropropoxyphene did not alter the prothrombin time in patients taking unspecified coumarins. There are isolated cases of patients on warfarin who have shown a marked increase in prothrombin times and/or bleeding when given co-proxamol (dextropropoxyphene with paracetamol).

Clinical evidence

(a) Co-proxamol (Dextropropoxyphene with paracetamol)

A man taking warfarin developed marked haematuria within 6 days of starting to take two tablets of co-proxamol three times a day. Thirteen days previously his warfarin dose had been increased from 6 mg to 7 mg daily (thrombotest 16%), and then 9 days previously it had been reduced back to 6 mg daily (thrombotest 5%). His plasma warfarin levels had risen by one-third (from 1.8 to 2.4 micrograms/mL) despite the reduction in warfarin dose. A woman stable for 6 weeks on warfarin developed gross haematuria 11 hours after starting co-proxamol. She had taken 6 tablets of co-proxamol over a 6-hour period. Her prothrombin time increased from about 30 to 40 seconds up to 130 seconds.

This interaction has been reported in 5 other patients taking warfarin 2-6. The prothrombin time of one of them rose from 28 to 44 seconds up to 80 seconds within 3 days of substituting paracetamol with two tablets of co-proxamol four times a day. Another developed a prothrombin time of more than 50 seconds after taking 30 tablets of Darvocet-N 100 (dextropropoxyphene 100 mg, paracetamol 650 mg) and possibly an unknown amount of ibuprofen over a 3-day period. Increased warfarin effects leading to severe retroperitoneal haemorrhage have also been briefly reported in a patient taking co-proxamol.

(b) Dextropropoxyphene

A double-blind study in 23 patients anticoagulated with un-named coumarol derivatives and given dextropropoxyphene 450 mg daily for 15 days or ibuprofen did not show any change in prothrombin times with either drug.

Mechanism

Not understood. The effect dextropropoxyphene has on the metabolism of the warfarin enantiomers does not appear to have been studied. Dextropropoxyphene does not interact with other cytochrome P450 isoenzyme CYP2C9 substrates such as ‘tolbutamide’, (p.486), although it does interact with the CYP3A4 substrate ‘carbamazepine’, (p.527). There is also the possibility that the paracetamol component had some part to play (see also ‘Coumarins + Paracetamol (Acetaminophen)’, p.438). Alternatively, these cases may just represent idiosyncratic reactions.

Importance and management

Information about this interaction is very sparse and seems to be limited to the reports cited. The cases cited could just be idiosyncratic reactions. Bear them in mind in the event of an unexpected response to treatment.

lo-humeral periarthritis following myocardial infarction. 13th International Congress of Rheu-
**Coumarins + Opioids; Hydrocodone**

In an isolated report, the anticoagulant effects of warfarin were increased by hydrocodone in one patient and in one healthy subject.

**Clinical evidence, mechanism, importance and management**

A patient, well stabilised on warfarin (and also taking digoxin, propranolol, clofibrate and spironolactone) had a rise in his prothrombin time of about 2 to 3 times his control value when he began to take **Tussionex** (hydrocodone with phenyltoloxamine) for a chronic cough. When the cough syrup was discontinued, his prothrombin time fell again. In a subsequent study in one healthy subject the equivalent dosage of hydrocodone increased the elimination half-life of warfarin from 30 to 42 hours. The reason for this interaction is not known, and this case appears to be the only information available. Any interaction is not therefore established. Be aware of the possibility of an interaction in the case of an unexpected increase in the response to warfarin.

**Coumarins + Opioids; Meptazinol**

The anticoagulant effects of warfarin were not altered by meptazinol in one study.

**Clinical evidence, mechanism, importance and management**

Meptazinol 200 mg four times daily for 7 days had no significant effect on the prothrombin indexes of 6 elderly patients stabilised on warfarin, nor on the required warfarin dose.1 No warfarin dose adjustments would be expected to be needed on concurrent use.

**Coumarins + Opioids; Tramadol**

In one study tramadol did not change the mean INR in response to phenprocoumon, although two patients had increases. Isolated cases of an increase in anticoagulant effects of warfarin and phenprocoumon have been reported. One retrospective cohort study also found an increased risk of bleeding when acenocoumarol or phenprocoumon was given with tramadol.

**Clinical evidence**

In a double-blind, placebo-controlled, crossover study the mean INRs of 19 patients anticoagulated with phenprocoumon were unchanged when they were given tramadol 50 mg three times daily for a week.1,2 Although the mean difference was not changed, one patient had an INR rise from 4 to 7.3, and another from a just under 5 to 6, while taking tramadol, but not while taking placebo.

A brief report describes 5 elderly patients (aged 71 to 84 years), anticoagulated with warfarin or phenprocoumon and taking a range of other drugs, who had clinically important rises in INRs (up to threefold) shortly after starting to take tramadol. One of the patients had gastrointestinal bleeding. Three of the patients were able to continue the tramadol with a reduced anticoagulant dosage.3

In another report, a 61-year old woman with a mitral valve replacement on warfarin developed ecchymoses about 2 weeks after starting tramadol 50 mg every 6 hours. Her prothrombin time was found to have risen to 39.6 seconds and her INR was 10.6. These values returned to normal when the tramadol was withdrawn and the warfarin temporarily stopped.4 Other cases have been reported with warfarin5 and phenprocoumon.6 In 2004, the Australian Adverse Drug Reactions Advisory Committee said they had received 11 reports of increases in INR or a haemorrhagic event in patients taking warfarin given tramadol. Two patients died of haemorrhagic stroke. They note that this number of cases suggests that the interaction is an uncommon event.7 Up until March 2003, the Swedish Adverse Drug Reactions Advisory Committee had received reports of 17 cases of a suspected interaction between tramadol and warfarin resulting in increases in the INR (to 3.4 to 8.5) and bleeding complications in 35% of patients. One patient who continued tramadol needed the warfarin dose to be almost halved.8

In a retrospective cohort study of patients taking acenocoumarol or phenprocoumon, tramadol was found to be associated with a threefold increased risk of bleeding. The study was specifically looking at potentially interacting drugs taken by at least 50 patients and with at least 5 cases of bleeding.9

**Mechanism**

Unknown. It has been suggested that the interaction might be related to a variation in CYP genotype. Seven of 10 patients from the 17 suspected cases of interaction in Sweden had defective CYP2D6 alleles. The authors suggested that since this isoenzyme metabolises tramadol, these patients might have changes in tramadol metabolism that could increase the risk of an interaction with warfarin via CYP3A4. However, CYP3A4 only has a role in the ‘metabolism’, (p.358), of R-warfarin, and inhibition of CYP3A4 usually results in just minor to modest increases in INR. Moreover, defective CYP2D6 alleles have a population prevalence of 42.2%, so if this were the mechanism, many more cases would be expected. Because of the rarity of reports, it could just be that it is not really an interaction, and that there were unknown confounding factors in the suspected cases. Further study is needed.

**Importance and management**

Not established. One pharmacological study did not show a clear interaction for phenprocoumon and tramadol, although data from 2 patients suggested the possibility. Moreover, isolated cases of an interaction with warfarin and phenprocoumon have been published or reported to regulatory authorities, but the incidence seems to be rare. Because of the uncertainty, it would be prudent to consider monitoring prothrombin times in any patient taking coumarins when tramadol is first added, being aware that a small proportion of patients may need a reduction in the anticoagulant dosage. More study is needed.

**Coumarins and related drugs + Orlistat**

Orlistat had no effect on the pharmacodynamics or pharmacokinetics of single-dose warfarin in healthy subjects. However, orlistat reduces fat absorption, and might therefore reduce vitamin K absorption. There is a published report of a patient taking warfarin who developed a modest increase in INR after taking orlistat.2 In addition, in 2001 the Canadian Anticoagulants 437
regulatory authorities reported that unexpected increases in INR were noted after orlistat was given to patients taking either warfarin or acenocoumarol. These were managed by dosage adjustments of the coumarin or discontinuation of orlistat.3

In a published report, a 66-year-old man stabilised on warfarin for 2.5 years who started taking orlistat 120 mg three times daily for weight reduction had a modest increase in his INR, from less than 3, to 4.7 within 18 days. Warfarin was withheld and he was later restabilised on approximately two-thirds of the previous dose while continuing the orlistat.4

Mechanism
Orlistat may reduce the absorption of fat soluble vitamins including vitamin K,4,5 and a change to a lower fat diet associated with the use of orlistat may also contribute to changes in the balance between vitamin K and warfarin.4

Importance and management
The manufacturers say that patients stabilised on anticoagulants and given orlistat should be closely monitored for changes in coagulation parameters.2,5 Given the reports of changes in INRs, and the fact that changes in dietary ‘vitamin K’, (p.409) are known to affect warfarin efficacy, this seems prudent in patients taking a coumarin or an indanedione.6

Clinical evidence
Over 10 published studies have investigated whether or not paracetamol alters the effect of coumarin anticoagulants, with equal numbers finding no effect,5,7,11 or an increased effect, see ‘Table 12.5’, (p.439). All the randomised, controlled studies showing an interaction have demonstrated a minor to modest effect (e.g. average increase in INR of 1.04 in one well-controlled study). The only study to show a much greater effect (an increased odds ratio of an INR above 6 ranging from 3.5 to 10 for different doses of paracetamol alone or combined with an opioid) was a retrospective case-control study,2,3 which has the limitations of being non-randomised with all the attendant problems of controlling for possible confounding variables.4,6 Excluding this study, there appears to be no obvious explanation for the disparate findings between the studies showing an interaction and those not, either by study group, coumarin used, or dose of paracetamol.

There are only 5 published case reports of a possible interaction between paracetamol without opioids and a coumarin (warfarin or acenocoumarol), which are summarised in ‘Table 12.5’, (p.439). In addition, there are two reports of a possible interaction with paracetamol combined with codeine or dihydrocodeine listed in ‘Table 12.5’, (p.439), and 7 others with paracetamol combined with ‘dextropropoxyphene (propoxyphene)’, (p.436). Note that this incidence is very rare, given the widespread use of paracetamol, and the fact that it is generally considered safe for use with warfarin.

Moreover, in response to one case-control study2 other clinicians running outpatient anticoagulant clinics have contended that they have not observed an interaction with paracetamol in their experience.5,6

Mechanism
Not understood. Paracetamol is mainly metabolised by glucuronidation and sulfation,7,8 but the cytochrome P450 isoenzymes CYP1A2, CYP3A4 and CYP2E1 metabolise up to 15% of paracetamol under normal conditions.7 R-warfarin is mainly metabolised by CYP3A4 and CYP1A2.7,8 It has been suggested that in conditions such as ageing, hypoxia or hypertension, the isoenzymes play a more important part in paracetamol metabolism. Consequently paracetamol may then compete with the metabolism of R-warfarin to a sufficient degree to provoke an interaction.1 However, as the S-warfarin enantiomer has significantly greater anticoagulant activity than the R-warfarin enantiomer, interactions with R-warfarin are considered by some to be of questionable significance.5 Moreover, this explanation might explain rare case reports, but not the slight increases in INR seen in some studies in otherwise healthy subjects and patients.

Another idea is that the toxic metabolite of paracetamol inhibits the enzymes in the vitamin K cycle, and so has additive effects with anticoagulants, but so far this mechanism has only been investigated in vitro.9 Yet another idea is that it is the indications for paracetamol use such as pain or fever that cause the interaction, rather than paracetamol per se,10 but this does not explain why an interaction has been found in otherwise healthy patients or subjects given paracetamol in controlled studies.

Importance and management
Despite the number of studies, an interaction between paracetamol and coumarin anticoagulants is not firmly established, and the importance of the findings remain controversial. Some consider that the dose of paracetamol and its duration of use should be minimised in patients taking coumarins. However, in randomised controlled studies, even maximum daily doses of paracetamol (4 g daily) for 2 weeks, had, at most, a modest effect, see ‘Table 12.5’, (p.439). A dose-related effect has been suggested in a case-controlled study,2 but a more recent randomised controlled study did not find a dose-response (i.e. there was a slight change in INR of 0.5 with both 1.5 g daily and 3 g daily).10 Further evidence is therefore required on the possible dose-response effect, and whether there is any value in minimising the dose. Moreover, on the basis of the studies suggesting an interaction, many have advocated increased monitoring in patients starting regular paracetamol. However, others consider that an increase in monitoring is unnecessary, or that increased monitoring during paracetamol use is not necessary unless the underlying illness (e.g. fever) requires increased monitoring. On the basis of the available data, it is not possible to firmly recommend increased monitoring, or dismiss its advisability. Further study is clearly needed.

Case report (2004) 76-year-old Warfarin Patient recently taking more paracetamol for a flare of arthiritis INR increase from 2.1 to 7, with haematuria and gingival bleeding 18

Paracetamol in combination with opioids†

Case report (1991) 66-year-old Warfarin Paracetamol/codeine; about 1.6 g daily of paracetamol over 10 days Increase in prothrombin time from range of 15 to 19 up to 96 seconds. Haematuria and gingival bleeding 19

Case report (1997) 63-year-old Warfarin a. Paracetamol/dihydrocodeine 500 mg/10 mg, four daily for 7 days b. Paracetamol/codeine 500 mg/30 mg, three daily for 8 days a. Increase in INR to 9.6 then 12, with gingival bleeding b. Increase in INR to 8.5 20

1 Note that this is an indanedione
2 Including 11 cases and 6 controls who reported taking a preparation of paracetamol in combination with an opioid, mostly codeine and oxycodone
3 There are also cases reported with dextropropoxyphene/paracetamol.

Paracetamol is still considered to be safer than ‘aspirin’, (p.385) or ‘NSAIDs’, (p.427), as an analgesic in the presence of an anticoagulant because it does not affect platelets or cause gastric bleeding.

Some studies have suggested that pentoxifylline does not alter the anticoagulant effects of phenprocoumon or acenocoumarol; however, one study suggests that there is an increased risk of serious bleeding if pentoxifylline is given with acenocoumarol. Pentoxifylline alone has rarely been associated with bleeding.

Clinical evidence

The anticoagulant effects of phenprocoumon were not altered by pentoxifylline 400 mg four times daily for 27 days in 10 patients on stable phenprocoumon therapy. Two patients had a slight increase in platelet aggregation.¹

In a placebo-controlled study of either pentoxifylline 400 mg three times daily, acenocoumarol (adjusted to maintain an INR of 2 to 4.5), or both drugs together, 3 major haemorrhagic problems (2 fatal cerebral, 1 gastrointestinal) occurred in the 36 patients taking both drugs. In the 36 patients taking acenocoumarol alone, one case of cerebral haemorrhage (resulting in hemiplegia) and another of haematuria with epistaxis occurred. This difference was not statistically significant, but the authors
considered that the risk of bleeding was probably increased by the combination. In this study, 69% of patients had an INR within desired range, and 7% had an INR above 4.5. In another randomised study in patients with recurrent venous thrombosis, there was no difference in dose of acenocoumarol necessary to reach an INR of 2.5 to 3.5 between 100 patients taking acenocoumarol with pentoxifylline 1.2 g daily and 100 patients taking acenocoumarol alone. No patients had severe bleeding, and 3 to 4% of patients in both groups had moderate bleeding (haematomas, haematuria).3

**Mechanism**

Pentoxifylline alone has rarely been associated with bleeding, indicating that bleeding may not necessarily be the result of an interaction. The manufacturers say that a causal relationship between pentoxifylline and bleeding has not yet been established.5,6

**Importance and management**

Information is limited, and an interaction is not established. In the US, the manufacturer recommends that patients taking warfarin should have more frequent monitoring of coagulation parameters when given pentoxifylline, and this seems a prudent precaution with this and any other coumarin.

**Coumarins + Phosphodiesterase type-5 inhibitors**

In pharmacological studies, sildenafil did not interact with warfarin or acenocoumarol. However, in pulmonary hypertension, there is some evidence of an increased risk of bleeding with concurrent use, and nosebleeds were a common adverse effect of sildenafil alone. There is also a report of two possible cases of rises in INRs in patients taking acenocoumarol or warfarin and sildenafil. Studies suggest that tadalafil and vardenafil do not interact with warfarin.

**Clinical evidence**

(a) Sildenafil

The manufacturer notes that no significant interaction occurred when sildenafil 50 mg was given with warfarin 40 mg.1,4 Or when sildenafil 100 mg was given with acenocoumarol.1 However, in studies in pulmonary hypertension, nosebleeds were a common adverse effect (13%), and concurrent use of vitamin K antagonists and sildenafil resulted in a greater incidence of reports of bleeding (primarily nosebleeds) than placebo.4 A 68-year-old man taking acenocoumarol and enalapril had an increase in his INR from 3.05 to 7.7 without bleeding complications after taking sildenafil. The patient continued to take sildenafil once a week, and the daily dose of acenocoumarol was split into two, with a return to stable therapeutic INR values. Another patient taking warfarin, ranitidine and pravastatin had a rise in INR on three occasions after taking sildenafil once a week, omitting the dose of ranitidine when he took the sildenafil. On one of these occasions, he had bleeding gums. This rise in INR no longer occurred when he started taking the ranitidine with the sildenafil.5

(b) Tadalafil

A double-blind, randomised, crossover study in which a single-dose of warfarin was given on day 7 of 12 consecutive days of treatment with either tadalafil 10 mg or placebo found that tadalafil did not affect the AUCs of either S-warfarin and R-warfarin, and prothrombin times were unchanged.6

(c) Vardenafil

No pharmacokinetic interaction was observed when vardenafil was given with warfarin,7,8 and the prothrombin time was unchanged.8

**Mechanism**

The two cases of interactions are unexplained. It is not obvious why dividing the acenocoumarol dose, or using ranitidine, would have reversed an interaction. No interaction via inhibition of coumarin metabolism is likely. Sildenafil alone appears to commonly cause nosebleeds in patients with pulmonary hypertension.

**Importance and management**

There is no established pharmacokinetic or pharmacodynamic interaction between the phosphodiesterase type-5 inhibitors and warfarin, and no warfarin dose adjustment would therefore be expected to be needed on concurrent use. However, in pulmonary hypertension, sildenafil appears to increase the risk of nosebleeds, and this may be greater in patients taking coumarins. Similarly, the two possible cases with acenocoumarol and warfarin, although not conclusive, do introduce a note of caution.

**Coumarins + Piracetam**

In a large clinical study, piracetam did not alter the dose of acenocoumarol required to produce a given INR. A single case report describes a woman stabilised on warfarin who began to bleed within a month of starting to take piracetam. Piracetam has antiplatelet activity, so some caution seems prudent on combined use.

**Clinical evidence, mechanism, importance and management**

In a randomised study in patients with recurrent venous thrombosis, there was no difference in dose of acenocoumarol necessary to reach an INR of 2.5 to 3.5 between 100 patients taking acenocoumarol with high-dose piracetam 9.6 g daily and 100 patients taking acenocoumarol alone. No patients had severe bleeding, and 3 to 4% of patients in both groups had moderate bleeding (haematomas, haematuria). The addition of piracetam decreased platelet aggregation, levels of fibrinogen, and blood viscosity.1 A woman taking warfarin, insulin, levothyroxine and digoxin complained of menorrhagia at a routine follow up. Investigations revealed that her British Corrected Ratio had risen to 4.1 (normal range 2.3 to 2.8), and that one month previously she had started to take low-dose piracetam 200 mg three times daily. Within 2 days of withdrawing both the warfarin and piracetam her BCR had fallen to 2.07, and the original dose of warfarin was restarted.2

Piracetam alone is known to decrease platelet aggregation, and might therefore be expected to increase the risk of bleeding with anticoagulants, similar to other drugs with antiplatelet activity such as ‘aspirin’, (p.385). The early case appears to be the only report of a possible interaction, but some caution might be prudent on concurrent use.

**Coumarins + Pirmenol**

The anticoagulant effects of warfarin are not altered by pirmenol.
Clinical evidence, mechanism, importance and management

The prothrombin time response to a single 25-mg dose of warfarin was slightly reduced in most of 12 healthy subjects (reductions ranged from 0.2 to 1.3 seconds) who had taken pirmenol 150 mg twice daily for 14 days, with the warfarin taken on day 8.1 This suggested that some changes in the dosage of warfarin might be required in practice, but a later placebo-controlled study found that the prothrombin times of 10 patients stabilised on warfarin were not significantly changed when they were given oral pirmenol 150 mg twice daily for 14 days.2 No warfarin dose adjustments would therefore be expected to be required on concurrent use.

Cumarins + Probeneicid

In healthy subjects, probenecid increased the clearance of single-dose phenprocoumon without altering its anticoagulant effect. The anticoagulant effects of multiple-dose phenprocoumon might be expected to be decreased by probenecid, but this requires confirmation.

Clinical evidence, mechanism, importance and management

In 9 healthy subjects probenecid 500 mg four times daily for 7 days reduced the AUC of a single 0.22-mg/kg dose of phenprocoumon given on day one by 47% and reduced the elimination half-life by about one-third. Nevertheless, the reduction in prothrombin time by phenprocoumon was not altered by probenecid.1

The reasons for this interaction are not understood, but one possibility is that, while probenecid inhibits the glucuronidation of phenprocoumon (its normal route of metabolism), it may also increase the formation of hydroxylated metabolites so that its overall loss is increased.1

Although the anticoagulant effect of single-dose phenprocoumon was not altered in this study, its findings suggest that, in the presence of probenecid, the dosage of phenprocoumon might need to be increased, but this awaits formal clinical confirmation in a multiple-dose study. Nothing further seems to have been published on this potential interaction, so bear its possibility in mind if probenecid is used in a patient taking phenprocoumon. There seems to be nothing documented about other coumarins.

Cumarins + Proguanil

An isolated report describes bleeding in a patient stabilised on warfarin after she took proguanil for about five weeks.

Clinical evidence, mechanism, importance and management

A woman stabilised on warfarin developed haematuria, bruising and abdominal and flank discomfort about 5 weeks after starting to take proguanil 200 mg daily. Her prothrombin ratio was found to be 8.6. Within 12 hours of being given fresh frozen plasma and vitamin K her prothrombin ratio had fallen to 2.3. During the 5 weeks she had travelled from Britain to Thailand, Bali, Australia and then New Zealand, and her prothrombin ratio had not been checked during this time. The mechanism of this potential interaction is unknown.1 Its general importance is uncertain, as factors related to travel (such as a changing diet and changing dose times in different time zones) may have had a part to play in this interaction.

Cumarins + Prolintane

The anticoagulant effects of ethyl biscoumacetate are not affected by prolintane.

Clinical evidence, mechanism, importance and management

The response to a single 20-mg/kg dose of ethyl biscoumacetate was examined in 4 healthy subjects given prolintane 20 mg daily for 4 days. Assesments were made before prolintane, on day 1 of prolintane, and 8 days after prolintane was stopped. The mean half-life of the anticoagulant and prothrombin times remained unchanged.1 No ethyl biscoumacetate dose adjustments would appear to be required on concurrent use.

Cumarins and related drugs + Propafenone

The anticoagulant effects of warfarin, and possibly fluindione and phenprocoumon, are increased by propafenone.

Clinical evidence

The mean steady-state plasma levels of 8 healthy subjects taking warfarin 5 mg daily rose by 38% after they took propafenone 225 mg three times daily for a week. Five of the 8 had a distinct prothrombin time increase. The average rise in prothrombin time of the whole group was about 7 seconds, which was considered to be clinically significant.1 Two case reports describe marked increases in the anticoagulant effects of fluindione and phenprocoumon in 2 patients taking propafenone.2,3

Mechanism

Propafenone may reduce the metabolism of these anticoagulants, thereby increasing their effects. From in vitro data, it was concluded that propafenone would affect only R-warfarin, whereas both R- and S-acenocoumarol were affected.4

Importance and management

Information seems to be limited to these reports but they suggest that anticoagulant control should be well monitored if propafenone is given to patients taking warfarin, and probably also phenprocoumon and the indanedione fluindione. The anticoagulant dosage should be reduced where necessary. It would be prudent to apply the same precautions with any other coumarin or indanedione anticoagulant.

Cumarins and related drugs + Prostaglandins

Limited evidence suggests that the combined use of intravenous high-dose epoprostenol and warfarin may increase the risk of pulmonary haemorrhage. Continuous subcutaneous treprostinil did not alter the pharmacokinetics or the INR in response to single-dose warfarin, and also did not appear to increase the risk of bleeding when used with warfarin in clinical studies. Because these prostaglandins inhibit platelet aggregation, some caution is appropriate on combined use with anticoagulants.

Clinical evidence

(a) Epoprostenol

In a small retrospective review of 31 patients with primary pulmonary hypertension receiving warfarin and continuous intravenous epoprostenol, 9 patients were identified who experienced 11 bleeding episodes (9 cases of pulmonary haemorrhage, 2 of nasal bleeding). Of the 9 cases of pulmonary haemorrhage, 8 were identified clinically by persistent haemoptysis, and 2 cases were associated with severe respiratory distress. Of the 7 patients with an INR available at the time of the first bleeding episode, 6 had an INR under 2 and one had an INR of 3.1. The dose of epoprostenol in patients with bleeds ranged from 28.1 to 164 nanograms/kg per minute,
and no patient receiving less than 28 nanograms/kg per minute had a bleed. There was no significant difference in survival in patients with a bleeding episode and those without. In contrast, the manufacturer states that there was no evidence of increased bleeding in patients taking anticoagulants and receiving infusions of epoprostenol in clinical studies.

(b) Treprostinil

In a crossover study in 15 healthy subjects, continuous subcutaneous treprostinil 5 then 10 nanograms/kg every minute for 9 days did not alter the pharmacodynamics (INR) of a single 25-mg oral dose of warfarin given on day 3. In addition, there was no change in the pharmacokinetics of R- and S-warfarin. In the discussion of this study, the authors mention an unpublished retrospective review of data from placebo-controlled clinical studies in patients with pulmonary artery hypertension. From this there was no evidence to suggest that concurrent warfarin and treprostinil (155 patients) was associated with increased bleeding or coagulation-related events, when compared with warfarin and placebo (156 patients).

Mechanism

Epoprostenol (prostacyclin) and its long-acting analogue treprostinil are vasodilators that also inhibit platelet aggregation. The related drug iloprost also has these actions. As such, it is anticipated that they might increase the potential for bleeding when given with other anticoagulants.

Importance and management

Anticoagulants such as warfarin are commonly used in patients with pulmonary artery hypertension, a condition for which epoprostenol and now treprostinil have been developed, so the combination is likely to be used frequently. Because these prostaglandins are potent inhibitors of platelet aggregation, they might increase the risk of bleeding with anticoagulants (including coumarins and indanediones), although the manufacturers say that there was no evidence of increased bleeding in clinical studies using epoprostenol or treprostinil. Nevertheless, limited evidence from the small survey in Japanese patients given epoprostenol suggests that this may be the case with high-dose epoprostenol. In this study, the authors commented that they no longer use anticoagulant therapy in patients receiving high-dose epoprostenol. However, the manufacturers information states that since almost all patients in clinical studies of epoprostenol were receiving oral anticoagulants, concurrent oral anticoagulation is recommended although the manufacturers say that there was no evidence of increased bleeding in clinical studies using epoprostenol or treprostinil.

There appears to be no direct information about iloprost but it seems likely that it will interact similarly. Some caution would be appropriate if any of these prostaglandins is given with a coumarin or indanedione.

Further study is needed.

Clinical evidence

(a) Acenocoumarol

A 46-year-old HIV-positive man with mitra-ortic valve replacements stabilised on acenocoumarol (INR 2.5 to 3.5) for 5 years and taking zidovudine and didanosine for 17 months was found to have a dramatic decrease in his INR when his drug regimen was changed to stavudine, lamivudine and ritonavir 600 mg twice daily. Increasing the acenocoumarol dosage over 5 days from an average of 24 mg to over 70 mg failed to increase the INR to target levels. The INR returned to previous levels within 4 days of stopping ritonavir, and the acenocoumarol dosage could be reduced to 3 mg daily. The patient was subsequently given nelfinavir and a similar, though less dramatic interaction occurred: while taking nelfinavir an INR of 2.5 was achieved with a 210% increase in the acenocoumarol dose.

(b) Warfarin

1. Indinavir. A 50-year-old HIV-positive man, stabilised on warfarin (prothrombin complex activity (PCA) range of 20 to 35%), started taking indinavir 800 mg every 8 hours, but it had to be withdrawn after 12 days because of a generalised skin rash. It was then found that the indinavir had caused a moderate reduction in his level of anticoagulation: 10 and 25 days after indinavir was stopped his PCA was 53% and 43%, respectively. The warfarin dosage was increased to 6.25 and 7.5 mg on alternate days for one week, during which time a PCA of 34% was achieved, and he was thereby given warfarin 6.25 mg daily.

2. Lopinavir/Ritonavir. In a pharmacokinetic study in healthy subjects, lopinavir 400 mg/100 mg twice daily for 10 days modestly decreased the AUCs of R- and S-warfarin by 37% and 29%, respectively, after a single 10-mg dose of warfarin and vitamin K were given on day 7. Vitamin K was given to inhibit the pharmacological effect of warfarin without affecting its pharmacokinetics.

3. Ritonavir. The manufacturer reports that, in 12 healthy subjects given ritonavir 400 mg every 12 hours for 12 days, the AUC of S-warfarin was increased by 9% (90% confidence interval, 17 to 44%) while that of R-warfarin was decreased by 33% (-38% to -27%) after a single 5-mg dose of warfarin. The effect of these changes on prothrombin time was not mentioned, but potentially could result in an increased warfarin effect due to the more potent S-warfarin, or a decreased effect due to the R-warfarin. Both of these outcomes have been reported in individual cases. An increase in warfarin effect was seen in a man taking warfarin 10 mg daily (INRs 2.4 to 3) when his treatment for HIV was changed from efavirenz and abacavir to ritonavir, nelfinavir and Combivir (zidovudine/lamivudine). Within 5 days his INR had risen to 10.4 without any sign of bleeding. It proved difficult to achieve acceptable and steady INRs both while in hospital and after discharge, but eventually it was discovered that the patient could not tolerate liquid ritonavir because of nausea and vomiting, so that he had sometimes skipped or lowered the ritonavir dose or even refused to take it. On the occasions where no ritonavir or low-dose ritonavir was taken, the INRs had been low, whereas when he took the full dose of ritonavir the INRs were high.

In contrast, the INR of a 27-year-old HIV-positive woman taking warfarin fell when she was given ritonavir, clarithromycin and zidovudine. It was necessary almost to double the warfarin dosage to maintain satisfactory INRs. Three months later when the ritonavir was withdrawn, her INR more than tripled within a week. Her final warfarin maintenance dose was half of that needed before the ritonavir was started, and a quarter of the dose needed just before she stopped the ritonavir. This case was complicated by the use or withdrawal of a number of other drugs (co-trimoxazole, rifabutin, oral contraceptive, megestrol), which can also interact with warfarin. Similarly, in another patient taking warfarin 6.25 mg daily with a prothrombin activity complex (PCA) of about 34%, a decrease in warfarin effects (PCA increase to 62%) was noted 20 days after starting ritonavir (escalating doses up to 600 mg every 12 hours). The warfarin dosage was then increased to 8.75 mg daily and 24 days later a satisfactory PCA of 33% was achieved. This patient had previously shown a decrease in warfarin effects while taking indinavir, see above.

Cumarins + Protease inhibitors

In pharmacokinetic studies, ritonavir slightly raised S-warfarin levels and modestly decreased R-warfarin levels, while lopinavir/ritonavir decreased S-warfarin levels. In case reports both increased and decreased warfarin effects have been reported with ritonavir. One of these reports also found that indinavir might cause a moderate reduction in anticoagulation. There is also a report of a marked reduction in anticoagulation in a patient taking acenocoumarol, which was associated with the concurrent use of ritonavir or nelfinavir. An isolated report describes a gradual INR rise in an elderly patient taking warfarin when he was given saquinavir.
**Mechanism**

Protease inhibitors are well known to alter the metabolism of many drugs via inhibition, but sometimes induction of, cytochrome P450 isoenzymes, see ‘Table 21.2’, (p.773), so it is not surprising that they have altered warfarin effects, although the precise mechanism is unclear. The findings of the two pharmacokinetic studies suggest that, with warfarin, induction predominates, and that the anticoagulant effects are likely to be decreased.

**Importance and management**

Pharmacokinetic studies have suggested that ritonavir and lopinavir/ritonavir can modestly reduce warfarin levels. Clinical information on an interaction between coumarins and protease inhibitors is limited to the case reports cited, which either show an increase in warfarin effects (ritonavir or saquinavir) or a decrease in warfarin or acenocoumarol effects (indinavir, nelfinavir, or ritonavir). These cases show how it would be prudent to monitor the prothrombin times and INRs of any patient if any HIV protease inhibitor is added, being alert for the need to modify the coumarin dosage.

**Coumarins + Proton pump inhibitors**

In pharmacological studies, omeprazole caused a minor increase in *R*-warfarin levels, with no or a minor increase in anticoagulant effect. Conversely, lansoprazole, pantoprazole and rabeprazole did not alter warfarin pharmacokinetics or anticoagulant effect. Omeprazole does not appear to alter the effects of acenocoumarol and pantoprazole does not appear to alter the effects of phenprocoumon. Nevertheless, a number of isolated reports describe increased anticoagulant effects when PPIs are given with coumarins.

**Clinical evidence**

**(a) Esomeprazole**

Esomeprazole is the S-isomer of omeprazole, and would be expected to behave similarly, see below. The manufacturers say that esomeprazole 40 mg daily did not cause any clinically relevant effects on anticoagulant times in patients stabilised on *warfarin*, but a few isolated cases of raised INRs have been reported post-marketing.1,2

**(b) Lansoprazole**

A study in 24 healthy subjects stabilised on *warfarin* found that lansoprazole 60 mg daily for 9 days had no effect on the pharmacokinetics of either *S*- or *R*-warfarin, and did not alter the effect of *warfarin* on prothrombin times.3

However, in 1998 the manufacturers of lansoprazole had on record two reports of possible interactions. An elderly patient taking *warfarin* developed an INR of 7 when lansoprazole was added. Despite a *warfarin* dosage adjustment he had a gastrointestinal haemorrhage, a myocardial infarction and died after 3 weeks. Another man taking *warfarin* (as well as amiodarone, furosemide and lisinopril) became confused, had hallucinations and developed an increased INR (value not known) when given lansoprazole. The lansoprazole was stopped after 4 days, and he then recovered. However, it is uncertain whether this was an interaction or whether he had taken an incorrect *warfarin* dosage because of his confusion.4

**(c) Omeprazole**

1. *Acenocoumarol*. In a placebo-controlled study in 8 healthy subjects, omeprazole 40 mg daily for 3 days had no effect on the pharmacokinetics of *R*- or *S*-acenocoumarol when a single 10-mg dose of acenocoumarol was given on day 2. In addition, omeprazole did not alter the anticoagulant effects of acenocoumarol.5 Similarly, there was no evidence of an interaction in a retrospective study of 118 patients given acenocoumarol with omeprazole and 299 patients taking acenocoumarol without omeprazole (matched for age and sex).6

However, an isolated case report describes a 78-year-old woman who had been taking acenocoumarol for 60 days and who developed gross haematuria within 5 days of starting omeprazole 20 mg daily. Her INR had risen from a range of 2.5 to 3 up to 5.7, and when the omeprazole was stopped, her INR fell.7

2. *Warfarin*. In 21 healthy subjects who had been stabilised on warfarin, omeprazole 20 mg daily for 2 weeks caused a small but statistically significant decrease in the mean thrombotest percentage, from 21.1 to 18.7%. S-warfarin serum levels remained unchanged, but a small 12% rise in *R*-warfarin levels was seen.8 In a further study, no changes in coagulation times or thrombotest values occurred in 28 patients anticoagulated with warfarin and given omeprazole 20 mg daily for 3 weeks. *S*-warfarin levels were unchanged, while a 9.5% increase in *R*-warfarin levels occurred.9

However, a man stabilised on warfarin 5 mg daily developed widespread bruising and haematuria 2 weeks after starting to take omeprazole 20 mg daily. His prothrombin time was found to have risen to 48 seconds. He was later restarted on omeprazole 20 mg daily with the warfarin dosage reduced to 2 mg daily.10

**(d) Pantoprazole**

In 26 healthy subjects, pantoprazole 40 mg daily for 8 days caused no change in the response to a single 25-mg dose of *warfarin* given on day 2. The pharmacokinetics of *R*- and *S*-warfarin were unaltered, and no changes in the pharmacodynamics of the *warfarin* (prothrombin time, factor VII) were seen.11 However, the manufacturer notes that there have been reports of increased INR and prothrombin time in patients taking pantoprazole and *warfarin*.12

No change in the prothrombin time ratio , was seen in 16 healthy subjects taking individualised maintenance *phenprocoumon* doses when they were given pantoprazole 40 mg daily for 5 days, nor was there any change in the pharmacokinetics of *R*- and *S*-phenprocoumon.13 However, there is a report of 2 possible cases of an interaction.14 One patient who was given *phenprocoumon* (loading dose 12 mg on day 1, 9 mg on day 2, 3 mg on day 3, and further as required) and omeprazole 20 mg daily concurrently, had an INR of 3.28 by the fourth day. The *phenprocoumon* was withdrawn, but the INR remained high for 9 days, when the omeprazole was stopped. Four days later the INR was 1.5 and *phenprocoumon* was restarted at 16.5 mg/week, and stabilised at 9 to 10.5 mg/week. She subsequently had a similar loading dose without problems, in the absence of omeprazole, when *phenprocoumon* was stopped for 3 weeks prior to surgery.14 Another patient stabilised on *phenprocoumon* 18 mg/week required a slight reduction in dose to 16.5 mg/week after starting omeprazole 20 mg daily.14

**(e) Rabeprazole**

In a placebo-controlled study a single 0.75-mg/kg dose of *warfarin* was given to 21 patients before and after rabeprazole 20 mg daily for 7 days. No significant changes in prothrombin times or in the pharmacokinetics of *R*- or *S*-warfarin were seen.15 However, the manufacturer notes that there have been reports of increased INR and prothrombin time in patients receiving rabeprazole and *warfarin*.16

**Mechanism**

Studies have shown that omeprazole partially inhibits the metabolism of *R*-warfarin, but not *S*-warfarin,17,18 which confirms the findings in the pharmacokinetic studies above. It also partially inhibits the metabolism of acenocoumarol.17 However, these small changes would generally not be expected to be clinically relevant. It has been suggested that the interaction might occur only in patients who are poor metabolisers of the cytochrome P450 isoenzyme CYP2C19 (seen in about 5% of Caucasians), who have five to tenfold higher levels of omeprazole than extensive metabolisers.5 Other proton pump inhibitors are generally considered to have less potential for pharmacokinetic interactions than omeprazole, but even with these, isolated cases of anticoagulant interactions have been reported. It is
possible that the isolated cases of interactions with proton pump inhibitors just represent idiosyncratic effects attributable to other factors, and not to any interaction.

Importance and management

The very minor pharmacokinetic interaction between omeprazole and warfarin, resulting in a less than 15% rise in just the R-warfarin level, is established, but probably of limited clinical relevance. This is borne out by the fact there is only one published case report of an interaction. No pharmacokinetic or pharmacodynamic interaction occurred between warfarin and lansoprazole, pantoprazole or rabeprazole in clinical studies. However, isolated cases of raised INRs have been reported for all the proton pump inhibitors (omeprazole, lansoprazole, pantoprazole, omeprazole and rabeprazole) and acenocoumarol (one published), phenprocoumon (2 published), and warfarin. When prescribing proton pump inhibitors to patients taking coumarins it would seem prudent to bear in mind that rarely bleeding can occur. Note that the US prescribing information for every proton pump inhibitor states that patients taking a proton pump inhibitor and warfarin may need to be monitored for increases in INR and prothrombin time. The advice in UK varies from recommending monitoring with warfarin and omeprazole or esomeprazole, recommending monitoring with pantoprazole and coumarins on the basis of it being good practice to increase monitoring with any change in concurrent therapy, to no advice with lansoprazole or rabeprazole. Further study is needed to determine whether the risk of an interaction with omeprazole is increased in poor metaboliser phenotypes for CYP2C19, as has been suggested.4

Covarsimuls + Quetiapine

A case report describes a woman taking warfarin who developed a raised INR when quetiapine was started.5

Clinical evidence, mechanism and management

A 71-year old woman receiving long-term treatment with warfarin, phenytoin, olanzapine and benzotropine had her warfarin dosage slightly reduced (from 20 to 19.5 mg weekly) because her INR was raised (from 1.6 to 2.6). Eight days later her treatment with olanzapine was changed to quetiapine 200 mg daily, and after 5 days her INR was 2.7. Two weeks later she was found to have an INR of 9.2. The quetiapine was stopped and she was given two doses of vitamin K by injection. The only clinical symptoms seen were a small amount of bleeding from the injection site and a bruise on her hand. She was eventually later reestablished on phenytoin, olanzapine and warfarin 21 mg weekly with an INR of 1.6.

The reasons for this apparent interaction are not known but the authors suggest that the quetiapine may have inhibited the metabolism of the warfarin (possibly by competitive inhibition of the cytochrome P450 isoenzymes CYP3A4 and CYP2C9), thereby increasing its effects. They also suggest that the phenytoin may have had some part to play.1 This is only an isolated case but bear it in mind in the case of an unexpected response to concurrent use.

Covarsimuls + Quinidine

Quinidine did not alter the anticoagulant effect of warfarin in a study in patients, nor in a retrospective analysis of patient data. However, isolated reports of increased warfarin effects and bleeding have been reported, although these stem from over 35 years ago, and nothing further seems to have been reported, suggesting that an interaction is unlikely. Quinidine did not alter the half-life of phenprocoumon in healthy subjects. A small decrease in the effects of dicoumarol and warfarin has also been reported with quinidine, which was attributed to changes in haemodynamic factors following cardioversion.

Clinical evidence

In a controlled study, 10 patients receiving long-term treatment with warfarin 2.5 to 12.5 mg daily had no significant alteration in their prothrombin times when they were given quinidine 200 mg four times daily for 2 weeks.12 Similarly, in a retrospective analysis of 8 patients stabilised on warfarin, there was no change in anticoagulant control associated with starting or stopping quinidine (600 mg to 1.2 g daily as sulfa or 660 mg daily as glucuronate). In the preliminary report of another study in 5 healthy subjects, quinidine 100 mg daily, started 7 days after a single 12-mg dose of phenprocoumon did not change the elimination half-life of phenprocoumon.10 In contrast, another report described 3 patients stabilised on warfarin, with Quick values within the range of 15 to 25%, who began to bleed within 7 to 10 days of starting to take quinidine 800 mg to 1.2 g daily. Their Quick values were found to have fallen to 6 to 8%. Bleeding ceased when the warfarin was withdrawn. In one other case report of haemorrhage associated with the concurrent use of warfarin and quinidine,4 and in an analysis of haemorrhage in patients taking anticoagulants, it was reported that quinidine seemed partly responsible for some cases.1

In a further report, 4 patients taking warfarin or dicoumarol needed dosage increases of 8 to 24% to maintain adequate anticoagulation after DC conversion for atrial fibrillation and starting quinidine 400 mg three times daily, an effect that was attributed to haemodynamic factors.9

Mechanisn

Uncertain. The cases of increased warfarin effects were attributed to quinidine possibly having a direct hypoprothrombinemic effect of its own.2 The addition of a slight decrease in anticoagulant effect was attributed to changes in haemodynamic factors as a result of cardioversion.8

Importance and management

In one study and one retrospective analysis, quinidine had no effect on the anticoagulant control with warfarin in patients. Therefore, no interaction would normally be anticipated. However, a few isolated cases of increased anticoagulant effect with bleeding have been reported. Nevertheless, the literature is limited, and based solely on evidence from more than 35 years
ago. The lack of reports of any further interactions in this time suggests that a clinically relevant interaction is unlikely. Limited evidence suggests that quinine does not alter phenprocoumon pharmacokinetics.

### Coumarins + Quinine

Isolated reports describe increased anticoagulant effects in two women taking warfarin and a man taking phenprocoumon, which were attributed to the quinine content of tonic water. Limited evidence suggests that quinine does not alter the half-life of phenprocoumon.

#### Clinical evidence

In the preliminary report of a study in 5 healthy subjects, quinine 100 mg daily started 7 days after a single 12-mg dose of phenprocoumon did not change the elimination half-life of phenprocoumon in the following 7 days.\(^1\)

However, a patient on long-term phenprocoumon treatment repeatedly developed extensive haematuria within 24 hours of drinking 1 litre of Indian tonic water containing 30 mg of quinine.\(^1\)

A woman stabilised on warfarin needed a dosage reduction from 6 mg to 4 mg daily when she started to drink 1 to 1.5 litres of tonic water containing quinine each day. Her warfarin requirements rose again when the tonic water was stopped. Another woman needed a warfarin dosage reduction from 4 mg to 2 mg daily when she started to drink over 2 litres of tonic water daily. They were probably taking about 80 to 180 mg of quinine daily.\(^2\)

#### Mechanism

Not understood. Two studies\(^3,4\) using the Page method (Russell viper venom)\(^3\) to measure prothrombin times showed that marked increases of up to 12 seconds could occur when 330-mg doses of quinine were given in the absence of an anticoagulant, but other studies\(^6,6\) using the Quick method found that the prothrombin times were only prolonged by up to 2.1 seconds. The changes in prothrombin times could be completely reversed by vitamin K (menadion sodium diphosphate),\(^3,4\) which suggests that quinine, like the oral anticoagulants, is a competitive inhibitor of vitamin K. However, because the only reports relate to tonic water, it cannot be excluded that some other ingredient is responsible for the effect seen in these patients. Also, they may just represent idiosyncratic reactions.

#### Importance and management

Not established. The lack of reports relating to the therapeutic use of quinine suggest that no interaction of clinical importance occurs. The isolated cases cited show that very exceptionally decreased anticoagulant requirements and even bleeding can occur when large quantities of tonic water are ingested. However, whether the effect seen was related to the quinine content of this beverage is not established.

### Coumarins +Raloxifene

In one study, raloxifene caused a minor increase in warfarin levels, but a 10% decrease in prothrombin time. The manufacturer notes that a small and slow decrease in prothrombin times may occur when raloxifene is given with warfarin, and possibly other coumarins.

#### Clinical evidence, mechanism, importance and management

In 15 healthy postmenopausal women, raloxifene 120 mg daily for 15 days had minor effects on the pharmacokinetics and pharmacodynamics of a single 20-mg dose of warfarin given on day 11. The clearance of both R- and S-warfarin was slightly decreased (by 7% and 14%, respectively), with similar increases in AUC. Conversely, the maximum prothrombin time was decreased by 10%.\(^1\) As has been suggested for ‘lasofoxifene’, (p.423), this might be because oestrogenic compounds increase plasma concentrations of vitamin K-dependent clotting factors, so antagonising the effect of warfarin.

The manufacturer recommends that because modest decreases in prothrombin times have been seen, which may develop over several weeks, prothrombin times should be checked. They extend this recommendation to cover the use of other coumarins.\(^2\)

### Coumarins + Retinoids

Case reports describe reduced warfarin effects in a patient given etretinate, and in a patient given isotretinoin. Acitretin did not significantly alter the anticoagulant effects of phenprocoumon in healthy subjects.

#### Clinical evidence

(a) Phenprocoumon

Acitretin 50 mg daily for 10 days slightly increased the Quick test of 10 healthy subjects stabilised on phenprocoumon, from 22 to 24%, and the corresponding INR value decreased from 2.91 to 2.71. However, these changes were not considered to be significant.\(^1\)

(b) Warfarin

1. Etretinate. A man with T-cell lymphoma who had recently been given chemotherapy (cyclophosphamide, doxorubicin, vincristine and prednisolone) was anticoagulated with warfarin after developing a pulmonary embolism. About three weeks later, he started etretinate 40 mg daily and it was found necessary to increase his warfarin dosage from 7 to 10 mg daily. His liver function tests were normal.\(^\) This patient had also recently started taking ‘co-proxamol’, (p.436), ‘tolbutamide’, (p.380) and ‘cimetidine’, (p.412), but all of these have been reported to only rarely increase the effect of warfarin.

2. Isotretinoin. A 61-year-old man stabilised on warfarin 2.5 mg daily for 2 to 3 years had a decrease in his INR to below 2.5 after starting oral cepfodoxime proxetil 200 mg twice daily and oral isotretinoin 30 mg daily for inflammatory lesions of the face. He required an increase in warfarin dose to 3.75 mg daily. The cepfodoxime was stopped after 10 days without a further change in warfarin requirement. However, when the isotretinoin was discontinued after 40 days, the INR progressively increased and the warfarin dose was eventually reduced to the pretreatment dose of 2.5 mg daily.\(^3\)

#### Mechanism

Not understood. It has been suggested that etretinate or isotretinoin may increase the rate of metabolism of warfarin.\(^2,3\)

#### Importance and management

Information appears to be limited to these reports. The clinical relevance of the two case reports of a modest increase in warfarin requirements on...
starting etretinate or isotretinoin is uncertain, but, until more is known, consideration could be given to monitoring the INR if patients are given warfarin and these retinoids. The study with acitretin suggests that no phenprocoumon dose adjustments are expected to be needed on starting acitretin.

**Coumarins + Ribavirin**

In a single patient, ribavirin appeared to decrease the effect of warfarin requiring a 40% increase in warfarin dose.

**Clinical evidence**

A 61-year-old patient who had been taking warfarin for a number of years with an INR in the range of 1.8 to 2.7 required a progressive 40% increase in warfarin dose (from 45 to 62.5 mg weekly) over the month after starting oral ribavirin 600 mg twice daily and subcutaneous interferon alfa-2b for active hepatitis C infection. During the following 11 months, the warfarin dose was stabilised at 57.5 mg weekly. Three weeks after discontinuation of the ribavirin and interferon, his INR had increased from 2.2 to 3.4 requiring a reduction in warfarin dose to 47.5 mg weekly. One year later, the patient was rechallenged with ribavirin 1 g daily for 4 weeks alone. At a weekly warfarin dose of 52.5 mg, his INR decreased from 2.6 to 1.8.1

**Mechanism**

Unknown. The few cases with ‘interferon’, (p.422) have suggested that this may increase the effect of warfarin. In this case, ribavirin seems to have decreased the effect of warfarin, and overridden any effect of interferon.

**Importance and management**

This is the only case of this interaction, so it is not established, although the evidence on rechallenge with ribavirin alone lends weight to it being an interaction. The authors recommend increased monitoring of anticoagulant effects in patients taking warfarin requiring ribavirin. Until more is known, this may be prudent.

**Coumarins + Ropinirole**

A man stabilised on warfarin had an increase in INR necessitating a 25% decrease in his warfarin dose while taking ropinirole.

**Clinical evidence, mechanism, importance and management**

A frail 63-year-old man taking levodopa/carbidopa daily and warfarin 4 mg daily with a stable INR ranging from 1.8 to 2.6 over the past 14 months was evaluated for possible progression of Parkinson’s disease. He was then given ropinirole 250 micrograms three times daily with a 25% reduction in his levodopa/carbidopa dose, and 9 days later his INR was noted to have increased to 4.6, but there were no apparent signs of bleeding. Warfarin was withheld for 4 days, and then restarted at 2 mg daily, and increased to 3 mg daily 19 days later when his INR was 1.2. After one month the ropinirole was discontinued because of adverse gastrointestinal effects, and 2 months later his INR was 1.4 necessitating an increase in the warfarin dose to the original dose of 4 mg daily.1

The mechanism of this probable interaction is unknown, and it appears to be the first evidence of such an interaction. No definite conclusions can be drawn from this isolated case.

**Coumarins + Sodium edetate**

A man had a reduction in the effects of warfarin, which was attributed to intravenous chelation therapy that included sodium edetate.

**Coumarins + Sevelamer**

Sevelamer does not alter the pharmacokinetics of warfarin.

**Clinical evidence, mechanism, importance and management**

In a study in healthy subjects, the pharmacokinetics of a single 30-mg oral dose of warfarin were not statistically changed by sevelamer 2.4 g (equivalent to 6 capsules). Five more doses of sevelamer were given with meals over 2 days to check whether it had any effect on the enterohepatic circulation. No effect was seen.1,3 Thus it appears that sevelamer does not bind to warfarin within the gut to reduce its absorption.

**Coumarins + SNRIs**

In at least six cases venlafaxine appears to have increased the INRs and caused bleeding in patients taking warfarin. A similar case has been seen with duloxetine and warfarin.

**Clinical evidence**

(a) Duloxetine

A woman taking warfarin with a stable INR (mean 2.2 over the previous year) developed petechiae and purpura 55 days after starting duloxetine 30 mg daily, and was found to have an INR of 5. Warfarin was stopped on day 58, but the INR continued to rise to greater than 19 on day 85, and she was given vitamin K. On day 94 the duloxetine was stopped. Warfarin was restarted on day 110 and by day 140 the INR was 2.2 with the warfarin dose stabilised at the original level.1

(b) Venlafaxine

The possible interactions of warfarin or other anticoagulants with venlafaxine do not appear to have been studied, but, as of May 2000, the manufacturers had on record 6 case reports of increased prothrombin times, raised INRs and bleeding (haematuria, gastrointestinal bleeding, melena, haemorrhaxis) in patients taking warfarin with venlafaxine.2

**Mechanism**

Just why these adverse interactions should have occurred is not understood, especially as no pharmacokinetic interaction is thought likely. Venlafaxine alone may uncommonly cause ecchymosis and mucosal bleeding and, rarely, prolonged bleeding time and haemorrhage.3 However, given the many other factors that can influence anticoagulant control, the reports of possible interactions could just represent idiosyncratic cases.

Clinical evidence, mechanism, importance and management

A 64-year-old man who had been taking warfarin for 3 weeks, with a gradually increasing dose to 25 mg weekly, had an INR decrease from 2.6 to 1.6 the day after he received intravenous chelation therapy with sodium edetate. He was given a single 10-mg dose of warfarin that day, then continued on his 25 mg weekly dose, with an INR in the range of 2.3 to 2.8. The chelation therapy also contained high-dose vitamin C along with various other vitamins and electrolytes.1

Whether this case represents an interaction with the chelation therapy is uncertain. Further study is needed.

Coumarins and related drugs + SSRIs

In a study, warfarin plasma levels were increased by 65% by fluvoxamine, and raised INRs have been seen in several cases. In another study with warfarin and paroxetine, the majority of patients experienced no interaction, but a few had minor bleeding events. Other studies suggest that citalopram and sertraline do not significantly alter the pharmacokinetics or effects of warfarin. However, isolated reports describe bleeding in patients taking SSRIs and coumarins or fluindione, and SSRIs alone have, rarely, been associated with bleeding.

Clinical evidence

(a) Citalopram

In a study in 12 healthy subjects given a single 25-mg oral dose of warfarin either alone or on day 15 of a 21-day course of citalopram 40 mg daily, the pharmacokinetics of both R- and S-warfarin remained unchanged in the presence of the citalopram, but the maximum prothrombin time was increased by 6.4% (1.6 seconds). This was considered to be clinically irrelevant.3

Nevertheless, a 63-year-old patient who had just started aconocoumarol 18 mg per week developed spontaneous gingival haemorrhage 10 days later after starting citalopram 20 mg daily for depression. Her INR had increased from a value of 1.8 to greater than 1.5. She was treated with 2 units of blood and citalopram was withdrawn. Her INR decreased to 1.95 within 5 days and she was able to continue on aconocoumarol 18 mg per week.2

(b) Escitalopram

Escitalopram is the S-isomer of citalopram, and as such would not be expected to interact pharmacokinetically with warfarin, see above.

(c) Fluoxetine

In a study in 3 healthy subjects, the half-life of a single 20-mg dose of warfarin was not altered by either a single 30-mg dose of fluoxetine given 3 hours before the warfarin, or by fluoxetine 30 mg daily for a week with the warfarin dose given 3 hours after the last dose of fluoxetine. In addition, fluoxetine had no effect on the warfarin-induced prolongation of prothrombin time.5 In another study, 6 patients stabilised on warfarin had no significant changes in their prothrombin times or INRs while taking fluoxetine 20 mg daily for 21 days. The maximum change was a decrease in prothrombin time of 3.5% (15%) in one patient.2

However, there are few reports of increases in INR in patients taking warfarin with fluoxetine. In one report, the INR of a man stabilised on warfarin, amiodarone, furosemide, digoxin, ciprofloxacin and levethromixin rose sharply from a range of 1.8 to 2.3 up to 14.9 within 5 days of starting fluoxetine 30 mg daily.7 The INR of another man with metastatic carcinoma taking warfarin, dexamethasone, bisacodyl and lactulose rose from a range of 2.5 to 3.5 up to 15.5 within 2 weeks of starting fluoxetine 20 mg daily. He showed microscopic haematuria but no bleeding.5 Other reports describe an abdominal haematoma,5 cerebral haemorrhage,6 severe bruising7 and increases in INRs8 in patients taking fluoxetine and warfarin.9 In 1993, the CSM in the UK was also said to have 4 other similar cases on record.8 In the preliminary report of one retrospective review of patients records, all of 8 evaluable cases of concurrent use of fluoxetine and warfarin had an abnormally prolonged prothrombin time.9

Bowel haemorrhage has been reported in a patient taking warfarin, fluoxetine and mefenamic acid,10 but it is likely that mefenamic acid was the contributing factor in this case.11

Conversely, in a case-control study in patients stabilised on warfarin, the increase in risk of hospitalisation for an upper gastrointestinal bleed after starting either fluvoxamine or fluoxetine was higher than for other SSRIs (relative risk 1.2) but this did not reach statistical significance (95% confidence interval 0.9 to 1.6).12 Note that these drugs were considered separately, and the number taking each individual SSRI was not stated.

(d) Fluvoxamine

In a study in healthy subjects, fluvoxamine 50 mg three times daily for 12 days increased steady-state plasma warfarin levels by about 65% and increased prothrombin times by 27.8%,13,14 A worldwide literature search by the manufacturers of fluvoxamine identified only 11 reported interactions between warfarin and fluvoxamine by 1995, all with clinical signs that included prolonged prothrombin times.15 An 80-year-old woman who had recently started taking warfarin, digoxin and ‘colchicine’, (p.397), had an increase in her INR from 1.8 to about 10 within a week of starting to take fluvoxamine 25 mg daily. Both the warfarin and fluvoxamine were stopped, but her INR only stabilised on the original dose of warfarin after the colchicine was withdrawn.16 Another report describes a 79-year-old woman admitted to hospital because of suicidal thoughts. She was taking warfarin (INR 1.6 to 1.8) and citalopram 10 mg at night and other medications including paracetamol with dextropropoxyphene. On the third day in hospital the citalopram dose was increased to 30 mg at bedtime and after 2 days it was discontinued and fluvoxamine 50 mg daily was started to treat depression and possibly obsessive thoughts. Within 4 days the patient’s INR had increased to 3.7. Fluvoxamine was replaced with venlafaxine and warfarin was omitted for 1 day. The INR gradually decreased to the normal range over about 7 days.17

A further isolated report describes a woman stabilised on fluindione whose INR rose to 7.13 (from a normal value of about 2.5) within 13 days of starting to take fluvoxamine 100 mg daily. She had received fluoxetine, dosulepin and lorazepam for 15 days before fluvoxamine was started.18

Conversely, in a case-control study in patients stabilised on warfarin, the increase in risk of hospitalisation for an upper gastrointestinal bleed after starting either fluvoxamine or fluoxetine was higher than for other SSRIs (relative risk 1.2) but this did not reach statistical significance (95% confidence interval 0.9 to 1.6).12 Note that these drugs were not considered separately, and the number given each individual SSRI was not stated.

(e) Paroxetine

Paroxetine 30 mg daily, given to healthy subjects with warfarin 5 mg daily, did not significantly increase mean prothrombin times, but mild, clinically significant bleeding was seen in 5 of 27 subjects given the combination. Two withdrew from the study because of increased prothrombin times, and another because of haematuria. The pharmacokinetics of the warfarin and the paroxetine remained unchanged by concurrent use.19 In a brief retrospective review, 4 patients taking warfarin were said to have had an increase in INR by an average of 3 points (increases of nearly 100% in some cases) associated with the use of paroxetine and sertraline.20

A single case report21 describes severe bleeding (abdominal haematoma) in a patient taking aconocoumarol and paroxetine when given phenytoin, but it is by no means clear whether the paroxetine had any part to play in what happened (see ‘Phenytoin + Coumarins and related drugs’, p.555).

(f) Sertraline

In a placebo-controlled study in healthy subjects, sertraline, in increasing doses up to 200 mg daily for 22 days, increased the prothrombin time AUC in response to a single 0.75-mg/kg dose of warfarin by 7.9%. This was statistically significant, but regarded as too small to be clinically relevant.22

In a brief retrospective review, 4 patients taking warfarin were said to have had an increase in INR by an average of 3 points (increases of nearly 100% in some cases) associated with the use of paroxetine and sertraline.20

Mechanism

Pharmacokinetic interactions. Fluvoxamine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which S-warfarin is metabolised, and is also a potent inhibitor of CYP1A2 and CYP2C19, by which the less active R-warfarin is metabolised. Consequently, fluvoxamine would be expected to increase warfarin effects. In vitro, fluvoxamine, paroxetine, sertraline, and citalopram had little or no inhibitory effect on CYP2C9 mediated S-warfarin hydroxylation.21 In addition, these SSRIs do not inhibit CYP1A2 or

NR = not reported.

Continued
CYP2C19, therefore they would not be anticipated to increase warfarin levels.

Pharmacodynamic interactions. Serotonin release by platelets plays an important role in haemostasis, and epidemiological studies and case reports suggest that SSRIs alone are rarely associated with bleeding events.22 There is no firm evidence that the risk of bleeding is increased if SSRIs are given with anticoagulants.

Importance and management

A pharmacokinetic interaction between fluvoxamine and warfarin that leads to increased anticoagulant effects is established. Therefore, the response should be monitored when fluvoxamine is first added, being alert to the need for the decrease the anticoagulant dosage.

None of the other SSRIs studied (citalopram, fluoxetine, paroxetine) have been shown to alter the pharmacokinetics of warfarin, and neither fluoxetine nor paroxetine increased the prothrombin time. However, citalopram and sertraline caused a less than 10% increase in prothrombin time, and a few patients taking paroxetine with warfarin had bleeds. However, in general, these effects would generally not be expected to be clinically relevant. Nevertheless, because SSRIs alone can rarely cause bleeding, some predict that this may result in additive effects with coumarins and indanediones, and recommend caution with all SSRIs. Note that there are case reports of interactions with warfarin for many of the SSRIs (citalopram, fluoxetine, paroxetine, sertraline).

## Coumarins and related drugs + Statins

Studies have suggested that fluvastatin and rosuvastatin can increase warfarin levels and/or effects. Other studies with atorvastatin, lovastatin, pravastatin, and simvastatin suggest that they do not usually significantly alter the effects of warfarin, although cases of bleeding have been seen when these statins were given with coumarins and fluindione.

### Clinical evidence

Pharmacological studies of the effect of statins on warfarin are summarised in Table 12.6, and case reports of interactions between statins and coumarins are summarised in Table 12.7. Early case reports described a patient stabilised on warfarin with low INR who was treated with simvastatin 10 mg daily for 3 weeks then 20 mg daily, with the INR raised to 4.3.

### Mechanism

Fluvastatin is a modest inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which the more potent S-warfarin is metabolised. Evidence from an interaction study with the CYP2C9 substrate diclofenac suggests that this interaction is most likely with higher and sustained fluvastatin levels, which might explain why, with warfarin, it was demonstrated in healthy subjects with the maximum recommended daily dose of 80 mg daily, but not the usual clinical dose of 40 mg daily, and why it has not been seen in all patients. Lovastatin and simvastatin appear less likely to interact via CYP2C9, although it is possible they might interact via other mechanisms.

†Switched from atorvastatin

‡Note that this is an indanedione

isoenzymes. It may be that because warfarin has multiple routes of metabo-
olism that other isoenzymes can ‘pick up’ warfarin metabolism if compe-
tition for metabolism occurs. Interactions may therefore only occur if
other confounding factors are present. Rosuvastatin clearly shows a dose
related increase in warfarin effects, but this was not due to an increase in
R- or S-warfarin levels, and the mechanism for this effect is currently un-
known.9

Importance and management
Data are limited, which is surprising given the widespread use of statins
and warfarin, and are sometimes contradictory, all of which complicates
making firm recommendations. Recent evidence suggests that a modest
pharmacokinetic interaction occurs between fluvastatin and warfarin at
high doses, and it would explain the case reports of an interaction with
this statin. The clinical evidence suggests that only some patients develop
an important interaction (3 of 25 evaluable patients in one analysis). In
the UK, the manufacturer states that concurrent use of fluvastatin and warfarin
may commonly cause significant increases in prothrombin time.10 Clearly,
with fluvastatin, increased monitoring is required when starting or stop-
ning the statin, or changing the dose. Similar advice also applies to rosu-
vastatin, which has the best pharmacological data on concurrent use in
patients, clearly showing that clinically important increases in INR can oc-
cur. In contrast to fluvastatin, this interaction does not appear to have a
pharmacokinetic basis.

Data for simvastatin appear to be limited to retrospective analyses. In
general these show that simvastatin can cause a minor increase in warfarin
effects. This would appear to be supported by the fact that there is only one
full published report of an interaction in a patient taking acenocoumarol.

Effects. This would appear to be supported by the fact that there is only one
vastatin

manufacturer also recommends increased monitoring.15 There appear to
of simvastatin, but it appears to interact similarly to simvastatin, and the
manufacturer does not give any advice on monitoring, 16 but in the UK, the
manufacturer does recommend close monitoring, 17 which seems over-
cautious. Limited data for pravastatin also suggest that no interaction oc-
curs with warfarin, although there is one isolated case report with the in-
cludedafluindione. No increased monitoring would appear to be
necessary on concurrent use.

Coumarins + Sucralfate

The simultaneous administration of warfarin and sucralfate did not alter the anticoagulant effect of warfarin in studies in patients on stable therapy. However, case reports describe a marked reduction in the effects of warfarin in four patients taking sucral-

Clinical evidence
In an open, crossover study in 8 elderly patients taking warfarin, their anticoagulant response (thromboplastin time) and plasma warfarin levels re-

mained unchanged while taking sucralfate 1 g three times a day over a 2-
week period.1 Similarly, in a preliminary report of another study, sucralfate 1 g four times daily for 2 weeks had no effect on prothrombin time or plas-
ma warfarin levels in 5 patients on stable warfarin therapy.2 In both these
studies, the daily warfarin dose was taken simultaneously with one of the
sucralfate doses.1,2

However, there are four case reports of reduced warfarin effects with sucral-

fate. In one of these, a man taking several drugs (digoxin, furosemide, chlorpropamide, potassium chloride) had serum warfarin levels that were about two-thirds lower when he was given sucralfate (dose not stated). When the sucralfate was withdrawn, his serum warfarin levels rose to their former levels accompanied by a prolongation of prothrombin times.3 Another patient taking sucralfate had subtherapeutic prothrombin times on starting warfarin, despite warfarin doses of up to 17.5 mg daily. When the sucralfate was stopped his prothrombin times rose to 1.5 times the control, even though the warfarin dose was reduced to 10 mg daily.4 One other pa-

tient appeared to have reduced responses to warfarin while taking sucral-

pate, despite separation of administration.5 However, another patient taking

warfarin and sucralfate had a reduced response to warfarin only when it

was taken simultaneously with sucralfate, but not when administration was

delayered.6

Mechanism
Unknown. It is suggested that the sucralfate may possibly adsorb the war-

farin so that its bioavailability is reduced.4

Importance and management
The documentation appears to be limited to the reports cited. Any interac-
tion would therefore seem to be uncommon. Concurrent use need not be
avoided, but bear this interaction in mind if a patient has a reduced antico-
agulant response to warfarin.

Coumarins + Sucrose polyesters

Short-term, moderate consumption of potato crisps containing sucrrose polyesters (Olestra, Oleian), which include vitamin K<sub>1</sub>, did not alter the INR response to warfarin.

Clinical evidence
In a randomised, double-blind, placebo-controlled study in 36 patients sta-

bilised on warfarin, sucrose polyester 12 g daily (as Pringles Original

Flavor Fat Free Potato Crisps with Olean 42 g) for one week did not sig-
nificantly alter the anticoagulant effects of warfarin (mean INR increase

of 0.02, versus 0.17 for placebo). After one week, greater than expected

numbers of patients from both the placebo and sucrose polyester groups

had INRs outside the therapeutic range of 2 to 3 (3 sucrose polyester re-

cipients and 3 placebo recipients had an INR above 3 (max 4.1) and 2 in

the sucrose polyester group and one in the placebo group had an INR less

than 2).
than 2). Two of each group also withdrew because of diarrhea: their INRs were therapeutic. Only 22 patients entered the second week of the study, and there was no important effect on INR in these patients after the second week.1

**Mechanism**

Sucrose polyesters are non-absorbable, non-calorific fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general, however, they are known to reduce the absorption of some fat-soluble vitamins, and therefore might lower vitamin K stores.2 Because of this, snacks containing Olestra are supplementated with vitamin K1 at a level of 8 micrograms per gram of Olestra.3 It is possible that this supplementation could be insufficient to offset the vitamin K-lowering effect and increase patient sensitivity to warfarin, or it could be too much and result in an antagonism of warfarin.

**Importance and management**

No evidence was found in the above study to suggest that short-term moderate consumption of a snack containing sucrose polyesters (12 g daily, including 96 micrograms of vitamin K daily) altered the anticoagulant effect of warfarin. In 1996, the US FDA considered that the changes in dietary intake similar to this of a ‘vitamin K1 supplement’, (p.401) has altered coagulation status in some subjects, and pure vitamin K1 is much more bioavailable than that from ‘plant sources’, (p.409). Some consider that the snacks may have an impact on serum vitamin K levels.4 Given these concerns, further study is probably needed.

### Coumarins + Sulfipyrazone

The anticoagulant effects of warfarin are markedly increased by sulfipyrazone, and there are case reports of moderate to serious bleeding on concurrent use. Achenocumarol is modestly affected. Phenprocoumon does not appear to be significantly affected. Bear in mind that the antiplatelet effects of sulfipyrazone might increase the risk of bleeding with coumarins.

**Clinical evidence**

(a) Achenocumarol

In a placebo-controlled, crossover study in 22 patients taking achenocumarol, sulfipyrazone 800 mg daily for 2 weeks led to a drop in the mean prothrombin time requiring a reduction in anticoagulant dosage by an average of 20%. Four patients withdrew because of bleeding episodes, 3 while taking sulfipyrazone and one while taking placebo.1

(b) Phenprocoumon

In a study in 6 healthy subjects, sulfipyrazone 400 mg daily for 17 days had little effect on phenprocoumon levels after a single 0.6-mg/kg dose of phenprocoumon given on day 4. The AUC of prothrombin time increased in 4 subjects and decreased in 2, for an overall non-significant mean increase of 16%.2 Similar findings were reported in another study of similar design.3

(c) Warfarin

In a double-blind, placebo-controlled study in 11 patients stabilised on warfarin, sulfipyrazone 200 mg four times daily for 6 to 12 months reduced the average warfarin dose requirement by 44% from 7.3 to 4.1 mg week, compared with no change in the placebo group. There were 4 episodes of bleeding (haematoma, epistaxes and bleeding gums) in 3 patients receiving sulfipyrazone and one in the placebo group. The authors noted it was difficult to regulate anticoagulant control in the patients taking sulfipyrazone.4,5 Similarly, in another study, the prothrombin ratios of 5 patients taking warfarin rose rapidly over 2 to 3 days after sulfipyrazone 200 mg every 6 hours was added. The average warfarin requirements fell by 46% and 2 patients needed vitamin K to combat the excessive hypoprothrombinemia. When the sulfipyrazone was withdrawn, the warfarin requirements returned to their former levels within 1 to 2 weeks.6

A number of case reports have described increased effects of warfarin in patients starting sulfipyrazone,7,12 or an exaggerated anticoagulant response in patients taking sulfipyrazone and then starting warfarin.13 This interaction has been described in numerous studies and case reports in those taking warfarin.4,5,7,14 Moderate to severe bleeding occurred in some instances.8,10,11 An increased anticoagulant effect of warfarin in the first 15 days after starting sulfipyrazone, followed by an unexplained progressive increased warfarin dose requirement has been described in one report.14 However, this may have had other explanations, since a constant potentiation of warfarin is usually seen on long-term sulfipyrazone use.5

In subsequent studies in healthy subjects, sulfipyrazone 200 mg twice daily for 10 days was shown to augment the effect of warfarin (99% or 83% increase in the AUC of the prothrombin time) by inhibiting the clearance of S-warfarin (by 51% or 40%) when a single dose of warfarin was given on day 4. In contrast, sulfipyrazone did not alter the effect of R-warfarin, and actually increased its clearance by 30% or 42%.15,16

**Mechanism**

Sulfipyrazone inhibits the metabolism of the more potent S-isomer of warfarin, probably because its sulfide metabolite inhibits the cytochrome P450 isoenzyme CYP2C9.17 It probably interacts by a similar mechanism with achenocumarol. It could be speculated that sulfipyrazone induces the metabolism of R-warfarin via CYP1A2, since it modestly induces the metabolism of ‘theophylline’, (p.1199). Some early in vitro evidence18 suggested that plasma protein binding displacement might explain this interaction, but a study in healthy subjects found that sulfipyrazone did not alter the free fraction of either R- or S-warfarin.19 Sulfipyrazone also has antiplatelet effects, so might be expected to increase the risk or severity of bleeding should over-anticoagulation occur.

**Importance and management**

The increased effect of warfarin with sulfipyrazone is a well established interaction of clinical importance. If sulfipyrazone is added, the prothrombin time should be well monitored and suitable anticoagulant dosage reductions made. Halving the dosage of warfarin4,6,20 has proven to be adequate in patients taking sulfipyrazone 600 to 800 mg daily. The interaction with achenocumarol1 is less marked, and a 20% dose reduction appears adequate in patients taking sulfipyrazone 600 to 800 mg daily. Phenprocoumon is reported not to have a pharmacokinetic interaction with sulfipyrazone. Bear in mind that the antplatelet effects of sulfipyrazone might increase the risk of bleeding with coumarins.

Thromboembolic disease in patients with cancer, warfarin is generally in-

British Comparative Ratios and 3 haemorrhaged. 3 In 1987, the manufac-

ing loading doses of patients not taking tamoxifen. Of the 5 taking tamoxifen, 2 had shown

study of the records of women with breast cancer who had been admitted

time within the range of 20 to 25 seconds. A subsequent retrospective

prothrombin time increased from 19 to 38 seconds. A warfarin dose reduc-
thrombosis. Seven weeks later tamoxifen 40 mg daily was started, and her

specifically contraindicates concurrent use with warfarin or other cou-

port of between one-half to two-thirds for warfarin. In the US, when tamoxifen

replacement (prothrombin time of 23 to 34 seconds taking

Fareston (Toremifene citrate). Orion Pharma UK Ltd. UK Summary of product characteristics, February 2006.

Cumarins + Tamoxifen or Toremifene

In one retrospective analysis, 5 patients taking tamoxifen were very sensitive to warfarin, and, in a second, 5 of 22 patients had problems with over-anticoagulation. Case reports also describe over-anticoagulation in three women taking warfarin and one woman taking acenocoumarol when they also took tamoxifen. It has been suggested that a similar interaction may occur with
toremifene.

Clinical evidence

A woman who had been taking warfarin for 11 years after a heart valve replacement (prothrombin time of 23 to 34 seconds taking warfarin 27 to 28.5 mg weekly), was given tamoxifen 10 mg twice daily as adjuvant ther-

apy after mastectomy for early breast cancer. Three days later her pro-

thrombin time was 39 seconds, and 3 weeks later it was 75.6 seconds, although this was attributed to a 5-day course of co-trimoxazole, and so the warfarin dose was unchanged. Six weeks later she developed haemate-

mesis, abdominal pain and haematuria, and her prothrombin time was found to be 206 seconds. She was restabilised on a little over half the war-

farin dosage (17.5 mg weekly) while continuing to take the tamoxifen. In another case, a 43-year-old woman was given warfarin for a deep vein thrombosis. Seven weeks later tamoxifen 40 mg daily was started, and her

prothrombin time increased from 19 to 38 seconds. A warfarin dose reduc-
tion from 5 to 1 mg daily was eventually needed to keep her prothrombin time within the range of 20 to 25 seconds. A subsequent retrospective study of the records of women with breast cancer who had been admitted to hospital for serious thromboembolism from 1981 to 1986 revealed 5 other patients taking tamoxifen when warfarin was started, and 13 pa-

ents not taking tamoxifen. Of the 5 taking tamoxifen, 2 had shown marked increases in prothrombin times, and bleeding, shortly after receiving loading doses of warfarin (three daily doses of 10 mg, 10 mg and 5 mg). The other 3 needed daily warfarin doses of 2 mg, 2 mg and 3 mg, respectively, which were about one-third of those taken by the 13 other pa-

ents not on tamoxifen (mean 6.25 mg). In another retrospective analysis of hospital admissions from 1980 to 1988, 22 patients were identified who had been given tamoxifen with war-

farin. Of these, 17 had no problems, but 2 developed grossly elevated

British Comparative Ratios and 3 haemorrhaged. In 1987, the manufactur-

ers of tamoxifen had one report of this interaction on their files. A 53-year-old woman who had been taking acenocoumarol for 2 years after a heart valve replacement died after a massive brain haemorrhage about 3 weeks after starting to take tamoxifen 20 mg daily for a benign breast condition. 4

Mechanism

Unknown. Tamoxifen can increase the risk of thrombosis, particularly when it is used with ‘antineoplastics’, (p.616).

Importance and management

Evidence is limited to the above reports, but it appears that a clinically im-

portant interaction between tamoxifen and warfarin can occur, which ap-

parently affects some but not all patients. Monitor the effects closely if
tamoxifen is added to treatment with warfarin or acenocoumarol and re-
duce the dosage as necessary. The reports cited here indicate a reduction of between one-half to two-thirds for warfarin. In the US, when tamoxifen

is being used for the primary prevention of breast cancer, the manufacturer specifically contraindicates concurrent use with warfarin or other cou-

marins. 5

Consider also that, from a disease perspective, when treating venous

thromboembolic disease in patients with cancer, warfarin is generally in-

ferior (higher risk of major bleeds and recurrent thrombosis) to low mol-

cular weight heparins. 6

Because of the data with tamoxifen, the manufacturers of toremifene

(indicated for hormone-dependent metastatic breast cancer in postmeno-

pausal women) contraindicate the concurrent use of coumarin anticoagu-

lants in the UK, 7 but just recommend careful monitoring of prothrombin time in the US. 8 However, there appear to be no published reports of any

interaction between toremifene and warfarin.

4. O’Sullivan DP, Needham CA, Bangs A, Atkin K, Kendall FD. Postmarketing surveillance of

apy

after a heart valve

Cumarins + Terbinafine

Terbinafine did not interact with warfarin in a study in healthy subjects, and patients have received the combination without apparent problems. However, two isolated cases describe reduced and increased anticoagulation, respectively. A cohort study found no increased risk of over-anticoagulation when acenocoumarol or phenprocoumon were given with terbinafine.

Clinical evidence

In a randomised, placebo-controlled, double-blind study in 16 healthy subjects, terbinafine 250 mg daily for 14 days did not alter the pharmacokinetics or anticoagulant effects of a single 30-mg oral dose of warfarin
given on day 8. 1 In a post-marketing surveillance study of terbinafine, 26 patients were identified who were also taking warfarin and there was no evidence to suggest an interaction in these patients. 2, 3 In one cohort study in patients taking acenocoumarol or phenprocoumon, the concurrent use of oral terbinafine (n=49) or cutaneous terbinafine (n=29) was not associ-

ated with an increased risk of over-anticoagulation (INR greater than 6). 4

However, an isolated report describes a 68-year-old woman taking long-
term warfarin whose INR fell from 2.1 to 1.1 within a month of starting a 3-month course of terbinafine 250 mg daily for tinea unguium. It was necessary to raise her warfarin dosage from 5.5 mg daily to a range of 7.5 to 8 mg daily while taking the terbinafine, and to reduce it stepwise to 5.5 mg over the 4 weeks after the terbinafine was stopped. 5 In contrast, an-
other isolated case report describes an elderly woman stabilised on war-

Mechanism

The isolated cases are not understood, and have been questioned. 7

Importance and management

Normally no interaction occurs between coumarins and terbinafine, while the two isolated cases cited are rarities, and unexplained. There appears therefore to be no reason for avoiding concurrent use, but bear these cases in mind if terbinafine is given to patients taking warfarin.

1. Guerret M, Franchetteau P, Hubert M. Evaluation of effects of terbinafine on single oral dose pharmacokinetics and anticoagulant actions of warfarin in healthy volunteers. Pharmacother-

y (1997) 17, 767–73.

2. O’Sullivan DP, Needham CA, Bangs A, Akin K, Kendall FD. Postmarketing surveillance of

Coumarins + Tetracyclic and related antidepressants

In one study mirtazapine caused a slight increase in INR in subjects given warfarin. In studies in patients, maprotiline did not alter the anticoagulant effect of acenocoumarol, and mianserin did not alter the anticoagulant effect of phenprocoumon. In isolated case reports, an increased effect of warfarin and a decreased effect of acenocoumarol was seen when mianserin was given.

Clinical evidence

(a) Maprotiline

The anticoagulant effects of acenocoumarol were not affected by maprotiline 50 mg three times daily for 2 weeks in 20 patients stabilised on acenocoumarol.1

(b) Mianserin

In a randomised, double-blind study in 60 patients taking phenprocoumon for 5 weeks, there was no difference in anticoagulant control and phenprocoumon dose between placebo recipients and those receiving either mianserin up to 30 mg daily or up to 60 mg daily for 20 days.2 A single case report describes a man stabilised on warfarin whose British standard ratio rose from 1.8 to 4.6 (prothrombin time rise from 20 to 25 seconds) after taking mianserin 10 mg daily for 7 days.3 However, another patient taking warfarin received mianserin in doses varying between 0 and 120 mg daily for 22 days without any change in prothrombin ratio.4 A further patient stabilised on acenocoumarol and amiodarone needed an increase in his acenocoumarol dosage after starting mianserin, and a decrease when this drug was stopped.5

(c) Mirtazapine

In a study in healthy subjects stabilised on individual doses of warfarin,6 mirtazapine 15 mg for 2 days then 30 mg daily for 5 days increased the mean INR from 1.6 to 1.8. This small increase was not considered clinically relevant by the authors of the study or one of the UK manufacturers.6,7 One UK manufacturer comments that a more pronounced effect cannot be excluded at higher doses of mirtazapine.8 However, there do not appear to be any published reports of interactions.

Mechanism

Not understood.

Importance and management

Maprotiline does not interact with acenocoumarol and mianserin does not interact with phenprocoumon. The isolated cases of an increase in warfarin effects and a decrease in acenocoumarol effects with mianserin are unexplained, and probably of little general relevance. One UK manufacturer of mirtazapine very cautiously advises that the prothrombin time should be controlled if mirtazapine is given with warfarin.8 However, there do not appear to be any reports of problems with this combination, and another manufacturer does not consider monitoring to be necessary.2

Coumarins and related drugs + Thyroid and Antithyroid compounds

Hypothyroidism and hyperthyroidism, respectively, decrease and increase the metabolism of the clotting factors. Correction of these disease states therefore alters anticoagulant requirements. Bleeding has been seen in patients given thyroid hormones without an adjustment of their warfarin dose, and increased warfarin requirements have been seen in a patient given thiamazole. This is more of a drug-disease interaction rather than a direct drug–drug interaction and is therefore likely to occur with any coumarin or indanedione given with any drug that affects thyroid function.

Clinical evidence

(a) Hypothyroidism and Thyroid compounds

In a study in 7 patients with myxoedema (hypothyroidism), the response to a single dose of warfarin was increased after 3 months of treatment with iotroxurone (when euthyroid), when compared with before treatment, without a change in plasma warfarin levels.1 Various case reports describe similar effects. In one report, brief mention is made of one patient who showed an increased response to warfarin after an increase in dose of thyroid replacement therapy, and of another patient on long-term warfarin who had a bleeding episode when thyroid replacement therapy was started.2 Another patient taking warfarin developed oral mucosal bleeding with an INR of greater than 11 when her hypothyroidism was overcorrected with levothyroxine, although she had no clinical signs of hyperthyroidism.3 In another case, a subdural haematoma occurred in a child stabilised on warfarin when levothyroxine was started, and her dose of warfarin was eventually reduced from 7.5 mg daily to 5 mg daily.4

A patient with myxoedema required a gradual reduction in his dosage of phenindione from 200 to 75 mg daily as his thyroid status was corrected by iotroxurone.5 A similar patient required a reduction in acenocoumarol dose from 16 mg daily to 5 mg daily when hypothyroidism was corrected with iotroxurone.5

(b) Hyperthyroidism and Antithyroid compounds

In 5 patients with hyperthyroidism, the response to a single dose of warfarin was decreased 3 months after treatment with iodine-131 (when euthyroid), when compared with before treatment. In addition, the plasma half-life and levels of warfarin were higher after treatment.6 A hyperthyroid patient taking warfarin had a marked increase in his prothrombin times on two occasions when his treatment with thiamazole (methimazole) was stopped and he became hyperthyroid again.7 Another similar case has been described where the required dose of warfarin increased from 35 mg weekly to 65 mg weekly as the patients hyperthyroid state was corrected with thiamazole 30 mg daily. However, the patient then became hypothyroid and required up to 85 mg weekly of warfarin. When the thiamazole dose was withheld for 5 days and then reduced to 5 mg daily, the patient rapidly developed a markedly raised INR of 7 without bleeding complications.8 In another report, a patient required just 0.5 mg of warfarin daily while hyperthyroid.9 Another case of possible enhanced response to warfarin in a hyperthyroid patient has been reported.9,10

Mechanism

In hypothyroid patients the catabolism (destruction) of the blood clotting factors (II, VII, IX and X) is low and this tends to cancel, to some extent, the effects of the anticoagulants, which reduce blood clotting factor synthesis. Conversely, in hyperthyroid patients in whom the catabolism is increased, the net result is an increase in the effects of the anticoagulants.11 In studies in healthy subjects, dextrothyroxine (which has weak thyroid activity compared with levothyroxine) potentiated the anticoagulant effect of dicoenol12 and warfarin13 without altering the half-life and plasma levels of the anticoagulants, and without altering vitamin K–dependent clotting activity.12 Because of this, it was suggested that the thyroid hormones might increase the affinity of the anticoagulants for its receptor sites.12,13
Importance and management

A well documented and clinically important interaction occurs if oral anticoagulants and thyroid hormones are taken concurrently.

Hypothyroid patients taking an anticoagulant who are subsequently treated with thyroid hormones as replacement therapy will need a downward adjustment of the anticoagulant dosage as treatment proceeds if excessive hypoprothrombinemia and bleeding are to be avoided. All of the oral anticoagulants may be expected to behave similarly. Conversely, as the thyroid status of hypothyroid patients returns to normal by the use of antithyroid drugs (e.g. carbimazole, thiamazole, propylthiouracil) an increase in the anticoagulant requirements would be expected. Close anticoagulant monitoring and dose adjustment are required, particularly while thyroid hormone levels are being stabilised. Note that, in one case the authors commented that the magnitude and clinical complexity of the interaction between the drugs and disease state was unexpected.

Note that propylthiouracil in the absence of an anticoagulant has very occasionally been reported to cause hypoprothrombinemia and bleeding.

Some drugs can alter thyroid status as an unwanted effect, and this will also alter the response to the oral anticoagulants. For example, 'iodomarine', (p.363) can cause thyrotoxicosis, which decreases warfarin requirements. Also, use of dextrothyroxine for hypercholesterolaemia decreased the required dose of warfarin and dicumarol, presumably because it has weak thyroid activity.

15. Gotta AW, Sullivan CA, Seaman J, Jean-Gilles B. Prolonged intraoperative bleeding caused by the smoking of cigarettes每日 (size unknown) and who were given warfarin to steady-state, smoking abstinence for about 6 weeks increased the average steady-state warfarin levels by 13%, decreased warfarin clearance by 13% and increased the warfarin half-life by 23%, but no changes in the prothrombin time occurred. In an 80-year-old man taking warfarin had a steady rise in his INR (from a range of 2 to 2.8 up to 3.7) over a 3-month period when he gave up smoking. No bleeding occurred. His dose of warfarin was reduced by 14%, and the INR stabilised at 2.3 to 2.8 over the next 9 months. Similarly, another patient required a 23% reduction in warfarin dose after stopping smoking following recovery from bacterial meningitis.

In contrast, in one retrospective study of patients who had undergone cardiac valve replacement, there was no statistically significant difference between the warfarin dosage requirements of 117 non-smokers, 23 light smokers (20 or less cigarettes daily) or 34 heavy smokers (greater than 20 cigarettes daily).

Mechanism

Some of the components of tobacco smoke act as cytochrome P450 isoenzyme inducers, which might cause a small increase in the metabolism of the warfarin. When smoking stops, the enzymes are no longer stimulated, and the metabolism of the warfarin falls slightly and its effects are correspondingly reduced. Tobacco smoke is known to induce CYP1A2, which has a partial role in the metabolism of the less active R-warfarin enantiomer. Note that smoking status had no effect on the S-warfarin AUC in one study.

The possible case of an interaction with smokeless tobacco was attributed to the very high ‘vitamin-K’, (p.458), content of tobacco resulting in relative warfarin resistance. However, there were two previous INR spikes in this patient, which were attributed to dietary changes, an explanation that seems unlikely if there was a high background vitamin K intake from the tobacco. This case is therefore unclear.

Importance and management

The overall picture seems to be that smoking (or giving up smoking) only has a slight to moderate effect on the response to warfarin, and only the occasional patient will need a small dosage alteration. This should easily be detected in the course of routine INR checks. Note that tobacco smoking increases cardiovascular disease risk, and patients requiring anticoagulants should be encouraged and helped to stop smoking.

The isolated case with smokeless tobacco is unclear, but consider the possibility that vitamin K from chewing tobacco may reduce warfarin effects. Further study is needed.

**Coumarins + Tobacco**

In one study in healthy subjects, stopping smoking caused a minor 13% increase in steady-state warfarin levels. Two cases have been reported of patients who required 14% and 23% reductions in warfarin dose, respectively, on stopping smoking. However, one analysis did not find any significant difference in warfarin dose by smoking status. One patient who stopped chewing tobacco had an increase in INR.

**Clinical evidence**

(a) **Chewing tobacco**

In a patient using smokeless tobacco (chewing tobacco) for greater than 85% of waking hours, the INR was found to have increased from 1.1 to 2.3 six days after discontinuation of the tobacco use. This patient had generally had an INR of 1.1 to 1.9 since restarting warfarin 4 months earlier, despite gradually increasing the warfarin dose from 10 mg daily to 25 mg daily alternating with 30 mg daily. However, during this time, he did have two INR spikes of 2.5 and 4.2, which were attributed to dietary changes, but see mechanism below.

(b) **Smoking tobacco**

In a controlled study in 9 healthy subjects who normally smoked at least one pack of cigarettes daily (size unknown) and who were given warfarin to steady-state, smoking abstinence for about 6 weeks increased the average steady-state warfarin levels by 13%, decreased warfarin clearance by 13% and increased the warfarin half-life by 23%, but no changes in the prothrombin time occurred. An 80-year-old man taking warfarin had a steady rise in his INR (from a range of 2 to 2.8 up to 3.7) over a 3-month period when he gave up smoking. No bleeding occurred. His dose of warfarin was reduced by 14%, and the INR stabilised at 2.3 to 2.8 over the next 9 months. Similarly, another patient required a 23% reduction in warfarin dose after stopping smoking following recovery from bacterial meningitis.

**Coumarins + Thiabendazole**

An isolated case report describes a marked increase in the anticoagulant effects of acenocoumarol in a patient given thiabendazole.

**Clinical evidence, mechanism, importance and management**

An increase in the anticoagulant effects of acenocoumarol occurred in a patient with nephrotic syndrome undergoing dialysis, who was given thiabendazole 8 g daily for 2 days on two occasions about 7 weeks apart. On both occasions, his INR rose from 2.9 to more than 5 without any clinical consequence. The reasons are not understood, nor is the general importance of this interaction known. There seem to be no other reports.

Anticoagulants

**Coumarins + Tolerodine**

In healthy subjects, tolerodine did not alter the pharmacokinetics or pharmacodynamics of warfarin, but isolated cases of raised INRs have been reported.

**Clinical evidence, mechanism, importance and management**

In a placebo-controlled study in healthy subjects, tolerodine 2 mg twice daily for 7 days did not affect the pharmacokinetics of R- or S-warfarin after a single 25-mg dose of warfarin given on day 4, nor were the pharmacokinetics of tolerodine altered by warfarin. In addition, the prothrombin time and factor VII activity were not altered by tolerodine. However, a report describes two patients on stable warfarin doses who had elevated INRs shortly after tolerodine 2 mg daily was started and stopped: one had an INR of 6.1 one day after stopping 13 days of tolerodine, and the other had an INR of 7.4 two days after stopping 8 days of tolerodine. In both cases no bleeding occurred and warfarin was withheld for three doses and successfully restarted at the original dose. Another case has been reported of a patient who required a 15% reduction in warfarin dose while taking tolerodine 4 mg daily. Her maximum INR had been 3.9. However, she had undergone several warfarin dose increases over the previous 2 months and her INR had been fluctuating.

The controlled study suggests that no warfarin dose adjustment would be needed when tolerodine is added to warfarin therapy. However, the controls introduce a note of caution. Although additional monitoring would seem over-cautious on the basis of these cases, bear them in mind in the case of an unexpected response to warfarin.

**Coumarins + Topical salicylates**

Increased warfarin effects have been seen when methyl salicylate or trolamine salicylate were used on the skin.

**Clinical evidence**

**Methyl salicylate**, in the form of gels, oil, or ointment applied to the skin, has been found to increase the effects of warfarin. Bleeding and bruising and/or raised INRs have been seen with both high and low doses of methyl salicylate. One report described the possible additive effects of methyl salicylate oil (Kwan Loong Medicated Oil) and a decoction of Danshen (the root of Salvia miltiorrhiza) on the response to warfarin (see also ‘Coumarins and related drugs + Herbal medicines; Danshen (Salvia miltiorrhiza)’, p.415). A raised prothrombin time has also been reported with topical trolamine salicylate.

**Mechanism**

Methyl and trolamine salicylates possibly interact like high-dose ‘aspirin’, (p.385), because they are absorbed through the skin.

**Importance and management**

Although the evidence is limited, it appears that topical methyl salicylate and trolamine salicylate can increase the effect of warfarin.

**Coumarins + Tricyclic antidepressants**

Amitriptyline and nortriptyline do not appear to alter the half-life of warfarin, but may possibly increase that of dicoumarol. Limited evidence from analyses of patients taking phenprocoumon or warfarin suggests that use of tricyclics is associated with greater variability in prothrombin times, which can make stable anticoagulation difficult. An isolated case of the potentiation of warfarin by lofepramine has been reported.

**Clinical evidence**

(a) Dicoumarol

A study in 6 healthy subjects given nortriptyline 200 micrograms/kg three times daily for 8 days indicated that the mean half-life of dicoumarol was increased from 35 to 106 hours. In a parallel group, the same dose of nortriptyline also increased the half-life of antipyrine. However, in later identical studies by the same research group, nortriptyline decreased the half-life of antipyrine in one study, and had no effect in another. The authors were unable to explain these disparate findings with antipyrine, and they cast doubt on the results seen with dicoumarol. In a later study by another group, both amitriptyline 75 mg daily and nortriptyline 40 mg daily had no consistent effect on the half-life of a single dose of dicoumarol, although there was some evidence of increased bioavailability.

(b) Phenprocoumon

In a retrospective analysis of 7 patients taking phenprocoumon and amitriptyline, unpredictable and ‘massive fluctuations’ in prothrombin times (increases and decreases) were noted, which were not seen in a control group of 7 other patients not taking amitriptyline. Note that the amitriptyline dose was not stable. Anticoagulant control improved on stopping the amitriptyline in 5 of the patients. The same authors reported another similar case in a patient taking phenprocoumon and amitriptyline.

(c) Warfarin

In a study in 12 healthy subjects, neither amitriptyline 75 mg daily nor nortriptyline 40 mg daily for 13 days affected the plasma half-life of a single dose of warfarin given on day 9.

However, in the preliminary report of an analysis of 500 patients taking warfarin, a statistically significant difference in the warfarin dose index (prothrombin time prolongation/cumulative warfarin dose) before, during and after therapy was detected for a number of unexpected drugs including amitriptyline. However, no further details were given. In another analysis of the stability of anticoagulant control in 277 patients, use of tricyclics (imipramine, amitriptyline, nortriptyline) in 16 patients was associated with an increased need for anticoagulant dose modifications (average 3.56 over 6 months). Most of the patients were taking warfarin. Another report briefly lists that potentiation of warfarin occurred in a patient given lofepramine.

**Mechanism**

Not understood. One suggestion is that the tricyclic antidepressants inhibit the metabolism of the anticoagulant (seen in animals with nortriptyline or amitriptyline and warfarin, but not with desipramine or acenocoumarol), but tricyclics are not established known inhibitors of the metabolism of any drug so this seems unlikely. Another idea is that the tricyclics slow gastrointestinal motility thereby increasing the time available for the dissolution and absorption of dicoumarol.

**Importance and management**

Information about interactions between anticoagulants and tricyclic antidepressants is limited, patchy and inconclusive. It appears that amitriptyline and nortriptyline do not alter the half-life of warfarin, but might increase that of dicoumarol. A greater fluctuation in anticoagulant control was noted in two analyses, one with warfarin and one with phenprocoumon. However, these were uncontrolled studies, and the findings need confirming in a randomised study. Moreover, there do not appear to be any
published case reports of an interaction between tricyclics and warfarin. Thus, there is insufficient evidence to recommend any special precautions in patients stabilised on coumarins requiring tricyclics. Bear the possibility of an interaction in mind in the event of unexpected responses to treatment.

**Coumarins + Valproate**

An isolated case describes a patient who had an increase in her INR the day after starting valproic acid, but was eventually restabilised on the original dose of warfarin while still taking the valproic acid. Valproic acid did not alter the anticoagulant effects of phenprocoumon in one patient. Valproate alone can cause altered bleeding time, bruising, haematomata, epistaxis and haemorrhage.

**Clinical evidence**

A woman was given warfarin for a deep vein thrombosis, and was stabilised on 5 mg alternating with 2.5 mg daily with an INR between 1.8 and 2.6. Valproic acid 250 mg twice daily and fluphenazine 5 mg once daily were then added. The morning after her first dose of valproic acid, the INR increased to 3.9, and warfarin dosage was decreased to 2.5 mg daily. Four days later the valproic acid dosage was doubled, and numerous warfarin dosage adjustments were needed to keep the INR therapeutic. However, 3 weeks after starting the valproic acid she was discharged on the same warfarin dose as before the valproic acid was started.1

In one patient taking phenprocoumon, valproic acid 500 mg to 1 g daily did not alter the prothrombin time ratio.2

**Mechanism**

There is in vitro evidence that the serum binding of warfarin is decreased by sodium valproate so that free warfarin levels rise,1,3,4 by 32% according to one study.1 The increase in free warfarin levels is transient until a new equilibrium is reached, but theoretically could result in a transient increase in INR, as is seen with ‘cloral hydrate’, (p.396).

Valproate inhibits the second stage of platelet aggregation, and a reversible prolongation of bleeding times and thrombocytopenia has been reported, usually with high doses, which can result in spontaneous bruising and bleeding.

**Importance and management**

There seem to be no other reports of problems associated with concurrent use nor any other direct evidence that an interaction of clinical importance normally occurs. It may be that any interaction occurs only transiently when valproate is added, and the situation rapidly restabilises without any real need to adjust the warfarin dosage. However, some manufacturers recommend closely monitoring the prothrombin time because of the possibility of warfarin protein binding displacement.3,5 Note that valproate alone can cause spontaneous bruising or bleeding, and if these effects occur, some manufacturers recommend withdrawing valproate pending investigation.5,7 A reduction of valproate dosage or permanent withdrawal of valproate may be required.5

**Coumarins and related drugs + Viloxazine**

A single report describes three cases where viloxazine possibly increased the anticoagulant effects of acenocoumarol and fluindione.

**Clinical evidence**

An 82-year-old woman with angiina, hypertension and atrial fibrillation, who was taking acenocoumarol, molsidomine and flunitrazepam, had a rise in her INR from 3.3 to 7.9 when she started to take viloxazine (dose not stated) for depression. Five days after stopping the viloxazine her INR had fallen to 2.6. This report also briefly describes 2 other cases where viloxazine possibly caused an increase in the anticoagulant effects of acenocoumarol and fluindione.1

**Mechanism**

Not understood. The authors of the report suggest that viloxazine possibly inhibits cytochrome P450 within the liver, resulting in a reduction in the metabolism and loss of the anticoagulants from the body.1

**Importance and management**

Information seems to be limited to this report so that its general importance is uncertain. Be alert for the need to reduce the dosage of acenocoumarol and fluindione if viloxazine is added to established anticoagulant treatment. Take the same precautions with any of the other coumarin or indanedione anticoagulants, but so far there seems to be no direct evidence that they interact.1

**Coumarins + Vinpocetine**

In healthy subjects, the anticoagulant effect of warfarin was slightly reduced by vinpocetine, and the warfarin AUC was also slightly reduced.

**Clinical evidence, mechanism, importance and management**

In a study in 18 healthy subjects taking vinpocetine 10 mg three times daily for 19 days, the anticoagulant effects and pharmacokinetics of a single 25-mg dose of warfarin were compared when given before vinpocetine for 19 days, the anticoagulant effects and pharmacokinetics of a single 25-mg dose of warfarin were compared when given before vinpocetine was started, and on day 15.1 A small 14.6% reduction in the mean prothrombin time occurred, and also an 8.4% reduction in the AUC of warfarin. More study is needed to find out whether these small changes are clinically important. Be aware of the small potential for interaction on concurrent use.1

**Coumarins and related drugs + Vitamin K substances**

The effects of the coumarin and indanedione anticoagulants can be reduced or abolished by vitamin K1 (phytomenadione). This is used as an effective antidote for excessive anticoagulation. However, unintentional and unwanted antagonism can occur in patients unknowingly taking vitamin K1. There is also a case of
antagonism of acenocoumarol in a patient using a proprietary chilblain product containing the vitamin K₄ substance acetomenaphthone.

**Clinical evidence**

A woman taking acenocoumarol had a fall in her British Corrected Ratio to 1.2 (normal range 1.8 to 3) within 2 days of starting to take a non-prescription chilblain preparation (Gon) containing acetomenaphthone 10 mg per tablet. She took a total of 50 mg of vitamin K₄ over 48 hours.¹

**Mechanism**

The coumarin and indanedione oral anticoagulants are vitamin K antagonists, and probably inhibit the enzyme vitamin K epoxide reductase so reducing the synthesis of vitamin K-dependent blood clotting factors by the liver. If the intake of vitamin K₁ increases, the competition swings in favour of vitamin K and the synthesis of the blood clotting factors begins to return to normal. As a result the prothrombin time also begins to fall to its normal value. The role of other vitamin K substances, such as K₄ and K₃, in coagulation is less clear.

**Importance and management**

The interaction with vitamin K₁ is very well established and clinically important, and is expected to occur with every coumarin and indanedione oral anticoagulant because they have a common mode of action as vitamin K antagonists. The drug intake and diet of any patient who shows ‘warfarin resistance’ should be investigated for the possibility of this interaction. It can be accommodated either by increasing the anticoagulant dosage, or by reducing the intake of vitamin K₁. However, the role of other vitamin K substances in coagulation is less clear. The case report with acetomenaphthone, a vitamin K₃ substance suggests that this can also antagonise the effect of vitamin K antagonists. It may be prudent for patients to avoid preparations containing this substance. Consider also ‘dietary supplements’, (p.401), ‘enteral feeds’, (p.406), ‘vitamin K₁–rich foods’, (p.409), and ‘fermented soya bean’, (p.408).

### Coumarins + Zileuton

**Zileuton slightly increases the anticoagulant effects of warfarin and slightly increases R-warfarin levels, but this probably has little clinical relevance.**

**Clinical evidence**

In a placebo-controlled study, zileuton 600 mg every 6 hours for 6 days or placebo was given to healthy subjects who had been stabilised on racemic warfarin to achieve prothrombin times of 14 to 18 seconds for one week. The zileuton had no effect on the pharmacokinetics of S-warfarin, but the R-warfarin AUC rose by 22%, and its clearance fell by 15%. The mean prothrombin times increased by 2.3 seconds (morning) and 2 seconds (evening) in the zileuton group. The corresponding increases in the placebo group were 0.7 and 0.2 seconds, respectively.¹

**Mechanism**

It seems likely that zileuton inhibits the metabolism of R-warfarin, probably by the cytochrome P450 isoenzyme CYP1A2.²

**Importance and management**

Information seems to be limited to this study, but the pharmacokinetic interaction appears to be established. The clinical significance of a 2 second rise in prothrombin times is unclear, but it seems likely to be small. The lack of any published reports of problems with the combination would tend to support this.

### Drotrecogin alfa + Other drugs that affect coagulation

The manufacturers of drotrecogin alfa contraindicate its use with therapeutic doses of heparin (15 units/kg/hour or more), but state that prophylactic heparin doses may be used concurrently. They also say that the risk benefit ratio of drotrecogin alfa should be carefully assessed in patients who have received thrombolytics in the last 3 days, or oral anticoagulants, aspirin or platelet inhibitors within 7 days.

**Clinical evidence, mechanism, importance and management**

The manufacturers of drotrecogin alfa note that no formal drug interaction studies have been conducted.¹,² However, because drotrecogin alfa increases the risk of bleeding, they have a number of cautions and contraindications regarding its use with other drugs affecting haemostasis.¹,² Nevertheless, they say that in phase III studies of drotrecogin alfa, two-thirds of patients received prophylactic doses of heparin or low-molecular-weight heparin, and there was no observed increase in the risk of serious bleeding events reported in patients receiving the combination.¹ Therefore, in the US, they specifically state that low-dose heparin may be given for the prophylaxis of venous thromboembolic events in patients receiving drotrecogin alfa.² However, they state that the increased risk of bleeding should be carefully considered when deciding to use drotrecogin alfa with therapeutic doses of heparin for treating an active thromboembolic event.² In the UK, the manufacturers specifically contraindicate use with heparin at doses of 15 units/kg per hour or more.¹ Because of the possible increased risk of bleeding, the manufacturers also state that the risks of giving drotrecogin alfa should be weighed against the benefits in patients who have received thrombolytics within 3 days, oral anticoagulants within 7 days, or aspirin (US information specifies greater than 650 mg daily) or other antiplatelet drugs within 7 days.¹,²

### Fondaparinux + Antiplatelet drugs and NSAIDs

Neither aspirin nor piroxicam altered the pharmacokinetics of fondaparinux, and there was no significant change in bleeding time during concurrent use. Nevertheless, the manufacturer recommends close monitoring if antiplatelet drugs or NSAIDs are used with fondaparinux, because of the increased risk of bleeding.

**Clinical evidence**

A single 975-mg dose of aspirin given on day 4 of an 8-day course of subcutaneous fondaparinux 10 mg daily had no effect on fondaparinux pharmacokinetics in 16 healthy subjects. The increase in bleeding time with fondaparinux and aspirin was greater than with aspirin alone, but this was not statistically significant. Aspirin had no effect on the small prolongation of aPTT seen with fondaparinux.¹

In another study, piroxicam 20 mg daily for 10 days was given to 12 healthy subjects with fondaparinux 10 mg daily starting on day 7. Both drugs were also given alone. Piroxicam had no effect on fondaparinux pharmacokinetics, and had no effect on the small prolongation of aPTT seen with fondaparinux. There was no difference in bleeding time between the treatments.¹

**Mechanism**

Fondaparinux commonly causes bleeding as a consequence of its action.² Since antiplatelet drugs and NSAIDs also increase the risk of bleeding, the risk and severity of bleeding is likely to be increased with the combination.

**Importance and management**

The pharmacological studies described show that the pharmacokinetics of fondaparinux are not changed by aspirin and piroxicam, and that there is only a minor increase in bleeding time. Nevertheless, the manufacturers of
fondaparinux say that antiplatelet drugs (aspirin, dipyridamole, sulfinpyrazone, ticlopidine, or clopidogrel) and NSAIDs should be used with caution because of the possible increased risk of haemorrhage. They recommend that if concurrent use is essential, close monitoring is necessary. This is considered particularly important in patients undergoing periperal or spinal anaesthesia or spinal puncture, in whom antiplatelet drugs, NSAIDs, and fondaparinux are possible risk factors for epidural or spinal haematoma resulting in prolonged or permanent paralysis.  

### Heparin and LMWHs + Antiplatelet drugs

In a pharmacodynamic study, the dose of heparin did not need changing when clopidogrel was also given, and the antiplatelet effects of clopidogrel were unaltered. Nevertheless, concurrent use of heparin or low molecular weight heparins and antiplatelet drugs such as clopidogrel and ticlopidine has the potential to increase the risk of bleeding and increased monitoring would be prudent.

#### Clinical evidence

**(a) Clopidogrel**

In a placebo-controlled study in 12 healthy subjects, the dosage of heparin given over 4 days did not need modification when clopidogrel 75 mg daily was also given, and the inhibitory effects of clopidogrel on platelet aggregation were unchanged on concurrent use.

The manufacturers of clopidogrel note that in various large clinical studies in patients with acute coronary syndrome or myocardial infarction, most patients received heparin or LMWHs without an obvious difference in the rate of bleeding or the incidence of major bleeding.

In one case the use of enoxaparin with clopidogrel was considered to be a contributing factor in a case of spinal epidural haematoma occurring after spinal anaesthesia. Another similar case occurred in a patient taking clopidogrel and given dalteparin.

Serious retroperitoneal bleeding occurred in a patient with acute coronary syndrome receiving enoxaparin, clopidogrel and aspirin.

**(b) Ticlopidine**

The manufacturer of ticlopidine notes that it has been used concurrently with heparin for about 12 hours in studies of cardiac stenting, but that longer-term safety has not been established.

#### Mechanism

Antiplatelet drugs increase the risk of bleeding, and the risk is likely to be increased further in patients who are anticoagulated with heparin or LMWHs.

### Importance and management

The combined use of heparin or LMWHs with antiplatelet drugs such as clopidogrel has been used in specific situations such as acute coronary syndrome. However, unless specifically indicated, concurrent use of heparin or LMWHs with antiplatelet drugs should probably be avoided because of the likely increase in haemorrhagic risk. If they are used together, the manufacturers of the LMWHs (low molecular weight heparins) recommend caution or careful clinical and laboratory monitoring. Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal-epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as antiplatelet drugs, and extreme caution is needed if combined use is considered appropriate in these situations.

Consider also ‘Heparin and LMWHs + Aspirin’, below and ‘Glycoprotein IIb/IIIa antagonists + Drugs that affect coagulation’, p.703.

### Heparin + Aprotinin

The activated clotting time (ACT) may not be a reliable method to monitor heparin therapy when aprotinin is used concurrently. This is because aprotinin increases the ACT monitored by some methods, without actually increasing anticoagulation.

#### Clinical evidence, mechanism, importance and management

Aprotinin prolongs the activated clotting time (ACT) as measured by a celite surface activation method, although the kaolin ACT is much less affected. Therefore, if the ACT is used to monitor the effectiveness of heparin anticoagulation during cardiopulmonary bypass incorporating aprotinin, this may lead to an overestimation of the degree of anticoagulation. This may result in patients not receiving additional necessary heparin during extended extracorporeal circulation, or receiving excess protamine to reverse the effects of heparin at the end of the procedure. The UK manufacturer of aprotinin notes that it is not necessary to adjust the usual heparin/proteamine regimen used in cardiopulmonary bypass procedures when aprotinin is also used. The US manufacturer provides additional detailed information on appropriate methods to monitor heparin anticoagulation in the presence of aprotinin.

### Heparin and LMWHs + Aspirin

The combined use of aspirin with heparin or low-molecular-weight heparins slightly increases the risk of haemorrhage. Combined use may be a contributing factor to the very rare complication of epidural or spinal haematoma.

#### Clinical evidence

**(a) Heparin**

Eight out of 12 patients with hip fractures developed serious bleeding when they were given heparin 5000 units subcutaneously every 12 hours and aspirin 600 mg twice daily as perioperative prophylaxis for deep vein thrombosis. Haematomas of the hip and thigh occurred in 3 patients, bleeding through the wound in 4, and uterine bleeding in the other patient. In a large, randomised, placebo-controlled study, aspirin 500 mg three times daily, subcutaneous heparin 5000 units twice daily, and the combi-
nation were compared for prophylaxis of deep vein thrombosis in 1210 pa-
tients undergoing surgery. Haemorrhage severe enough to discontinue
the prophylaxis occurred in significantly more patients in the combina-
tion group (11 of 402 patients versus 3 of 404 patients in the heparin and aspi-
rin alone groups). In addition, minor haemorrhage occurred more fre-
quently in the combination group (89 patients) compared with aspirin
alone (41 patients) or heparin alone (30 patients).12 In another randomised
study in patients with acute unstable angina, the combination of aspirin
325 mg twice daily and an intravenous infusion of heparin
1000 units/hour resulted in slightly greater incidence of serious bleeding
than either drug alone (3.3% versus 1.7% and 1.7%).13

In an epidemiological study of hospitalised patients receiving heparin,
the incidence of bleeding was almost 2.4 times higher in 302 patients also
receiving aspirin than in 2354 patients not given aspirin (doses not stated).
Surgical patients were excluded from this analysis, as were patients with
a discharge diagnosis of cancer or haematological disease.4

Mechanism

Aspirin inhibits platelet aggregation and prolongs bleeding times, and increases
the risk of upper gastrointestinal haemorrhage, even at doses of
300 mg daily and less.12 This risk is likely to be higher in patients also tak-
ing anticoagulants. See also ‘Coumarins and related drugs + Aspirin’, p.385.

Importance and management

The combined use of heparin or LMWHs with aspirin is indicated in spe-
cific situations such as the prophylaxis of ischaemic complications of un-
stable angina.12 However, unless specifically indicated, it may be prudent
to avoid the combined use of aspirin with these drugs, because of the likely
increased risk of bleeding. If they are used together, the manufacturers of
the LMWHs (heparin, dalteparin, enoxaparin, tinzaparin) recommend
careful attention to the risk of bleeding in patients also on
antiplatelet agents.

Heparin + Dextran

Additive effects on coagulation occur when heparin is given with
dextran.

Clinical evidence, mechanism, importance and management

A study in 9 patients with peripheral vascular disease given 500 mL of
dextran showed that the mean clotting time 1 hour after an infusion of
10 000 units of heparin was increased from 36 to 69 minutes. Dextran
alone had no effect, but the mean clotting time after 5000 units of heparin
with dextran was almost the same as after 10 000 units of heparin alone.12
This study would seem to support two other reports123 of an increase in
the incidence of bleeding in those given both heparin and dextran. Une-
ventful concurrent use5,6 has been described with dextran 40. Note that
this is probably of little clinical significance if these drugs are given for
their anticoagulant effects; however, increased anticoagulation may be un-
desirable if dextran 40 is given as a volume expander to a patient already
receiving heparin. In this situation some caution is warranted.

Heparin + LMWHs

There is some evidence that patients receiving enoxaparin preop-
eratively require more heparin during surgery.

Clinical evidence, mechanism, importance and management

In a clinical study, 30 patients with unstable coronary disease treated pre-
operatively with enoxaparin needed more heparin to maintain an activat-
ed clotting time above 480 seconds during surgery than 31 stable control
patients not treated with enoxaparin. In addition, the enoxaparin recipi-
ents had higher heparin levels and lower antithrombin values compared with
control patients. All patients were taking low-dose aspirin until the
day before surgery, and received tranexamic acid as a bolus dose before
cardiopulmonary bypass.1

Reasons for these differences are unclear, and their clinical relevance is
uncertain. Further study is needed.

resistance and increased platelet activation in coronary surgery patients treated with enoxa-

Heparin + Miscellaneous

Changes in the protein binding of diazepam, propranolol, quini-
dine and verapamil caused by heparin do not appear to be of clinical
importance.
Clinical evidence, mechanism, importance and management

A number of studies have found that heparin reduces the plasma protein binding of several drugs including diazepam,1,2 propranolol,3 quinidine4 and verapamil5 in man and in animals. For example, 3 patients taking oral propranolol and 5 patients given intramuscular diazepam 10 mg were given 3000 units of heparin just before cardiac catheterisation. Five minutes after the heparin was given, the free fraction of diazepam was found to have risen fourfold (from 1.8 to 7.9%) while the free diazepam levels had risen from 2 to 8.4 nanograms/mL. The free fraction of the propranolol rose from 7.4 to 12.5% and the free levels rose from 1.7 to 2.7 nanograms/mL.1

It was suggested that these changes occur because heparin displaces these drugs from their binding sites on the plasma albumins and that these changes in protein binding might possibly have some clinical consequences. For example, there could, theoretically, be sudden increases in sedation or respiratory depression because of the rapid increase in the active (free) fraction of diazepam.

However, these changes are unlikely to be of clinical importance (see ‘Protein-binding interactions’, (p.3)). One study even suggested that the heparin-induced protein binding changes are an artefact of the study methods used,5 and this would seem to be supported by an experimental study, which found that heparin did not have any effect on the beta-blockade caused by propranolol.6 Moreover there seem to be no other reports confirming that these interactions are of real clinical importance. No special precautions would seem to be necessary.

Heparin + Nitrates

The effects of heparin were reduced by the infusion of glyceryl trinitrate in some studies, but other studies have failed to confirm this interaction. On balance, the evidence favours there being no clinically important interaction. No interaction has been seen with heparin and isosorbide dinitrate or molsidomine.

Clinical evidence

(a) Glyceryl trinitrate (Nitroglycerin)

An interaction between heparin and glyceryl trinitrate was originally reported1 in 1985. They found a lower aPTT value in patients receiving both glyceryl trinitrate and heparin, when compared with control patients. In one study, there was some evidence that the effect might occur only at high doses of intravenous glyceryl trinitrate (above 350 micrograms/minute),5 whereas in another, an effect was seen at low doses of 25 to 50 micrograms/minute.6

In contrast to the above studies, a total of 12 other studies have found no changes in aPTT in patients7,16 or healthy subjects17,18 given intravenous glyceryl trinitrate with heparin. In the randomised, placebo-controlled studies in healthy subjects, a 60-minute infusion of glyceryl trinitrate 5 mg had no effect on the aPTT or PT following a 5000 unit intravenous injection of heparin,17 and a 100 micrograms/minute infusion of glyceryl trinitrate did not alter the anticoagulant effect of a 40 units/kg bolus of heparin in 7 healthy subjects.18 Two randomised, placebo-controlled studies in patients have also failed to find an effect of intravenous glyceryl trinitrate on a heparin infusion titrated to a given effect,1,2 or on an intravenous heparin bolus dose.14 In the first of these studies, the glyceryl trinitrate preparation contained propylene glycol.12

(b) Isosorbide dinitrate

In a randomised, placebo-controlled study in 12 patients receiving a stable infusion of heparin, the use of isosorbide dinitrate 4.8 ± 0.8 mg/hour for 24 hours did not alter the AUC of PT values, when compared with placebo, nor was there any change in PT values in the 5 hours after stopping the nitrate.12 Similarly, other studies have failed to find an important change in anticoagulation when intravenous isosorbide dinitrate is given with heparin.8,14,16

(c) Molsidomine

In a study in 15 patients treated with intravenous heparin then given intravenous molsidomine 2 hour/mg, molsidomine had no effect on the PT.19

Mechanism

Not understood. One study suggests that what occurs is related to a glyceryl trinitrate-induced antithrombin III abnormality, and is apparent at doses above 350 micrograms/minute.1 These studies have found that heparin levels were lowered,2 whereas another reported unchanged heparin levels.5

Importance and management

The discord between these reports is not understood. However, the best controlled studies in the largest number of patients have failed to find evidence of an interaction. On balance therefore, it appears that a clinically relevant interaction is generally unlikely to be seen. Moreover, given that heparin is routinely monitored, it is likely that if any interaction occurs, it will be rapidly detected and compensated for. No special precautions would appear to be needed if heparin is given with molsidomine or isosorbide dinitrate.

**Heparin and LMWHs + NSAIDs**

The bleeding time was prolonged by the concurrent use of dalteparin and ketorolac in healthy subjects, but not by the use of heparin and ketorolac. Parecoxib did not alter the effect of heparin on aPTT. In a small clinical study, intramuscular ketorolac and subcutaneous enoxaparin appeared not to increase measures of postoperative bleeding when compared with opioids. Cases of spinal haematomas have been reported with concurrent use of heparin or low-molecular-weight heparins and NSAIDs. Note that ketorolac may possibly cause serious gastrointestinal bleeding and in the UK it is considered to be contraindicated in patients taking anticoagulants.

**Clinical evidence**

(a) Ibuprofen

Use of heparin and ibuprofen were considered to be contributing factors in a case of spinal haematoma occurring after epidural anaesthesia.1

(b) Ketorolac

1. **1.** In a crossover, placebo-controlled study in healthy subjects, there was no evidence of an interaction between ketorolac and heparin in terms of prolongation of skin bleeding time, platelet aggregation, anti-factor Xa activity, or kaolin-cephalin clotting time. In this study, two doses of oral ketorolac were given (the previous evening, and in the morning), then two 10-mg intramuscular doses of ketorolac were given at 10 am and 2 pm, with simultaneous doses of subcutaneous heparin 5000 units.7

2. **2.** Low-molecular-weight heparins. In a crossover, placebo-controlled study in healthy subjects, giving ketorolac with dalteparin resulted in prolongation of the skin bleeding time, when compared with ketorolac alone (13.95 minutes versus 10.55 minutes). Dalteparin alone had no effect on the bleeding time when compared with placebo. In this study, two doses of oral ketorolac 30 mg were given the day before, and one dose an hour after a single 5000-unit subcutaneous dose of dalteparin. The combination did not have any greater effect on platelet aggregation, anti-factor Xa activity or aPTT time than the individual drugs alone.3 However, a study in hip replacement patients given subcutaneous enoxaparin 40 mg once daily found that there were no significant differences in intra-operative blood loss, post-operative drainage, transfusion requirements, bruising, wound oozing, and leg swelling between 34 patients given enoxaparin and 35 patients given ketorolac alone. This showed that ketorolac had no effect on the haemostatic response to enoxaparin in the absence of antiplatelet drugs.4

(c) Parecoxib

In an open-label, crossover study in 18 healthy subjects, administration of heparin on day 5 of treatment with 40 mg of intravenous parecoxib twice daily for 6 days produced no clinically or statistically significant differences in coagulation parameters (PT, aPTT and platelet counts), when compared with heparin alone (bolus dose of heparin 4000 units then a 36-hour infusion of 10 to 14 units/kg). Use of these drugs together was well tolerated. However, prolongation of bleeding time was not assessed.8

**Mechanism**

NSAIDs, to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Many also have antplatelet activity, which can prolong bleeding times.

**Importance and management**

The CSM in the UK and the UK manufacturers say that ketorolac is contraindicated with anticoagulants, including low-dose heparin.9,10 Conversely, the US manufacturers of ketorolac advise that physicians should carefully weigh the benefits against the risks and use concurrent heparin only extremely cautiously.11 If NSAIDs and LMWHs are used together, the manufacturers of the LMWHs (bemiparin, dalteparin, enoxaparin, tinzaparin) recommend caution or careful clinical and laboratory monitoring. Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal/epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as ketorolac or other NSAIDs, and extreme caution is needed if combined use is considered appropriate in these situations.

**Heparin + Probencid**

An isolated case report from the 1950s suggests that the effects of heparin may be possibly increased by probenecid, and bleeding may occur.

**Clinical evidence, mechanism, importance and management**

In 1950 (but not reported until 1975) a woman with subacute bacterial endocarditis was given probenecid orally and penicillin by intravenous drip, which was kept open with minimal doses of heparin. After a total of about 20 000 units of heparin had been given over a 3-week period, increasing epistaxes developed and the clotting time was found to be 24 minutes (normal 5 to 6 minutes). This was controlled with protamine.1 However, no reports of this interaction appear to have been made subsequently. This interaction seems unlikely to be of general significance.

**Heparin and LMWHs + SSRIs**

Severe bleeding was attributed to the use of tinzaparin in an elderly woman with renal impairment taking fluoxetine.

**Clinical evidence, mechanism, importance and management**

A 78-year-old woman taking fluoxetine was started on once-daily subcutaneous injections of weight-adjusted tinzaparin for treatment of deep vein thrombosis. Five days later she suffered a massive contralateral and parietal haematoma. Poor renal function in this patient could have led to accumulation of the low-molecular-weight heparin, but fluoxetine was also considered a contributing factor because SSRIs have antplatelet effects and can contribute to bleeding.1 Consider also ‘Coumarins and relat-ed drugs + SSRIs’, p.448.

Heparinoids; Danaparoid + Diuretics

Chlortalidone had no clinically relevant effect on the anti-Xa activity of danaparoid in healthy volunteers, but caused an increase in the volume of distribution of antithrombin activity of uncertain relevance. Nevertheless, in clinical use danaparoid is frequently used with a number of other drugs including diuretics, and there is no evidence of an interaction.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in healthy subjects, a slight decrease in clearance (7%) and volume of distribution (19%) of the anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) occurred when it was given about 12 hours after a single 100-mg dose of chlortalidone. Conversely, the apparent volume of distribution of antithrombin activity showed an 80% increase. However, chlortalidone did not change the effect of danaparoid on clotting tests, except for a 4% increase in prothrombin time, which was thought to be a spurious finding. The reasons for these changes are uncertain.

The minor changes in anti-Xa activity are unlikely to be clinically relevant. However, the authors considered that relevance of the change in antithrombin activity was uncertain. Nevertheless, the manufacturer notes that in clinical use danaparoid has frequently been used with a variety of drugs, including diuretics, and that there is no evidence of any direct interaction with danaparoid.

Heparinoids; Danaparoid + Penicillins

Cloxacillin and ticarcillin caused an increase in elimination half-life of anti-Xa activity of danaparoid, which was not considered clinically relevant. Ticarcillin had no effect on haemostasis, but cloxacillin appeared to have some pro-coagulant effects, which were not likely to be due to an interaction with danaparoid. The manufacturer notes that in clinical use danaparoid is frequently used with a number of other drugs, including antibacterials, and there is no evidence of a direct interaction.

Clinical evidence

(a) Cloxacillin

In a randomised, crossover study in 6 healthy subjects, there was a 74% increase in the elimination half-life of the plasma anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) when combined with oral cloxacillin 500 mg four times daily for 3 days beginning 24 hours before the danaparoid. Unexpectedly, there were slight decreased effects on thrombin time and bleeding time, and increased effects on aPTT with the combination, effects that were attributed to cloxacillin alone.

(b) Ticarcillin

In a randomised, crossover study in 12 healthy subjects, there was a 56% increase in the elimination half-life of the plasma anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) when combined with intravenous ticarcillin 4 g four times daily for 2 days beginning immediately before the danaparoid. There were no changes in haemostatic parameters when ticarcillin was given with danaparoid.

Mechanism

Uncertain, but penicillins might compete with danaparoid for renal tubular secretion.

Importance and management

The pharmacokinetic changes seen in the studies with cloxacillin and ticarcillin were not considered clinically relevant. In addition, the haemostatic changes seen in the study with cloxacillin were unlikely to be due to an interaction. The manufacturer notes that in clinical use danaparoid has frequently been used with a variety of drugs, including antibacterials, and that there is no evidence of any direct interaction with danaparoid.

Clinical evidence, mechanism, importance and management

A man stabilised on phenindione 50 mg daily was given haloperidol by injection (5 mg every 8 hours for 24 hours) followed by 3 mg twice daily by mouth. Adequate anticoagulation was not achieved even when the phenindione dosage was increased to 150 mg daily. When the haloperidol dosage was halved, the necessary dose of anticoagulant was reduced to 100 mg daily, and only when the haloperidol was withdrawn was it possible to achieve adequate anticoagulation with the original dosage. The reasons for this are not understood. This appears to be the only report of an interaction, and its general importance is therefore limited. Bear it in mind in the event of an unexpected response to treatment.

Indanediones + Oxaceprol

An isolated report describes a marked fall in the response to fluindione in a patient given oxaceprol.

Clinical evidence, mechanism, importance and management

A 77-year-old woman with hypertension and atrial fibrillation, taking propafenone, furosemide, enalapril and fluindione 15 mg daily, started taking oxaceprol 300 mg daily. Within 2 days her Quick Time had risen from 26 to 57% and by the end of the week to 65%. When the oxaceprol was withdrawn, her Quick value returned to its previous values of 23 to 30%. The mechanism is not understood. The general importance of this interaction is not known but bear it in mind when prescribing oxaceprol and fluindione. Be alert for the need to modify the anticoagulant dosage.

Thrombin inhibitors + Antiplatelet drugs and Thrombolytics

Low-dose aspirin did not alter the pharmacokinetics or pharmacodynamic effects of argatroban. Neither abciximab nor epifibatide appeared to alter argatroban pharmacokinetics. There is no pharmacodynamic interaction between bivalirudin and aspirin, ticlopidine, clopidogrel, abciximab, epifibatide or tirofiban. Nevertheless, the manufacturers warn of the increased bleeding risks if argatroban, bivalirudin or lepirudin are used with antiplatelet drugs or thrombolytics.

Clinical evidence, mechanism, importance and management

(a) Argatroban

1. Antiplatelet drugs. In a study in healthy subjects, pretreatment with oral aspirin 162.5 mg, given 26 and 2 hours prior to argatroban 1 microgram/kg per minute over 4 hours, caused no changes in the pharmacokinetics or pharmacodynamic effects of the argatroban. In a large clinical study of the combination of argatroban and a glycoprotein IIb/IIIa-receptor antagonist (abciximab or epifibatide) in patients undergoing percutaneous coronary intervention, using a population model assessment, the pharmacokinetics of argatroban were similar to those previously seen in healthy subjects. This suggests that neither abciximab nor epifibatide alter argatroban pharmacokinetics. Nevertheless, the manufacturer warns that the use of argatroban with antiplatelet drugs may increase the risk of bleeding.

2. Thrombolytics. The manufacturer notes that, in patients with acute myocardial infarction, the incidence of intracranial bleeding was 1% (8 out of 810 patients) in patients receiving both argatroban and thrombolytic therapy (streptokinase or alteplase). They therefore state that the safety and effectiveness of argatroban with thrombolytics has not been established, and that concurrent use may increase the risk of bleeding.

(b) Bivalirudin

1. Antiplatelet drugs. The UK manufacturer says that no pharmacodynamic interactions were detected when bivalirudin was used with platelet inhibitors, including aspirin, ticlopidine, clopidogrel, abciximab, epifibatide, or tirofiban. The US manufacturer states that bivalirudin is intended for use with aspirin 300 to 325 mg daily, and has been studied only in patients receiving aspirin. Both manufacturers state that bivalirudin may be used with a glycoprotein IIb/IIIa-receptor antagonist (e.g. abciximab, epifibatide, tirofiban). Nevertheless, the US manufacturer states that in clinical studies, the concurrent use of bivalirudin with these inhibitors was associated with increased risks of major bleeding events compared to patients not receiving them. The UK manufacturer recommends regular monitoring of haemostasis when bivalirudin is used with platelet inhibitors.

2. Thrombolytics. In the US, the manufacturers state that the concurrent use of bivalirudin with thrombolytics was associated with increased risks of major bleeding events.

(c) Lepirudin

The manufacturers of lepirudin say that no formal interaction studies have been done but they reasonably warn that the concurrent use of lepirudin and other thrombolytics (they name alteplase and streptokinase) may increase the risk of bleeding complications and considerably enhance the effect of lepirudin on the aPTT. They also warn about the increased risks of bleeding if antiplatelet drugs such as clopidogrel, ticlodipine, abciximab, epifibatide or tirofiban are used concurrently.

Use of argatroban with warfarin and related oral anticoagulants has an effect on the measurement of the INR, and the manufacturer provides equations to adjust for this. Argatroban does not alter warfarin pharmacokinetics. The manufacturers warn of the increased bleeding risks if argatroban, bivalirudin or lepirudin are used with other anticoagulants.

Clinical evidence, mechanism, importance and management

(a) Argatroban

In 12 healthy subjects, argatroban 1.25 micrograms/kg per minute was given for 100 hours, with a single 7.5-mg dose of warfarin given at hour 4. Neither drug affected the pharmacokinetics of the other. The single dose of warfarin in this study did not add to the anticoagulant effect of argatroban.

(b) Bivalirudin

In a study in healthy subjects, pretreatment with oral aspirin 1 microgram/kg per minute over 4 hours, caused no changes in the pharmacokinetics or pharmacodynamics of argatroban. Nevertheless, the manufacturers warn of the increased bleeding risks if argatroban, bivalirudin or lepirudin are used with antiplatelet drugs or thrombolytics.

Anticoagulants 465
30 minutes after stopping intravenous heparin, but 8 hours should be left after stopping a low-molecular-weight heparin given subcutaneously. They recommend regular monitoring of haemostasis when bivalirudin is used with other anticoagulants.

(c) Lepirudin

The manufacturers of lepirudin say that no formal interaction studies have been done but they reasonably warn about the increased risks of bleeding if vitamin K antagonists (i.e. coumarins and indanediones) are used concurrently. Their recommendation for changing from lepirudin to an oral anticoagulant is to reduce the lepirudin dosage gradually to reach an aPTT ratio just above 1.5 before beginning the oral anticoagulant, which should be started at the intended maintenance dose without a loading dose. They suggest that parenteral anticoagulation should be continued for 4 to 5 days, and then stopped when the INR stabilises within the target range.

Thrombin inhibitors; Argatroban + Erythromycin

Erythromycin has no effect on the pharmacokinetics or activity of argatroban.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects, erythromycin 500 mg four times daily was given for 7 days with a 5-hour intravenous infusion of argatroban 1 microgram/kg per minute given before erythromycin and on day 6. Erythromycin had no effect on the pharmacokinetics of argatroban, and had no effect on the argatroban-induced prolongation of aPTT. No special precautions are likely to be required on concurrent use of argatroban and erythromycin or other inhibitors of the cytochrome P450 3A4 for a list, see ‘Table 1.4’, (p.66).

There was no pharmacokinetic interaction between argatroban and lidocaine, and no further change in coagulation parameters when both drugs were given together in a study.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, lidocaine 2 mg/kg per hour was infused for 16 hours (after a loading dose of 1.5 mg/kg over 10 minutes) alone, then in combination with intravenous argatroban 1.5 micrograms/kg per minute for 16 hours. Concurrent use did not affect the pharmacokinetics of either drug. Lidocaine did not alter the effect of argatroban on aPTT. No special precautions appear likely to be necessary on concurrent use of lidocaine and argatroban.

Aspirin did not alter the pharmacokinetics of melagatran, the active metabolite of ximelagatran, or its effects on the aPTT, but the combination had additive effects on bleeding time. Erythromycin increases the AUC of melagatran, the active metabolite of ximelagatran, and causes a small additional effect on coagulation parameters. The concurrent use of amiodarone and ximelagatran caused a slight increase in the AUC of melagatran and a slight decrease in the AUC of amiodarone, but the clinical relevance of this is unknown.

No pharmacokinetic interaction occurs between ximelagatran and atorvastatin or digoxin, and concurrent use does not change coagulation status. No pharmacokinetic interaction appears to occur between ximelagatran and diazepam, diclofenac or nifedipine. This suggests that ximelagatran has no clinically relevant effect on drugs that are substrates for the cytochrome P450 isoenzymes CYP2C9, CYP2C19, and CYP3A4.

Clinical evidence, mechanism, importance and management

(a) Amiodarone

In a placebo-controlled study in 26 healthy subjects, ximelagatran 36 mg was given every 12 hours for 8 days with a single 600-mg dose of amiodarone on day 4. On combined use there was a slight 21% increase in the AUC of melagatran (the active metabolite of ximelagatran), and a slight 15% decrease in the AUC of amiodarone. Amiodarone did not alter the effect of melagatran on aPTT.

The mechanism of this interaction is unknown. The pharmacokinetic changes seen were not considered to be clinically relevant.

(b) Aspirin

In young healthy subjects, aspirin 450 mg the day before, and 150 mg just before melagatran had no effect on the pharmacokinetics of intravenous melagatran 4.12 mg. In addition, aspirin did not alter the increases seen in aPTT or activated clotting time seen with melagatran. Both aspirin and melagatran increased bleeding time, and the increase with the combination was additive.

(c) Atorvastatin

In 15 healthy subjects, ximelagatran 36 mg twice daily was given for 5 days with a single 40-mg dose of atorvastatin on day 4. There was no change in the pharmacokinetics of either drug or their active metabolites. Atorvastatin did not alter the effect of melagatran on aPTT.

No special precautions are expected to be needed if ximelagatran is used in patients taking atorvastatin.
(d) Diazepam

In 24 healthy subjects, ximelagatran 24 mg twice daily was given for 8 days with a single 100-microgram/kg intravenous dose of diazepam on day 3. There was no change in the pharmacokinetics of either drug or of N-desmethyl-diazepam.\(^4\)

Metabolism of diazepam to N-desmethyl-diazepam occurs via the cytochrome P450 isoenzyme CYP2C19, and \textit{in vitro} studies had shown that melagatran was a weak inhibitor of this isoenzyme.\(^4\) However, the lack of a pharmacokinetic interaction with diazepam suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP2C19 substrates\(^4\) (for a list see ‘Table 1.3’, (p.6)).

(e) Diclofenac

In a single-dose study in 24 healthy subjects, simultaneous administration of ximelagatran 24 mg and enteric-coated diclofenac 50 mg caused no change in the pharmacokinetics of either drug. In this study, there was also no additional effect of the combination on activated partial thromboplastin time or capillary bleeding time, suggesting that no pharmacodynamic interaction occurs.\(^4\)

Diclofenac is a substrate for the cytochrome P450 isoenzyme CYP2C9, and \textit{in vitro} study has shown that ximelagatran and melagatran are weak inhibitors of this isoenzyme.\(^4\) However, the lack of a pharmacokinetic interaction with diclofenac suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP2C9 substrates\(^4\) (for a list see ‘Table 1.3’, (p.6)).

(f) Digoxin

In a double-blind, crossover study, 16 healthy subjects were given oral ximelagatran 36 mg twice daily or placebo for 8 days and a single 500-microgram oral dose of digoxin on day 4. Ximelagatran had no effects on the pharmacokinetics of digoxin. Similarly, digoxin had no effects on the pharmacokinetics of melagatran (the active metabolite) when ximelagatran was given orally. The anticoagulant effect of melagatran (measured as aPTT prolongation) was not altered by digoxin.\(^5\)

(g) Erythromycin

In 16 healthy subjects, erythromycin 500 mg three times daily was given for 5 days with a single 36-mg oral dose of ximelagatran given before erythromycin, and on day 5. Erythromycin increased the AUC of melagatran (the active metabolite of ximelagatran) 1.8-fold, and the maximum plasma level 1.7-fold. This resulted in a small increase in peak aPTT from 41 to 44 seconds.\(^6\)

Ximelagatran is not metabolised by cytochrome P450 isoenzymes, so the known inhibitory effect of erythromycin on CYP3A4 is not thought to be the mechanism for this interaction.

The findings of a pharmacokinetic interaction with a small pharmacodynamic effect indicate that further study is needed. Until more is known, it would certainly be prudent to be cautious if ximelagatran is used in patients taking erythromycin, although note that the pharmacodynamic effect was small and all patients tolerated the combination well.\(^6\)

(h) Nifedipine

In a single-dose study in 34 healthy subjects, giving ximelagatran 24 mg four hours after slow-release nifedipine 60 mg caused no change in the pharmacokinetics of either drug.\(^4\)

Nifedipine is a substrate for the cytochrome P450 isoenzyme CYP3A4, and \textit{in vitro} studies had shown that ximelagatran metabolites might be weak inhibitors of this isoenzyme.\(^4\) However, the lack of a pharmacokinetic interaction with nifedipine suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP3A4 substrates\(^4\) (for a list see ‘Table 1.4’, (p.6)).

The antidiabetics are used to control diabetes mellitus, a disease in which there is total or partial failure of the beta-cells within the pancreas to secrete enough insulin, one of the hormones concerned with the handling of glucose. In some cases there is evidence to show that the disease results from the presence of factors that oppose the activity of insulin. With insufficient insulin, the body tissues are unable to take up and utilise the glucose that is in circulation in the blood. Because of this, glucose, which is derived largely from the digestion of food, and which would normally be removed and stored in tissues throughout the body, accumulates and boosts the glucose in the blood to such grossly elevated proportions that the kidney is unable to cope with such a load and glucose appears in the urine. Raised blood glucose levels (hyperglycaemia) with glucose and ketone bodies in the urine (glycosuria and ketonuria) are among the manifestations of a serious disturbance in the metabolic chemistry of the body, which, if untreated, can lead to the development of diabetic coma and death.

There are two main types of diabetes: one develops early in life and occurs when the ability of the pancreas suddenly, and often almost totally, fails to produce insulin. This type is called type 1, juvenile, or insulin-dependent diabetes (IDDM), and requires insulin replacement therapy. The other form is type 2, maturity-onset, or non-insulin dependent diabetes mellitus (NIDDM), which is most often seen in those over 40 years old. This occurs when the pancreas gradually loses the ability to produce insulin over a period of months or years and/or resistance to the action of insulin develops. It is often associated with being overweight and can sometimes be satisfactorily controlled simply by losing weight and adhering to an appropriate diet. This may then be augmented with oral antidiabetic drugs, and eventually insulin. A classification of the antidiabetics is given in Table 13.1, p.469.

**Modes of action of the antidiabetics**

**A. Parenteral antidiabetics**

(a) **Amylin analogues**

Pramlintide is a synthetic analogue of amylin, a pancreatic hormone involved in glucose homoeostasis. It slows the rate of gastric emptying and reduces appetite. It is given subcutaneously immediately prior to meals, and is used in patients already receiving insulin.

(b) **Incretin mimetics**

Exenatide is an incretin mimic that acts as a glucagon-like peptide-1 (GLP-1) receptor agonist. This increases insulin secretion when glucose levels are high. It is given subcutaneously as an adjunct in type 2 diabetes in patients already receiving metformin, a sulphonylurea, or both.

(c) **Insulin**

Insulin extracted from the pancreatic tissue of pigs and cattle is so similar to human insulin that it can be used as a replacement. However, human insulin, manufactured by genetically engineered microorganisms, is more commonly used. Insulin is usually given by injection in order to bypass the enzymes of the gut, which would digest and destroy it like any other protein. The onset and duration of action of insulin may be prolonged by complexing with zinc or protamine. More recently, various insulin analogues have been developed, which have specific pharmacokinetic profiles. Insulin aspart and lispro have a faster onset and shorter duration of action than soluble insulin. Insulin glargine and detemir both have a prolonged duration of action.

An inhaled form of insulin has been approved by The European Medicines Agency for use in adult patients with diabetes mellitus.

**B. Oral antidiabetics**

(a) **Aldose reductase inhibitors**

Epalrestat inhibits the enzyme aldose reductase, which converts glucose to sorbitol. The accumulation of sorbitol may play a role in some diabetic complications.

(b) **Alpha-glucosidase inhibitors**

Acarbose, miglitol and voglibose act against alpha glucosidases and specifically against sucrase in the gut to delay the digestion and absorption of monosaccharides from starch and sucrose.

(c) **Biguanides**

The mode of action of the biguanides, such as metformin, is obscure, but they do not stimulate the pancreas like the sulphonylureas to release insulin, but appear to facilitate the uptake and utilisation of glucose by the cells in some way. Their use is restricted to type 2 diabetes because they are not effective unless insulin is present.

(d) **Meglitinides**

The meglitinides (e.g. repaglinide) increase endogenous insulin secretion, and so are used in type 2 diabetes.

(e) **Sulphonylureas**

The sulphonylurea and other sulfonamide-related compounds such as chlorpropamide and tolbutamide were the first synthetic compounds used in medicine as antidiabetics. Among their actions they stimulate the remaining beta-cells of the pancreas to grow and secrete insulin which, with a restricted diet, controls blood glucose levels and permits normal metabolism to occur. Clearly they can only be effective in those diabetics whose pancreas still has the capacity to produce some insulin, so their use is confined to type 2 diabetes.

(f) **Thiazolidinediones**

The thiazolidinediones (e.g. rosiglitazone) appear to decrease insulin resistance through activation of gamma-PPAR (peroxisome proliferator-activated receptor). They are used in type 2 diabetes.

(g) **Other oral antidiabetics**

Outside orthodox Western medicine, there are herbal preparations which are used to treat diabetes and which can be given by mouth. Blueberries were traditionally used by the Alpine peasants, and bitter gourd or karela (Momordica charantia) is an established part of herbal treatment in the Indian subcontinent and elsewhere. Traditional Chinese medicine also has herbal medicines for diabetes. As yet it is not known how these herbal medicines act and their efficacy awaits formal clinical evaluation.

**Interactions**

The commonest interactions with antidiabetic drugs are those that result in a rise or fall in blood glucose levels, thereby disturbing the control of diabetes. These are detailed in this section. Other interactions where the antidiabetic drug is the affecting drug are described elsewhere.

Neomycin may increase the efficacy and the gastrointestinal adverse effects of acarbose. There is some indirect evidence that acarbose with alcohol may increase the hepatotoxicity of paracetamol (acetaminophen). Paralytic ileus has been reported in a Japanese patient treated with acarbose and promethazine, an antimuscarinic drug.

Clinical evidence, mechanism, importance and management

(a) Antimuscarinics

A 69-year-old man with a partial gastrectomy and type 2 diabetes, treated with insulin 24 units and acarbose 300 mg daily, was admitted to hospital with diabetic gangrene. After developing cold symptoms he was given PL granules (salcyclamide, paracetamol, caffeine, promethazine, methylene disilicylate). The next day he experienced sudden abdominal pain, nausea and vomiting, which was diagnosed as paralytic ileus. He was given intravenous fluids and piperacillin. Oral intake and acarbose were withheld and the ileus resolved after 2 days. The authors note that there are several reports of ileus developing in Japanese patients within 3 months of treatment with alpha-glucosidase inhibitors such as acarbose. The risk seems to be increased with age, a history of abdominal surgery, and a Japanese diet (high in carbohydrates and fibre) rather than Western diet. However, in this case the patient had been taking acarbose for 15 months without problem and it is possible that the antimuscarinic effects of promethazine in the PL granules may have contributed to the development of ileus. The general clinical relevance of this case is uncertain. However, the authors consider that patients at risk should be monitored if they are given alpha-glucosidase inhibitors, especially if the dose is increased or if antimuscarinics are also given.

(b) Neomycin

Neomycin alone can reduce postprandial blood glucose levels and may enhance the reduction in postprandial glucose levels associated with acarbose. Neomycin 1 g three times daily increased the unpleasant gastrointestinal adverse effects (flatulence, cramps and diarrhoea) of acarbose 200 mg three times daily in 7 healthy subjects. The manufacturers suggest that if these adverse effects are severe the dosage of acarbose should be reduced.

(c) Paracetamol

Studies in rats have found that acarbose alone or in combination with alcohol may potentiate the hepatotoxicity of paracetamol. However, it is not known whether this has any clinical relevance.

Alpha-glucosidase inhibitors + Charcoal or Digestive enzymes

The manufacturers of acarbose and miglitol reasonably suggest that intestinal adsorvents (e.g. charcoal) or digestive enzyme preparations (such as amylase, pancreatin) should be avoided because, theoretically, they would be expected to reduce the effects of these alpha glucosidase inhibitors.

### Alpha-glucosidase inhibitors + Other antidiabetics

Some minor decreases in the plasma levels of glibenclamide (glyburide), metformin, and rosiglitazone have been seen with acarbose or miglitol, but these are not clinically relevant. Voglibose had no effect on glibenclamide pharmacokinetics. Alpha glucosidase inhibitors cause a moderate additional blood glucose-lowering effect when used with other antidiabetics, and a possible increased risk of hypoglycaemia should be borne in mind. In patients taking alpha-glucosidase inhibitors, treatment of hypoglycaemia should be with a monosaccharide such as glucose (dextrose) or glucagon, not a disaccharide such as sucrose. The manufacturer of pramlintide recommends that it should not be used in patients taking alpha-glucosidase inhibitors.

### Clinical evidence

(a) Glibenclamide (glyburide)

Pramlintide had no effect on the pharmacokinetics of glibenclamide in a double-blind crossover trial in 12 healthy male subjects. In this study, subjects were given either voglibose 5 mg or a placebo three times daily for 8 days and a single 1.75-mg dose of glibenclamide on the morning of day 8, taken at the same time as the first dose of the voglibose or placebo. Similarly, the manufacturer of acarbose noted that it had no effect on the absorption or disposition of glibenclamide in diabetic patients.

However, in a randomised, double-blind, placebo-controlled study in 28 patients with type 2 diabetes mellitus, miglitol reduced the maximum plasma glibenclamide levels and its AUC by 16 and 19%, respectively. The patients were given glibenclamide 2.5 mg twice daily with either miglitol 100 mg three times daily or placebo for 2 days. Nevertheless, the average blood glucose levels were reduced more by the drug combination than by the glibenclamide alone: over 5 hours there was a 15% greater reduction, and over 10 hours a 9% greater reduction.

(b) Metformin

A study in 6 healthy subjects found that acarbose 50 to 100 mg three times daily reduced the maximum serum levels and the AUC 0-9 of metformin 1 g by about 35%, but the 24-hour urinary excretion was unchanged.

Another study in 19 diabetic patients given acarbose 50 or 100 mg three times daily and metformin 500 mg twice daily, also found that acarbose lowered metformin levels (AUC reduced by 12 to 13%, maximum plasma levels reduced by 17 to 20%). Nevertheless, the drug combination reduced the postprandial glucose concentration at 3 hours by 15% more than metformin alone. Similarly, the manufacturer notes that, in a study in healthy subjects, miglitol 100 mg three times daily for 7 days reduced the AUC and maximum level of a single 1-g dose of metformin by 12% and 13%, respectively, although this difference was not statistically significant.

(c) Pramlintide

The manufacturer of pramlintide suggests that it should not be used in patients taking drugs that slow the intestinal absorption of nutrients, such as the alpha-glucosidase inhibitors. This is because pramlintide slows gastric emptying (see also ‘Pramlintide + Miscellaneous’, p.513). Clinical study is needed to see if there is any important effect if the drugs are used together.

(d) Rosiglitazone

A study in 16 healthy subjects found that acarbose 100 mg three times daily for a week slightly reduced the absorption of a single 8-mg oral dose of rosiglitazone (AUC reduced by 12%), but this was not considered to be clinically relevant.

### Mechanism

The reason for the minor pharmacokinetic changes is uncertain.

### Importance and management

The pharmacokinetic changes seen are minor and unlikely to be clinically relevant. The manufacturers say that while alpha glucosidase inhibitors such as acarbose and miglitol do not cause hypoglycaemia when given alone, they may increase the blood glucose-lowering effects of insulin and...
the sulphonylureas, for which reason it may be necessary to reduce their dosages. Monitor the outcome when acarbose, miglitol, or voglibose is first given. Any hypoglycaemic episodes should be treated with glucose (dextrose), not sucrose, because alpha-glucosidase inhibitors delay the digestion and absorption of disaccharides such as sucrose, but do not affect monosaccharides.1,2,5 Patients taking alpha-glucosidase inhibitors should not be given pramlintide until the combination has been studied clinically.

Antidiabetics + ACE inhibitors

The concurrent use of ACE inhibitors and antidiabetes normally appears to be uneventful but hypoglycaemia, marked in some instances, has occurred in a small number of diabetics taking insulin or sulphonylureas with captopril, enalapril, lisinopril or perindopril. This has been attributed, but not proved, to be due to an interaction. The United Kingdom Prospective Diabetes Study Group (UKPDS) found no difference in the incidence of hypoglycaemia between patients taking atenolol and those taking captopril. No pharmacokinetic interaction has been found to occur between spirapril and glibenclamide. Subcutaneous exenatide has no important effect on the pharmacokinetics of lisinopril, and does not alter its efficacy.

Clinical evidence

Numerous case reports, small case-control studies, and a pharmacological study in healthy subjects suggest that ACE inhibitors increase the risk of hypoglycaemia in patients receiving insulin or oral antidiabetics, and these are summarised in ‘Table 13.2’, (p.472). Conversely several larger case-control studies and two randomised controlled studies have not found a significantly increased risk of hypoglycaemia with ACE inhibitors, and these are also summarised in Table 13.2. It is worth highlighting that one of these, the United Kingdom Prospective Diabetes Study Group (UKPDS), found that the number of patients experiencing hypoglycaemic attacks did not differ between patients receiving atenolol 50 to 100 mg daily or captopril 25 to 50 mg twice daily for hypertension.1 A brief report states that spirapril does not have a pharmacokinetic interaction with glibenclamide.2 The manufacturer of exenatide notes that, in a study in hypertensive patients exenatide 10 micrograms twice daily did not alter the steady-state AUC or maximum level of lisinopril 5 to 20 mg daily, but did delay the time to maximum level by 2 hours. However, exenatide did not alter the blood-pressure lowering effect of lisinopril.3

Mechanism

Not understood. An increase in glucose utilisation and increased insulin sensitivity have been suggested.4,5 Other possibilities (e.g. altered renal function) are discussed in a series of letters in The Lancet.2 There is also an isolated report of persistent severe hypoglycaemia in a non-diabetic patient associated with both captopril and ramipril.2 Conversely, high natural ACE activity has been associated with a higher risk of severe hypoglycaemia.13

Importance and management

This interaction is not well established nor understood, and it remains the subject of considerable study and debate. However, some cases of severe hypoglycaemia have undoubtedly occurred due to the use of ACE inhibi-

Antidiabetics + Alcohol

Diabetic patients stabilised with insulin, oral antidiabetics or diet alone need not abstain from alcohol, but they should drink only in moderation and accompanied by food. Epidemiological evidence suggests that heart disease may be less common in diabetic patients who drink in moderation. However, alcohol makes the signs of hypoglycaemia less clear and delayed hypoglycaemia can occur. The CNS depressant effects of alcohol plus hypoglycaemia make driving or the operation of dangerous machinery much more hazardous. A flushing reaction is common in patients taking chlorpropamide who drink alcohol, but is less common with other sulphonylureas. Limited evidence suggests that alcoholic patients may require above-average doses of tolbutamide.

Clinical evidence

(a) Antidiabetes, general

1. Effect on glucose levels. The blood glucose levels of diabetics may be reduced, remain unchanged, or increased by alcohol, depending on the amount drunk at one time, if it is drunk with food or not, and if use is chronic and excessive.1 In one early study, 2 out of 7 diabetics receiving insulin became severely hypoglycaemic after drinking the equivalent of about 3 measures of spirits.2 In a hospital study over a 3-year period, 5 type I diabetics were hospitalised with severe hypoglycaemia after binge-drinking. Two of them died without recovery from the initial coma and the other 3

Continued
suffered permanent damage to the nervous system.\(^3\) In another study it was found that alcohol was involved in about 4% of hypoglycaemic episodes requiring hospitalisation.\(^4\) In contrast to these alcohol-induced hypoglycaemic episodes, it was found in two other studies\(^5,6\) that pure alcohol and dry wine had little effect on blood glucose levels. In a recent review of six studies, it was concluded that consumption of a moderate amount of alcohol does not acutely impair glycaemic control in diabetic patients, and may in fact result in a small decrease in plasma glucose concentration.\(^7\) However, another study found that 46 patients with type 2 diabetes and a mean age of 67 years who were regular chronic alcohol users (mean 45 g/day) had a reversible deterioration in metabolic control (higher fasting and postprandial glucose levels and higher glycosylated haemoglobin levels), when compared with 35 non-alcohol users.\(^8\) Another study reported similar findings.\(^9\)

2. Effect on diabetic complications. A review of 4 epidemiological studies concluded that heart disease is less common in people with diabetes who drink moderate amounts of alcohol than in those who do not.\(^7\)

(b) Biguanides

A controlled study in 5 ketosis-resistant patients with type 2 diabetes taking phenformin 50 to 100 mg daily found that the equivalent of about 85 mL (3 oz) of whiskey markedly raised their blood lactate and lactate-pyruvate levels. Two of them had blood-lactate levels of more than

50 mg%, and one of these patients had previously experienced nausea, weakness and malaise while taking phenformin and alcohol.10 The ingestion of alcohol is described in other reports as having preceded the onset of phenformin-induced lactic-acidosis.11-13 Some patients have complained that alcohol tastes metallic.

(c) Rosiglitazone

An 8-week study in type 2 diabetes taking rosiglitazone 8 mg daily or a placebo found that 0.6 g/kg of alcohol taken with a meal did not have a clinically relevant effect on plasma glucose levels and no episodes of hypoglycaemia were seen.14

(d) Sulphonylureas

About one-third of those taking chlorpropamide who drink alcohol, even in quite small amounts, experience a warm, tingling or burning sensation of the face, and sometimes the neck and arms as well. It may also involve the conjunctivae. This can begin within 5 to 20 minutes of drinking, reaching a peak within 30 to 40 minutes, and may persist for 1 to 2 hours. Very occasionally headache occurs, and light-headedness, palpitations, wheezing and breathlessness have also been experienced.15,16

This disulfiram-like flushing reaction has been described in numerous reports (far too many to list here) involving large numbers of patients taking chlorpropamide. These reports have been extensively reviewed.15,16 A similar reaction can occur, but much less frequently, with other sulphonylureas including carbutamide,20 glibenclamide (glyburide),16,21 gliclazide,22 glipizide,16 tolazamide,22 and tobutamides.24,25

In one crossover study, evident flushing phenomenon, after an oral ethanol-loading test, was seen in 6 of 10 patients taking chlorpropamide, 3 of 10 taking tobutamides, 2 of 10 taking glibenclamide, one of 10 taking glimepiride and none of 10 taking glipizide.26 A study found that the mean half-life of tolbutamide in alcoholics was about one-third lower than in control subjects.27 Alcohol is also reported to prolong but not increase the blood glucose-lowering effects of glipizide.28 Another study found that intravenous infusion of ethanol (equivalent to 1 to 2 units of alcoholic drinks) significantly decreased the nadir plasma glucose level during a fast in 10 elderly patients (age range 60 to 75 years) with type 2 diabetes taking glibenclamide 20 mg daily.29

Mechanism

The exacerbation of hypoglycaemia by alcohol is not fully understood. However, it is known that if hypoglycaemia occurs when liver glycogen stores are low, the liver turns to the formation of new glucose from amino acids (gluconeogenesis). This gluconeogenesis is inhibited by the presence of alcohol so that the fall in blood glucose levels may not be prevented and a full-scale hypoglycaemic episode can result.

The chlorpropamide-alcohol flush reaction, although extensively studied, is by no means fully understood. It seems to be related to the disulfiram-alcohol reaction, and is accompanied by a rise in blood-acetdehyde levels (see also ‘Alcohol + Disulfiram’, p.61). It also appears to be genetically determined30 and may involve both prostaglandins and endothelial opioids.31 The decreased half-life of tolbutamide in alcoholics is probably due to the inducing effects of alcohol on liver microsomal enzymes.27,31,32

The reasons for the raised blood lactate levels seen during the concurrent use of phenformin and alcohol are not clear, but one suggestion is that it may possibly be related to the competitive demands for isoenzymes by the reactions that convert alcohol to acetaldheyde, and lactate to pyruvate.33 A study in healthy subjects found that moderate alcohol consumption both improves insulin action, without affecting non-insulin mediated glucose uptake, and decreases lactate clearance. The increase in blood lactate with alcohol is therefore mainly due to inhibition of clearance. Alcohol did not appear to significantly affect beta-cell function.34

Importance and management

The documentation of the interactions between anti diabetic drugs and alcohol is surprisingly patchy (with the exception of chlorpropamide and alcohol) but they are of recognised clinical importance.

General comments

The following contains the main recommendations of Diabetes UK (formerly The British Diabetic Association) based on a review of what is currently known.35 Most diabetics need not avoid alcohol totally, but they are advised not to exceed 2 drinks (for women) or 3 drinks (for men) daily. A drink (or unit) is defined in ‘Table 3.1’, (p.41). The intake of drinks with high-carbohydrate content (sweet sherrys, sweet wines, most liqueurs, and low alcohol wines) should be limited. Diabetics should not drink on an empty stomach and they should know that the warning signs of hypoglycaemia may possibly be obscured by the effects of the alcohol. Driving or handling dangerous machinery should be avoided because the CNS depressant effects of alcohol plus hypoglycaemia can be particularly hazardous. Warn patients of the risks of hypoglycaemia occurring several hours after drinking. Those with peripheral neuropathy should be told that alcohol may aggravate the condition and they should not have more than one drink daily. Provided drinking is restricted as suggested, and drinks containing a lot of carbohydrate are avoided, there is no need to include the drink in the dietary allowance. However, diabetics on a weight-reducing diet should try to limit intake to the occasional drink and should include it in their daily calorie allowance.

The advice of the American Diabetes Association is similar: If individual wish to drink alcohol, daily intake should be limited to 1 drink (for women) or 2 drinks (for men). To reduce the risk of hypoglycaemia, alcohol should be consumed with food.1

There is some evidence that heart disease in patients with diabetes may be less common in patients who consume moderate amounts of alcohol, but this is currently not sufficient to recommend that patients who do not drink alcohol should begin to drink in moderation.7

Specific comments about oral antidiabetics

The chlorpropamide-alcohol interaction (flushing reaction) is very well documented, but of minimal importance. It is a nuisance and possibly socially embarrassing but normally requires no treatment. Patients should be warned. The incidence is said to lie between 13 and 33%36,37 although one study claims that it may be as low as 4%.38 Since it can be provoked by quite small amounts of alcohol (half a glass of sherry or wine) it is virtually impossible for sensitive patients to avoid it if they drink. Most manufacturers issue warnings about the possibility of this reaction with other sulphonylureas, but it is very rarely seen and can therefore almost always be avoided by replacing chlorpropamide with another sulphonylurea. Alcoholic subjects may need above-average doses of tolbutamide.

Metformin does not carry the same risk of lactic acidosis seen with phenformin and it is suggested in a paper34 prepared for and approved by The British Diabetic Association [now Diabetes UK] that one or two drinks a day are unlikely to be harmful in patients taking metformin. However, the drug should not be given to alcoholic patients because of the possibility of liver damage.

Allopurinol adversely affected glycaemic control in a patient with type 2 diabetes receiving insulin. Allopurinol caused an increase in the half-life of chlorpropamide, and a minor decrease in the half-life of tolbutamide, but the effect of these changes on the hypoglycaemic response of patients is uncertain. Marked hypoglycaemia and coma occurred in one patient taking gliclazide and allopurinol.

Clinical evidence
A. Insulin
A case report describes improved glycaemic control in a type 2 diabetic patient after allopurinol was stopped. Despite restricted food intake and an increasing dose of insulin, his glycaemic control was poor (fasting blood glucose 14.8 mmol/L) when he took allopurinol 100 mg twice daily. However, within a few days of stopping the allopurinol, an unexpected improvement in glycaemic control was observed (fasting blood glucose reduced to less than 11 mmol/L). He was later rechallenged with allopurinol, which resulted in reduced glucose tolerance, but increased insulin resistance. Hyperuricaemia was later controlled with probenecid, which did not adversely affect glycaemic control.1

B. Sulphonylureas
(a) Chlorpropamide
A brief report describes 6 patients taking chlorpropamide with allopurinol. The half-life of chlorpropamide in one patient with gout and normal renal function exceeded 200 hours (normally 36 hours) after allopurinol had been taken for 10 days, and in 2 others the half-life was extended to 44 and 55 hours. The other 3 patients were given allopurinol for only 1 or 2 days and the half-life of chlorpropamide remained unaltered.2

(b) Gliclazide
Severe hypoglycaemia (1.6 mmol/L) and coma occurred in a patient with renal impairment taking gliclazide and allopurinol.2 Hypoglycaemia has been seen in another patient taking both drugs, but an interaction is less clear, as enalapril and ranitidine, which may also (rarely) interact were also involved.3

(c) Tolbutamide
Allopurinol 2.5 mg/kg twice daily for 15 days reduced the half-life of intravenous tolbutamide in 10 healthy subjects by 25%, from 360 to 267 minutes.4 5

Mechanism
Not understood. In the case of chlorpropamide it has been suggested that it possibly involves some competition for renal tubular mechanisms.2

Importance and management
Information is very limited. Only gliclazide has been implicated in severe hypoglycaemia with allopurinol and there seem to be no reports of either grossly enhanced hypoglycaemia with chlorpropamide and allopurinol, or a reduced effect with tolbutamide and allopurinol. More study is needed to find out whether any of these interactions has general clinical importance, but it seems unlikely.

Antidiabetics + Anabolic steroids
Nandrolone, methandienone, testosterone and stanozolol can enhance the blood glucose-lowering effects of insulin.

Clinical evidence
In a study in 54 diabetics taking nandrolone phenylpropionate 25 mg weekly or nandrolone decanoate 50 mg given every 3 weeks by intramuscular injection, it was found necessary to reduce the insulin dosage in an average of 36% (reduction range 4 to 56 units) in about one-third of the patients.1 Other reports similarly describe an enhanced reduction in blood glucose levels in diabetics receiving insulin and nandrolone,2,3 methandienone,4 testosterone propionate5 or stanozolol.6 A reduction in blood glucose levels has also been seen in healthy subjects given testosterone propionate.7 No changes were seen when ethyltestosterone was used.1

Mechanism
Uncertain.

Importance and management
Established interactions but the total picture is incomplete because not all of the anabolic steroids appear to have been studied and they may not necessarily behave identically. A fall in the dosage requirements of insulin may be expected in many patients with the steroids cited. An average reduction of a third is reported.8 Given these results, and the fact that anabolic steroids have been shown to impair glucose tolerance it would seem prudent to closely monitor the concurrent use of any anti-diabetic drug.

Antidiabetics + Angiotensin II receptor antagonists

Glibenclamide (glyburide) causes a small reduction in valsartan plasma levels, but this is unlikely to be of any clinical significance. No clinically relevant pharmacokinetic interaction occurs between glibenclamide and candesartan or telmisartan, or between tolbutamide and irbesartan. Eprosartan does not alter the efficacy of glibenclamide. Losartan and possibly eprosartan may reduce awareness of hypoglycaemic symptoms.

Clinical evidence and mechanism

A. Insulin

(a) Eprosartan

A study in 16 healthy subjects found that a single 600-microgram dose of eprosartan did not significantly affect adrenaline (epinephrine) release in response to insulin-induced hypoglycaemia, but the eprosartan tended to blunt some of the haemodynamic responses to hypoglycaemia. Theoretically, therefore, hypoglycaemic symptoms could be reduced in some diabetic patients.

(b) Losartan

Three patients with type 1 diabetes spontaneously reported reduced awareness of hypoglycaemic symptoms (tremor, palpitations, nervousness) after initiation of losartan therapy. A placebo-controlled study in 18 healthy subjects given losartan 50 mg daily for 8 days confirmed an attenuation of the symptomatic and hormonal responses to hypoglycaemia.

B. Glibenclamide (Glyburide)

(a) Candesartan

Glibenclamide 3.5 mg daily did not significantly affect the pharmacokinetics of candesartan 16 mg daily, both given for 7 days, although the maximum plasma concentration of candesartan was slightly increased by 12%. The pharmacokinetics of glibenclamide were not altered by the candesartan.

(b) Eprosartan

Fifteen type 2 diabetes stabilised taking glibenclamide 3.75 to 10 mg daily for at least 30 days had no changes in their 24-hour plasma glucose concentrations when eprosartan 200 mg twice daily was added, for a further 7 days. Concurrent use was safe and well tolerated and it was concluded that there is no clinically relevant interaction between these two drugs.

(c) Valsartan

In a randomised, crossover study, 12 healthy subjects were given single oral doses of valsartan 160 mg and glibenclamide 1.75 mg alone and together. Glibenclamide appeared to decrease the valsartan AUC by 16%, but the plasma concentrations of valsartan showed wide variations between subjects. The pharmacokinetics of glibenclamide were not affected. The changes in valsartan pharmacokinetics seen with glibenclamide appear to have little or no clinical relevance.

C. Tolbutamide

A study in 18 healthy subjects given irbesartan 300 mg daily and tolbutamide 1 g daily, either alone or in combination, found that no clinically important pharmacokinetic interactions occurred.

Importance and management

No special precautions would appear to be needed if candesartan, eprosartan, telmisartan or valsartan are given with glibenclamide, or if irbesartan is given with tolbutamide. However, symptoms of hypoglycaemia may be reduced by losartan and possibly other angiotensin II receptor antagonists. Further clinical study is needed, but note that this is similar to the effect of ‘ACE inhibitors’.

Antidiabetics + Antacids

The rate of absorption of some antidiabetics is increased by some antacids, but there appear to be no reports of adverse responses in diabetic patients as a result of any of these interactions.

Clinical evidence

(a) Acarbose

A single-dose study in healthy subjects found that magnesium hydroxide 850 mg had little effect on the rate or extent of absorption of a micronised glibenclamide preparation (Semi-Euglucon), but it caused a threefold increase in the peak plasma concentration and the bioavailability of a non-micronised preparation (Gilemid). Magnesium hydroxide increased the AUC of glibenclamide (given as Daonil) by one-third, and its maximum serum level by 50%. The absorption of glibenclamide is increased significantly by magnesium hydroxide, but the plasma concentrations of glibenclamide showed wide variations between subjects. The pharmacokinetics of glibenclamide were not affected. The changes in glibenclamide pharmacokinetics seen with magnesium hydroxide appear to have little or no clinical relevance.

(b) Chlorpropamide

Magnesium hydroxide 850 mg increased the rate of absorption of chlorpropamide 250 mg in healthy subjects, but the insulin and glucose responses were unaffected.

(c) Glibenclamide (Glyburide)

A single-dose study in healthy subjects found that magnesium hydroxide 850 mg had little effect on the rate or extent of absorption of a micronised glibenclamide preparation (Semi-Euglucon), but it caused a threefold increase in the peak plasma concentration and the bioavailability of a non-micronised preparation (Gilemid). Magnesium hydroxide increased the AUC of glibenclamide (given as Daonil) by one-third, and its maximum serum level by 50%. The absorption of glibenclamide is increased significantly by magnesium hydroxide, but the plasma concentrations of glibenclamide showed wide variations between subjects. The pharmacokinetics of glibenclamide were not affected. The changes in glibenclamide pharmacokinetics seen with magnesium hydroxide appear to have little or no clinical relevance.

(d) Glibenclamide (Glyburide)

A single-dose study in healthy subjects found that magnesium hydroxide 850 mg had little effect on the rate or extent of absorption of a micronised glibenclamide preparation (Semi-Euglucon), but it caused a threefold increase in the peak plasma concentration and the bioavailability of a non-micronised preparation (Gilemid). Magnesium hydroxide increased the AUC of glibenclamide (given as Daonil) by one-third, and its maximum serum level by 50%. The absorption of glibenclamide is increased significantly by magnesium hydroxide, but the plasma concentrations of glibenclamide showed wide variations between subjects. The pharmacokinetics of glibenclamide were not affected. The changes in glibenclamide pharmacokinetics seen with magnesium hydroxide appear to have little or no clinical relevance.

(e) Glipizide

Sodium bicarbonate 1 to 3 g very markedly increased the early bioavailability of non-micronised glibenclamide in healthy subjects, but its activity remained unaltered.

(f) Miglitol

The manufacturer notes that an antacid (not specified) did not alter the pharmacokinetics of miglitol in healthy subjects.

(g) Tolbutamide

Magnesium hydroxide 850 mg increased the 0 to 1-hour and 2-hour AUCs of a single 500-mg dose of tolbutamide 5-fold and 2.5-fold, respectively, in healthy subjects. The total AUC was unaffected. The maximum insulin response was increased fourfold and occurred about an hour earlier, and the glucose responses were also larger and occurred earlier.

Mechanism

Uncertain. The small increase in gastric pH caused by these antacids possibly increases the solubility of these sulphonylureas and therefore increases their absorption.

Importance and management

Although some interactions certainly occur in healthy subjects, their clinical importance in patients with diabetes is uncertain. No reports of adverse reactions appear to have been published, but note that patients taking glibenclamide with sodium bicarbonate or magnesium hydroxide, or tolbutamide with magnesium hydroxide may experience transient hypoglycaemia. Generally no action seems necessary, but if a problem does occur, separating the dosages as much as possible would probably minimise any
Antidiabetics + Antimalarials

Hydroxychloroquine may reduce insulin requirements by about 25%, and a case of hypoglycaemia has been reported. Similarly, hypoglycaemia has occurred in a patient taking chloroquine and insulin. Reduced glucose levels or hypoglycaemia have been reported with mefloquine, quinidine, quinine, and sulfadoxine-pyrimethamine. Note that falciparum malaria per se can result in severe hypoglycaemia, and quinine in particular may contribute to this.

Clinical evidence, mechanism, importance and management

(a) Effect on diabetic control

1. Chloroquine. A case report describes a patient with type 1 diabetes who had developed insulin resistance and was maintained on intravenous insulin, who showed a dramatic return of sensitivity to subcutaneous insulin, heralded by a series of hypoglycaemic attacks, within 15 days of starting to take chloroquine phosphate 200 mg every 8 hours.1 Similarly, chloroquine phosphate (150 mg of chloroquine base) four times daily improved severe hypoglycaemia, and quinine in particular may contribute with mefloquine, quinidine, quinine, and sulfadoxine-pyrimethamine.10

2. Hydroxychloroquine. The effect of hydroxychloroquine on diabetic control with insulin or glibenclamide (glyburide) was investigated in a randomised, double-blind, placebo-controlled study in 38 patients with poorly controlled type 2 diabetes. The addition of hydroxychloroquine 200 mg three times daily to insulin caused a significant improvement in the glycemic profile and the daily insulin dose had to be reduced by about 25%. Patients taking glibenclamide with hydroxychloroquine also had a significant improvement in their plasma glucose levels. One patient receiving insulin and hydroxychloroquine had severe hypoglycaemia after 2 months of treatment, and it was necessary to drastically reduce the daily dose of insulin.3 The authors suggested that hydroxychloroquine might inhibit insulin degradation or increase glucose utilisation in peripheral tissues.3

(b) Treatment of malaria

Hypoglycaemia is a complication of falciparum malaria, which occurs mainly in severe life-threatening disease,5,6 in pregnant women7 or children,8,9 and in patients who are given quinine or quinidine.3,9,10 The reasons are not fully understood but renal impairment and poor nutrition, may be contributing factors. In severe malaria, hypoglycaemia may increase as the patient’s glucose production becomes insufficient for the host/parasite relationship to continue, and the patient’s glucose production becomes insufficient for the host/parasite relationship to continue. In severe malaria, hypoglycaemia may increase as the patient’s glucose production becomes insufficient for the host/parasite relationship to continue. 25% of patients.10 Quinine has been shown to have a similar effect.11 Whether these changes can also occur in patients with quinine- or quinidine-treated malaria and diabetes, despite their pancreatic beta cell impairment, seems not to have been studied, although one isolated report argues against significant quinine-mediated mechanisms.12,13 Profound and persistent hypoglycaemia was seen in a diabetic patient (type 2 diabetes) with severe falciparum malaria treated with quinine, but the hypoglycaemia evolved prior to quinine therapy and resolved as the parasitaemia was successfully eradicated, despite continuation of the quinine. Subsequently, as she had discontinued anti-diabetic medication (chloropropamide) prior to hospital admission, hyperglycaemia developed (blood glucose ranging from 7.5 to 16 mmol/L) despite continuing to take quinine.14 Any interpretation of disturbances in the control of the diabetes should take into account the severity of the malaria and the possible effects of these drugs.

An isolated report describes life-threatening hypoglycaemia in a 3-year-old boy, with uncomplicated malaria. 90 minutes after he took sulfadoxine-pyrimethamine (Fansidar)15 Mefloquine has been reported to reduce plasma glucose levels in healthy subjects.16 Arteisinin derivatives such as artesunate may be associated with fewer episodes of hypoglycaemia than quinine in children with severe malaria.17 Chloroquine, amoquinina and halofantrine do not apparently stimulate the release of insulin.18,19

(c) Treatment of cramps

A study in 12 patients (age 51 to 79 years) with type 2 diabetes taking glimeclazide, and 10 similar, non-diabetic subjects, found that a single 600-mg dose of quinine sulphate at night reduced serum glucose levels in both groups, without affecting serum insulin concentrations.18 Quinine has been responsible for hypoglycaemia in non-diabetic patients, one of whom was taking quinine sulphate 325 mg four times daily for leg muscle cramps.20 Two other non-diabetic patients, one with congestive heart failure and the other with terminal urinary cancer, similarly developed hypoglycaemia when given quinine for leg cramps.21,22

Antidiabetics + Antineoplastics

Asparaginase sometimes induces temporary diabetes mellitus. It seems possible that some diabetics will need changes in the dose of their antidiabetic drugs. There is also evidence that the control of diabetes can be severely disturbed in patients given cyclophosphamide. Captopitaine may cause hyperglycaemia and therefore could aggravate diabetes.

Clinical evidence and mechanism

(a) Asparaginase (Colaspase)

Three patients with acute lymphocytic leukaemia developed diabetes after receiving asparaginase with or without corticosteroids. In two of them this occurred 2 and 4 days after a single dose of asparaginase, and in another patient it occurred 2 days after the fourth dose. Plasma insulin was undetectable. A normal insulin response returned in one patient after 23 days, whereas the other 2 showed a suboptimal response 2 weeks, and 9 months afterwards.1 In another study, 5 out of 39 patients (3 adults, 2 children) developed hyperglycaemia and glycosuria after treatment with asparaginase. This responded to insulin, and blood glucose levels returned to normal in about 2 weeks.2 In a retrospective analysis, it was found that about 10% of 421 children with leukaemia treated with asparaginase and prednisone developed hyperglycaemia, which resolved in all patients. A family history of diabetes and obesity were found to be risk factors.3 Other cases have been described,4,6 including one who, unusually, developed persistent hyperglycaemia and required long-term treatment with oral antidiabetics.5 The reasons for this reaction are not understood but suggestions include inhibition of insulin synthesis,1 direct damage to the islets of Langerhans,6 and reduced insulin binding.3 Hyperglycaemia can be caused by ‘corticosteroids’ (p.485), and their combined use with asparaginase is probably a contributing factor.

(b) Capecitabine

There appear to be no reports of adverse interactions between antidiabetics and capecitabine, but the manufacturer notes that the control of diabetes may be affected by capecitabine, for which reason they advise caution.8

(c) Cyclophosphamide

Acute hyperglycaemia has been described in 2 diabetic patients receiving insulin and carbutamide who were also given cyclophosphamide.3 Three cases of diabetes, apparently induced by the use of cyclophosphamide, have also been reported.10 The reasons are not understood.

Importance and management

Strictly speaking probably none of these reactions is an interaction, but they serve to underline the importance of monitoring the diabetic control of patients receiving asparaginase, captopitaine or cyclophosphamide.

Clinical evidence

(a) Phenothiazines and Butyrophenones

A long-term study was undertaken over the period 1955 to 1966 in a large number of women treated for a year or longer with chlorpromazine 100 mg daily or more, or corresponding doses of perphenazine, thioridazine, trifluoperazine. This found that about 25% developed hyperglycaemia accompanied by glycosuria, compared with less than 9% in a control group who were not taking phenothiazines. Of those given a phenothiazine, about a quarter had complete remission of the symptoms when the drug was withdrawn or the dosage reduced. Thioridazine appeared to be less diabetogenic than the other phenothiazines used.1

There are other reports of this response to chlorpromazine.2-11 However, in contrast one study in 850 patients suggests that chlorpromazine has no effect on blood glucose levels; 22 diabetic patients in the study had no significant changes in their blood glucose levels. Five patients developed diabetes, but this was believed to be due to factors other than chlorpromazine treatment.12 Chlorpromazine 50 to 70 mg daily does not affect blood glucose levels significantly.11 Further, a more recent analysis discussed in (b) below did not find an increased risk of glucose intolerance with chlorpromazine or haloperidol, and notes that the number of reports of glucose intolerance with these drugs has remained small.13

(b) Atypical antipsychotics

An analysis of reports of glucose intolerance in the adverse reaction database of the WHO Collaborating Centre for International Drug Monitoring found that clozapine, olanzapine and risperidone were associated with an increased risk of glucose intolerance. It is uncertain whether this is a dose-related effect. Additional risk factors with these antipsychotics were an underlying diabetic condition, weight increase, male gender, or the concurrent use of valproic acid, SSRIIs or bupropion.14

Mechanism

Although some studies found that drugs such as chlorpromazine and haloperidol were not associated with glucose intolerance,11,13 it seems that chlorpromazine can inhibit the release of insulin, and possibly cause adrenaline release from the adrenals, both of which could result in a rise in blood glucose levels. This may be a dose-related effect.15 Further, chlorpromazine may cause aggregation and inactivation of insulin by reduction of disulfide bonds.14 Clozapine may induce insulin resistance and a compensatory increase in insulin secretion. Patients may develop diabetes if this compensatory increase is not achieved. Clozapine and olanzapine may cause weight gain and hypertriglyceridaemia.13 Schizophrenia itself may be associated with an increased risk of hyperglycaemia.

Importance and management

A long-established reaction first recognised in the early 1950s. The incidence of hyperglycaemia with chlorpromazine in doses of 100 mg or more is about 25%. Increases in the dosage requirements of the antidiabetic should be anticipated during concurrent use.1 Smaller chlorpromazine doses, of 50 to 70 mg daily do not appear to cause hyperglycaemia. There seems to be little clinical evidence that other phenothiazines or butyrophenones significantly disturb blood glucose levels in diabetics. The atypical antipsychotics, clozapine, olanzapine and risperidone appear to be associated with an increased risk of glucose intolerance and regular monitoring is recommended in the presence of additional risk factors for diabetes mellitus.13

Antidiabetics + Antipsychotics

Chlorpromazine may raise blood glucose levels, particularly in daily doses of 100 mg or more, and disturb the control of diabetes. Clozapine, olanzapine and risperidone may disturb the control of diabetes with an increased risk of glucose intolerance.
Fluconazole appears not to affect the diabetic control of most patients taking sulphonylureas, but isolated reports describe hypoglycaemic coma in one patient taking glipizide and glybenclamlide and aggressive behaviour in a patient taking gliclazide. There is some evidence that the blood glucose-lowering effects of both glipizide and glibenclamide (glyburide) may be modestly increased. Fluconazole may cause increases in plasma levels of glimepiride (marked) and nateglinide (modest).

Clinical evidence

(a) Chlorpropamide

After taking fluconazole 100 mg daily for 7 days, the AUC of single 250-mg doses of chlorpropamide was increased by 28% in 18 healthy subjects but the maximum plasma levels and blood glucose levels were unchanged. There was no evidence of hypoglycaemia.1

(b) Glibenclamide (Glyburide)

After taking fluconazole 100 mg daily for 7 days, the AUC of a single 5-mg dose of glibenclamide was increased by 44% and maximum plasma levels rose by 19% in 20 healthy subjects. The change in blood glucose levels was not statistically significant but the number of subjects who had symptoms of hypoglycaemia increased.2 In another study, a group of 14 postmenopausal diabetic women with vulvovaginal candidiasis taking either gliclazide or glibenclamide were given fluconazole 50 mg daily for 14 days. In contrast, none of the patients in this study developed symptoms of hypoglycaemia and their glycosylated haemoglobin and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.3

(c) Gliclazide

A group of 14 postmenopausal diabetic women with vulvovaginal candidiasis taking either gliclazide or glibenclamide were given fluconazole 50 mg daily for 14 days. None of the patients developed symptoms of hypoglycaemia and their glycosylated haemoglobin and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.3

However, a 56-year-old HIV-positive patient (antiretroviral treatment refused) and type 2 diabetes who had been taking glipizide for 2 years was given fluconazole 50 mg daily for 2 weeks for oral candidiasis, and prophylactic co-trimoxazole (sulfamethoxazole 400 mg and trimethoprim 80 mg daily). One week after the re-introduction of fluconazole at a higher dose of 200 mg daily he was hospitalised because of weakness and aggressive behaviour. His blood glucose level was 2.2 mmol/L and glipizide dose of 200 mg daily he was hospitalised because of weakness and aggressive behaviour. He experienced brief loss of consciousness 2 days later while driving his car, but his condition then improved and neurological symptoms did not recur during 3 months follow-up without glipizide treatment.4 For the possible contribution of sulfamethoxazole to this interaction, see Mechanism, below.

(d) Glimepiride

A double-blind study in 12 healthy subjects found that fluconazole 400 mg on day one then 200 mg daily for a further 3 days increased the AUC and peak plasma level of a single 0.5-mg dose of glimepiride by about 2.5-fold and 1.5-fold, respectively. Fluconazole increased the mean elimination half-life of glimepiride from 2 to 3.3 hours.5

(e) Glipizide

After taking fluconazole 100 mg daily for 7 days, the AUC of a single 2.5-mg dose of glipizide was increased by 49% and their maximum serum levels rose by 17% in 13 healthy subjects. Although blood glucose levels were lowered the change was not statistically significant. However, the number of subjects who had symptoms suggestive of hypoglycaemia increased.6 A diabetic patient taking glipizide 2.5 mg three times daily went into a hypoglycaemic coma within 4 days of starting to take fluconazole 200 mg daily. Her blood glucose levels had fallen to less than about 0.05 mmol/L. She rapidly recovered when given glucose.7

(f) Nateglinide

In a randomised, double-blind, crossover study, 10 healthy subjects were given a single 30-mg dose of nateglinide on day 4 of a course of fluconazole (given as 400 mg on day one, then 200 mg daily). Fluconazole raised the AUC of nateglinide by 48% (range 20 to 73%) and increased the nateglinide half-life from 1.6 to 1.9 hours. Despite these pharmacokinetic changes fluconazole did not potentiate the blood glucose lowering effects of nateglinide.8 It was predicted that this interaction may occur with micronazole (which inhibits the same isoenzymes as fluconazole), but this needs confirmation.

(g) Tolbutamide

After taking a single 150-mg dose and a further 6 doses of fluconazole 100 mg daily, the AUC of a single 500-mg dose of tolbutamide was increased by about 50%, and the peak plasma levels were raised in 13 healthy subjects. The half-life of the tolbutamide was increased about 40%. Blood glucose levels remained unaltered and none of the subjects showed any evidence of hypoglycaemia.9,10 However, the authors cautions against extrapolating this finding to diabetic patients taking tolbutamide regularly.9,10

Mechanism

Fluconazole is an inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which many of the sulphonylureas are metabolised. Inhibition of this isoenzyme leads to an accumulation of the sulphonylurea and therefore an increase in its effects. The hypoglycaemia in the patient taking gliclazide and fluconazole may have been enhanced by sulfamethoxazole, which also inhibits CYP2C9 (see also ‘sulfonamides’ (p.506)).4 The moderate pharmacokinetic changes seen when fluconazole is given with nateglinide are also thought to be mediated by CYP2C9.

Importance and management

The almost total absence of adverse reports implies that fluconazole does not usually markedly disturb the control of diabetes in those taking sulphonylureas. For fluconazole the increased plasma levels of glipizide and gliclazide, and the single case of severe hypoglycaemia, as well as the hypoglycaemic symptoms shown by those taking glibencamidine (glyburide) or gliclazide suggest that patients taking these sulphonylureas in particular should be warned to be alert for any evidence of hypoglycaemia. However, there seems to be no reason for avoiding concurrent use. Note that in the study of fluconazole with nateglinide a sub-therapeutic dose was given to healthy subjects, so in clinical practice a greater blood glucose-lowering effect may possibly occur.

Antidiabetics + Azoles; Itraconazole or Ketoconazole

Itraconazole also appears not to affect diabetic control in most patients, but there are reports of hypoglycaemia or hyperglycaemia associated with its use. Itraconazole causes modest increases in repaglinide and nateglinide levels, but has no effect on pioglitazone pharmacokinetics. Ketoconazole increases the blood glu-
Hypoglycaemia has been seen in few diabetics taking tolbutamide, glibenclamide or glipizide when they were given miconazole. Posaconazole slightly enhanced the blood glucose-lowering effects of glipizide in healthy subjects, but did not affect the metabolism of a single dose of tolbutamide. Voriconazole is predicted to increase the levels of the sulphonylureas. Clotrimazole used intravaginally appears not to interact with glipizide or glibenclamide.

Clinical evidence
(a) Clotrimazole
A group of 15 postmenopausal diabetic women with vulvovaginal candidiasis taking either glipizide or glibenclamide (glyburide) were treated with intravaginal clotrimazole 100 mg daily for 14 days. None of the patients developed symptoms of hypoglycaemia and their glycosylated haemoglobin and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.1

(b) Miconazole
A diabetic patient taking tolbutamide was hospitalised with severe hypoglycaemia about 10 days after starting to take miconazole.2 In 1983 the French Commission Nationale de Pharmacovigilance reported 6 cases of hypoglycaemia in diabetics taking sulphonylureas (5 with gliclazide and one with glibenclamide (glyburide)), which occurred within 2 to 6 days of miconazole being started.2 The same organisation reported a further 8 cases in the 1985 to 1990 period but individual sulphonylureas were not named.3 Three other cases of hypoglycaemia (two with gliclazide and one with glibenclamide) are reported elsewhere, in patients given miconazole up to 750 mg daily.4 Miconazole has been predicted to interact with nateglinide, see ‘fluconazole’, (p.479).

(c) Posaconazole
A study in 12 healthy subjects found that posaconazole 400 mg twice daily for 10 days had no significant effects on the steady-state pharmacokinetics of glipizide 10 mg daily, but there was a small significant decrease in blood glucose levels following concurrent use. Glipizide did not affect the pharmacokinetics of posaconazole.5

(d) Voriconazole
The manufacturers of voriconazole predict that it will raise the levels of the sulphonylureas.6

Mechanism
Miconazole and voriconazole are inhibitors of the cytochrome P450 isoenzyme CYP2C9, by which many of the sulphonylureas are metabolised. Inhibition of this isoenzyme would therefore be expected to lead to an accumulation of the sulphonylurea and therefore an increase in its ef-
fects, as seen with miconazole. Clotrimazole is probably not absorbed in sufficient quantities to cause an interaction.

Importance and management

The interaction between miconazole and the sulphphonylureas is established and clinically important, but of uncertain incidence. Concurrent use need not be avoided but it should be monitored and the dosage of the sulphphonylurea reduced if necessary. Patients should be warned. Information about other sulphphonylureas not cited is lacking but it seems possible that they may interact similarly with miconazole.

Posaconazole slightly enhanced the blood glucose-lowering effects of glipizide in healthy subjects, but the clinical relevance of this is not known. Posaconazole does not appear to affect tolbutamide metabolism.

The manufacturers of voriconazole advise increased blood-glucose monitoring in patients taking sulphphonylureas, and until more is known this seems prudent.

Information about intravaginal clotrimazole is very sparse, but it appears not to interact with gliclazide or glibenclamide, and probably not with any of the other oral antidiabetics, not least because its absorption from the vagina is very small.

Antidiabetics + Benzodiazepines

No adverse interaction normally occurs between antidiabetics and benzodiazepines, but an isolated case of hyperglycaemia has been seen in an insulin-treated patient with type 2 diabetes associated with the use of chlorldiazepoxide. The effects of lorazepam were found to be increased in patients given beef/pork insulin rather than human insulin. Pioglitazone caused a minor decrease in the AUC of midazolam, which is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Insulin

A woman with long-standing type 2 diabetes, which was stabilised with 45 units of insulin suspension daily, had a rise in her mean fasting blood glucose from about 12 to 21 mmol/L during a 3-week period while taking chlorldiazepoxide 40 mg daily.1 A preliminary report in 8 healthy type 1 diabetics given lorazepam 2 mg suggested that while they were taking human insulin they were more alert and less sedated than when taking beef/pork insulin.2

There seems to be nothing in the literature to suggest that a clinically important adverse interaction normally takes place between insulin and the benzodiazepines. No special precautions would appear to be necessary.

(b) Oral antidiabetics

Four patients with type 2 diabetes, two diet-controlled and two taking tolbutamide, had no changes in blood glucose levels while taking chlorldiazepoxide.3 In another study diazepam did not change the half-life of chlorpropamide.3 The manufacturer notes that pioglitazone 45 mg once daily for 15 days reduced the AUC and maximum level of a single dose of midazolam syrup by 26% in healthy subjects.4 This is possibly because pioglitazone is a weak inducer of the cytochrome P450 isoenzyme CYP3A4,4 by which midazolam is metabolised. The clinical relevance of this small decrease in midazolam levels has not been assessed, but it is likely to be minor.

Antidiabetics + Beta blockers

In diabetes using insulin, the normal recovery reaction (blood sugar rise) if hypoglycaemia occurs may be impaired to some extent by propranolol, but serious and severe hypoglycaemia seems rare. Cardioselective beta blockers seem less likely to interact.

The blood glucose-lowering effects of the sulphphonylureas may possibly be reduced by the beta blockers. Whether insulin or oral antidiabetic drugs are given, patients should be made aware that some of the familiar warning signs of hypoglycaemia (tachycardia, tremor) may not occur, although sweating may be increased. Hypoglycaemia in patients taking beta blockers has been noted to result in significant increases in blood pressure and possibly bradycardia in some studies. Miglitol has been found to reduce the bioavailability of propranolol by 40%.

Clinical evidence

(a) Insulin

1. Hypoglycaemia. Although propranolol has occasionally been associated with spontaneous episodes of hypoglycaemia in non-diabetics,1 and a number of studies in diabetic patients2-4 have found that propranolol impairs the normal blood sugar rebound if blood sugar levels fall, there appear to be few reports of severe hypoglycaemia or coma in diabetics receiving insulin and propranolol. Marked hypoglycaemia and/or coma occurred in 5 diabetic patients receiving insulin due to the use of propranolol,2,5 pindolol,8 or timolol eye-drops.9 Other contributory factors (fasting, haemodialysis, etc.) probably had some part to play.8 Metoprolol interacts like propranolol but to a lesser extent3,6 whereas acebutolol,2,5 alprenolol,1,7 atenolol,2,12,13 exprenolol,10 penbutolol,6 and pindolol14 have been found to interact minimally or not at all. The situation with pindolol is therefore not clear. Carvedilol has been associated with the onset of diabetes mellitus in one patient.13 Propranolol (a peripheral vasodilator) has also been found to reduce the rate of absorption of subcutaneous insulin by almost 50%, but the importance of this is uncertain.16

However, a large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years old receiving insulin and taking either cardioselective beta blockers (atenolol and metoprolol) or non-selective beta blockers (propranolol and nadolol) when compared with patients taking no anti-hypertensive drugs. Overall, of the different anti-hypertensive drug classes, the risk of hypoglycaemia was lowest with cardioselective beta blockers and highest with non-selective beta blockers, although none of the changes were statistically significant when controlled for demographic factors and markers of comorbidity.17 Similarly, in 2 other case-control studies, there was no increase in the risk of hypoglycaemia in patients with diabetes receiving insulin and also taking a beta blocker.18,19

2. Hypertension. Marked increases in blood pressure and bradycardia may develop if hypoglycaemia occurs in diabetes receiving insulin and a beta blocker.20 In one study in diabetics, insulin-induced hypoglycaemia resulted in blood pressure rises of 38.8/14.3 mmHg in those taking propranolol 80 mg twice daily, 27.9/0 mmHg in those taking atenolol 100 mg daily and in those taking placebo the systolic blood pressure rose by 15.2 mmHg whereas the diastolic blood pressure fell by 9.9 mmHg.21 In another study, insulin-induced hypoglycaemia resulted in blood pressure rises of 27/14 mmHg in those taking alprenolol 200 to 800 mg daily, but no rise occurred in those taking metoprolol 100 to 400 mg daily.22 A report describes a blood pressure rise to 258/144 mmHg in a patient having a hypoglycaemic episode within 2 days of starting propranolol.7 Another patient taking metoprolol 50 mg twice daily experienced a rise in blood pressure from 190/96 to 230/112 mmHg during a hypoglycaemic episode.20
1. Effects on blood glucose. The sulphonylurea-induced insulin-release from the pancreas can be inhibited by beta blockers so that the blood glucose-lowering effects are opposed to some extent.

- **Acelebutol** appears to inhibit the effects of *glibenclamide,* but has no effect on *tolbutamide.* Also, two isolated cases of hypoglycaemia have been seen with acebutol, in one patient taking gliclazide and one patient taking *chlorpropamide.*

- **Betaxolol** had no effect on the response to *glibenclamide* or metformin in one study.

- **Metoprolol** did not affect the insulin-response to *tolbutamide* in one study.

- **Propranolol** inhibits the effects of *glibenclamide* (*glyburide*), and *chlorpropamide* and reduced the insulin-response to *tolbutamide* in one study, but not in another. Also, an isolated report describes hyperglycaemic non-ketotic coma in a patient taking *tolbutamide* and propranolol.

2. Pharmacokinetic studies. *Acarbose* 300 mg daily for one week had no effect on the pharmacokinetics or pharmacodynamics of a single 80-mg dose of *propranolol* in healthy subjects. Conversely, the manufacturer of *miglitol* notes that it reduced the bioavailability of *propranolol* by a modest 40%.

No pharmacokinetic interaction was seen in a study in healthy subjects given a single 1.75-mg dose of *glibenclamide* with *carvedilol* 25 mg daily for 6 days.

**Mechanism**

One of the normal physiological responses to a fall in blood sugar levels is the mobilisation of glucose from the liver under the stimulation of adrenaline from the adrenals. This sugar mobilisation is blocked by non-selective beta blockers (such as propranolol) so that recovery from hypoglycaemia is delayed and may even proceed into a full-scale episode in a hypoglycaemia-prone diabetic. Normally the adrenaline would also increase the heart rate, but with the beta-receptors in the heart already blocked this fails to occur. A rise in blood pressure occurs because the stimulant effects of adrenaline on the beta-2 receptors (vasodilation) are blocked leaving the alpha (vasoconstriction) effects unopposed.

Non-selective beta blockers can also block beta-2 receptors in the pancreas concerned with insulin-release, so that the effects of the sulphonylureas may be blocked.

**Importance and management**

Extremely well-studied interactions. Concomitant use can be uneventful but there are some risks. Diabetics receiving insulin may have a prolonged or delayed recovery response to hypoglycaemia while taking a beta blocker, but very severe hypoglycaemia and/or coma is rare. If hypoglycaemia occurs it may be accompanied by a sharp rise in blood pressure. The risk is greatest with propranolol and possibly other non-selective blockers and least with the cardio-selective blockers. The cardioselectivity of a number of beta blockers is given in ‘Table 22.1’ (p.833). Monitor the effects of concurrent use well, avoid the non-selective beta blockers where possible, and check for any evidence that the insulin dosage needs some adjustment. Warn all patients that some of the normal premonitory signs of a hypoglycaemic attack may not appear, in particular tachycardia and tremors, whereas the hunger, irritability and nausea signs may be unaffected and sweating may even be increased.

Diabetics taking oral sulphonylureas rarely seem to have serious hypoglycaemic episodes caused by beta blockers, and any reductions in the blood glucose-lowering effects of the sulphonylureas normally appear to be of little clinical importance. The selective beta blockers are probably safer than those that are non-selective. Nevertheless, always monitor concurrent use to confirm that diabetic control is well maintained, adjusting the dose of antidiabetic as necessary, and warn all patients (as above) that some of the premonitory signs of hypoglycaemia may not occur.

One experimental study indicated that no interaction occurred between betaxolol and *metformin,* but direct information about other beta blockers seems to be lacking.

There is also a hint from one report that the peripheral vasoconstrictive effects of non-selective beta blockers and the poor peripheral circulation in diabetics could be additive, which is another possible reason for avoiding this type of beta blocker in diabetics.

Antidiabetics + Bile-acid binding resins

A report suggests that the hypocholesterolaemic effect of colestipol is unaffected in insulin-treated diabetics but it may be ineffective in those taking phenformin and sulphonylureas. Diabetic control was not affected. Colestyramine may enhance the effect of acarbose, and insulin levels may rebound if both drugs are stopped at the same time. There is evidence that the absorption of glipizide may be reduced by about 30% if it is taken at the same time as colestrylamine, but tolbutamide does not appear to be affected.

Clinical evidence

(a) Colestipol

The concurrent use of phenformin and a sulphonylurea (chlorpropamide, tolbutamide or tolazamide) inhibited the normal hypocholesterolaemic effects of the colestipol in 12 diabetics with elevated serum cholesterol levels. No such antagonism was seen in two patients with type 2 diabetes receiving insulin. The control of diabetes was not affected by the colestipol.

(b) Colestyramine

1. Acarbose. Colestyramine 12 g daily for 6 days, given to 8 healthy subjects taking acarbose 100 mg three times daily, improved the reduction in postprandial insulin levels. The mean serum insulin levels fell by 23% while taking both drugs, but showed a ‘rebound’ 31% increase above baseline when both were stopped.

2. Glipizide. Colestyramine 8 g in 150 mL of water reduced the absorption of a single 5-mg dose of glipizide in 6 healthy subjects by a mean of 29%. One subject had a 41% reduction in glipizide levels. Peak serum levels were reduced by 33%. The AUC<sub>T</sub> was used to measure absorption.

3. Tolbutamide. A single-dose study indicated that colestyramine 8 g, given 2 minutes before, and 6 and 12 hours after a 500-mg dose of tolbutamide, did not reduce the amount of tolbutamide absorbed, although the rate of absorption may have changed.

Mechanism

Colestyramine is an anion-exchange resin, intended to bind to bile acids within the gut, but it can also bind with some acidic drugs thereby reducing the amount available for absorption.

Importance and management

Information about glipizide is limited to a single-dose study so that the clinical importance of the reduction in glipizide levels with colestyramine is unknown, but it would seem prudent to monitor the effects of concurrent use in patients. It has been suggested that the glipizide should be taken 1 to 2 hours before the colestrylamine to minimise admixture in the gut, but this may only be partially effective because it is believed that glipizide undergoes some entero-hepatic circulation (i.e. after absorption it is excreted in the bile and reabsorbed). The effect of colestyramine on other sulphonic acids is uncertain, with respect to insulin levels.

The study with colestipol suggests that it may not be suitable for lowering the blood cholesterol levels of diabetics taking chlorpropamide, tolbutamide, or tolazamide or phenformin, but more study is needed to confirm these findings. Phenformin has been withdrawn from many countries because of severe, often fatal, lactic acidosis.

Antidiabetics + Calcium-channel blockers

Calcium-channel blockers are known to have effects on insulin secretion and glucose regulation, but significant disturbances in the control of diabetes appear to be rare. A report describes a patient whose diabetes worsened, requiring an increase in the dose of insulin when diltiazem was given, and a similar case has occurred in a patient taking nifedipine. Deterioration in glucose tolerance has also occurred during nifedipine use. Hypoglycaemia occurred in a patient taking gliclazide and nicardipine. No clinically important changes in nifedipine pharmacokinetics have so far been seen with acarbose, miglitol, pioglitazone or rosiglitazone; in glibenclamide pharmacokinetics with nimodipine or verapamil; in gliclazide or repaglinide pharmacokinetics with nifedipine; or between tolbutamide and diltiazem.

Clinical evidence

A. Dihydropyridines

(a) Effect on glucose tolerance

A study in 20 patients with type 2 diabetes (5 taking metformin and 15 diet-controlled) found that both nifedipine 10 mg every 8 hours and nicardipine 30 mg every 8 hours for 4 weeks did not affect either glucose tolerance tests or the control of the diabetes, but both systolic and diastolic blood pressures were reduced by 4 to 7 mmHg. No important changes in glucose metabolism occurred in six type 2 diabetic patients taking glibenclamide (gliclazide) when they were given nifedipine 20 to 60 mg daily for 12 to 25 weeks. Similarly, other studies have found no important changes in glucose tolerance or control of diabetes in patients taking chlorpropamide, glibenclamide, gliclazide, glipizide, unspecified antidiabetics, nimodipine or nitrendipine. No change in insulin dose was seen in one patient taking nicardipine and in 4 patients taking nitrrendipine.

However, there are reports of a deterioration in glucose tolerance during the use of nifedipine in a total of 12 subjects with impaired glucose tolerance. A further case report describes a 30% increase in the insulin requirements of a diabetic man after he took nifedipine 60 mg daily. An isolated case of hypoglycaemia has been described in a patient taking gliclazide when nicardipine was given. However, a large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years old taking insulin or sulphonylureas, who were also taking calcium-channel blockers (nifedipine and verapamil) as the most frequently used, when compared with patients not taking antihypertensive drugs.

(b) Pharmacokinetic studies

1. Alpha-glucosidase inhibitors. The manufacturers of acarbose say that in a pilot study of a possible interaction with nifedipine, no significant or reproducible changes were seen in plasma nifedipine profiles. Similarly, the manufacturers of miglitol note that it had no effect on the pharmacokinetics and pharmacodynamics of nifedipine.

2. Insulin. One study found that nifedipine 10 mg increased the rate of absorption of subcutaneous insulin by about 50%. Similarly, the manufacturers of pioglitazone or rosiglitazone. Rosiglitazone 8 mg daily for 2 weeks was found to have no clinically relevant effect on the pharmacokinetics of nifedipine in 28 healthy subjects. The manufacturer notes that pioglitazone 45 mg once daily for 7 days given with nifedipine extended-release 30 mg once daily for 4 days resulted in a small but highly variable change in nifedipine pharmacokinetics.

3. Repaglinide. A three-period cross-over open-label study in healthy subjects found that nifedipine 10 mg daily decreased the maximum plasma level of repaglinide 2 mg three times daily by 2.7% and increased the bioavailability of repaglinide by 11%, but this was not statistically significant. There was a higher incidence of adverse effects during concurrent use.

4. Sulphonylureas. A study in six type 2 diabetics found that a single 20-mg dose of nifedipine had no effect on the pharmacokinetics of glipizide 5 to 30 mg daily. Similarly, nimodipine caused no change in the pharmacokinetics of glibenclamide in 11 patients.

References

B. Diltiazem

A patient with type 1 diabetes developed worsening and intractable hyperglycaemia (mean serum glucose levels above 13 mmol/L) when given diltiazem 90 mg every 6 hours. Her insulin requirements dropped when the diltiazem was withdrawn. When she started taking diltiazem 30 mg every 6 hours her blood glucose levels were still high, but she needed less insulin than when taking the higher diltiazem dosage.22

A study in 12 healthy subjects found that diltiazem 60 mg three times daily had no effect on the secretion of insulin or glucagon, or on plasma glucose levels.23 Similarly, diltiazem 120 mg three times daily for 3 days had no effect on insulin and glucose levels during an oral glucose tolerance test in 10 patients taking gliclazide.5

A study in 8 healthy subjects found that a single 500-mg dose of tolbutamide had no effect on the serum levels of a single 60-mg dose of diltiazem. There was a minor increase of about 10% in the AUC0-24 and maximum serum levels of tolbutamide in the presence of diltiazem but the blood glucose-lowering effects of tolbutamide were not significantly changed.24

C. Verapamil

A study in 23 type 2 diabetes, 7 of whom were taking glibenclamide (glyburide), found that verapamil improved the response to an oral glucose tolerance test but did not increase the blood glucose-lowering effects of glibenclamide.25 Two studies in type 2 diabetics found that verapamil improved the response to glucose tolerance tests,26,27 but in one of the studies, no alterations in the blood glucose-lowering effects of glibenclamide were found.28 A study in healthy subjects found that verapamil modestly raised the glibenclamide AUC by 26% but plasma glucose levels were unchanged.29 A large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years old taking insulin or sulphonylureas, who were also taking calcium-channel blockers (nifedipine and verapamil) were the most frequently used), when compared with patients not taking antihypertensive drugs.30

Mechanism

The changes that occur are not fully understood. Suggestions include: inhibition of insulin secretion by the calcium-channel blockers and inhibition of glucagon secretion by glucose; changes in glucose uptake by the liver and other cells; blood glucose rises following catecholamine release after vasodilation, and changes in glucose metabolism. In contrast, one study in non-diabetics suggested that long-acting nifedipine could improve insulin sensitivity.29

Importance and management

Very extensively studied, but many of the reports describe single-dose studies or multiple-dose studies in healthy subjects (only a few are cited here), which do not give a clear picture of what may be expected in diabetic patients. Those studies that have concentrated on diabetics indicate that the control of the diabetes is not usually adversely affected by calcium-channel blockers, although isolated cases with diltiazem, nicardipine and nifedipine have been reported.12,13,22 Similarly, there appear to be no important pharmacokinetic interactions with any of the combinations studied. However, if an otherwise unexplained worsening of diabetic control occurs it may be prudent to consider the use of a calcium-channel blocker as a possible cause. Therefore, in general, no particular precautions normally seem necessary.

Antidiabetics + Cibenzoline (Ciflene)

Hypoglycaemia has been seen in a few patients taking cibenzoline alone, and in one case with gliclazide. The risk factors appear to be age, renal insufficiency, malnutrition and high dosage.

Clinical evidence, mechanism, importance and management

Cibenzoline occasionally and unpredictably causes hypoglycaemia, which may be severe. Marked hypoglycaemia was seen in a 67-year-old non-diabetic patient when cibenzoline was given.1 A further case report describes hypoglycaemia in an 84-year-old, in whom age, renal impairment and/or malnutrition acted as facilitating factors.2 The authors of this report noted that hypoglycaemia has been reported in another 20 cases, where the dose was not corrected for age and renal function.2 A more recent report describes an elderly patient with type 2 diabetes control who developed hypoglycaemia and associated dementia-like symptoms during treatment with low dose cibenzoline.3 Hypoglycaemia also occurred in a 61-year-old patient with renal insufficiency taking gliclazide and cibenzoline.4 The reasons are not understood. However, in a controlled study in patients with abnormal glucose tolerance and ventricular arrhythmias, cibenzoline exerted a hypoglycaemic effect by facilitating insulin secretion.5 This appears to be a drug-disease rather than a drug-drug interaction and diabetic patients do not seem to be at risk than non-diabetics, but good monitoring is advisable if cibenzine is given.

There is evidence that clonidine may possibly suppress the signs and symptoms of hypoglycaemia in diabetic patients. Marked hyperglycaemia occurred in a child using insulin when clonidine was given. However, the effect of clonidine on carbohydrate metabolism appears to be variable, as other reports have described both increases and decreases in blood glucose levels. Clonidine premedication may decrease or increase the hyperglycaemic response to surgery.

Clinical evidence, mechanism, importance and management
(a) Non-diabetic patients
Studies in healthy subjects and patients with hypertension found that their normal response to hypoglycaemia (tachycardia, palpitations, perspiration) caused by a 0.1 unit/kg dose of insulin was markedly reduced when they were taking clonidine 450 to 900 micrograms daily.1,2 In contrast, a study in healthy subjects and non-diabetic patients found that clonidine raises blood glucose levels, apparently by reducing insulin secretion, and hypoglycaemia was associated with clonidine testing for growth hormone deficiency in 4 children.4
(b) Diabetic patients
A 9-year-old girl with type 1 diabetes stabilised with insulin 4 units daily, developed substantial hyperglycaemia and needed up to 56 units of insulin daily when she began to take clonidine 50 micrograms daily for Tourette’s syndrome. When the clonidine was stopped, she had numerous hypoglycaemic episodes, and within a few days it was possible to reduce her daily dosage of insulin to 6 units.5 A patient with type 2 diabetes and hypertension experienced elevated blood glucose levels and decreased insulin secretion when clonidine was given.6 However, a study in 10 diabetic patients with hypertension found that although clonidine impaired the response to an acute glucose challenge, it did not significantly affect diabetic control over a 10-week period.7
In contrast, a placebo-controlled, crossover study in 20 patients with type 2 diabetes found that transdermal clonidine significantly reduced mean fasting plasma glucose levels by 9%.8
(c) Hyperglycaemia during surgery
Forty patients with type 2 diabetes (controlled by diet alone, sulphonylureas, biguanides, or insulin), having eye surgery under general anaesthesia, were given either clonidine 225 to 375 micrograms or fluindrapezam as premedication. In diabetic patients there is an increase in blood glucose during stress because of an increase in catecholamine release. Therefore the patients were also given a continuous infusion of insulin to maintain blood glucose at 5.5 to 11.1 mmol/L. Clonidine decreased the insulin requirement because of improved blood glucose control due to inhibition of catecholamine release.9 Contrast results were found in a study in 16 non-diabetic women undergoing abdominal hysterectomy. Eight were given intravenous clonidine 1 microgram/kg and 8 control patients were given saline. Intraoperative plasma glucose levels were higher in the clonidine group and these patients also had lower insulin levels.10
Mechanism
The suggested reason for a reduced response to hypoglycaemia is that clonidine depresses the output of the catecholamines (adrenaline, noradrenaline), which are secreted in an effort to raise blood glucose levels, and which are also responsible for these signs.5 It seems possible that clonidine will similarly suppress the signs and symptoms of hypoglycaemia that can occur in diabetics, but there seem to be no reports confirming this.
Importance and management
The effect of clonidine on carbohydrate metabolism in diabetic patients appears to be variable and the general importance of these interactions is uncertain. In diabetic patients there is an increase in blood glucose during stress because of an increase in catecholamine release. The influence of clonidine on the surgical stress response appears to vary depending on the dose of clonidine and the type of surgery.10 Thus, clonidine at about 4 micrograms/kg may attenuate the hyperglycaemic response to neurosurgical and non-abdominal procedures, but low-dose clonidine accentuates the hyperglycaemic response to lower abdominal surgery, which results from a decrease in plasma insulin.9,10

1. Inhaled. A 67-year-old man with diabetes taking glibenclamide 5 mg daily and metformin 1.7 g daily had a deterioration in diabetic control (glycosuria and increased glycosylated haemoglobin) 3 weeks after starting inhaled fluticasone 2 mg daily, by metered dose inhaler with a spacer device, for asthma. The fluticasone dose was gradually decreased to 600 micrograms daily after about 3 months, with an improvement in diabetic control. Subsequently, the fluticasone dose was increased from 0.5 to 1 mg, and within a week he again developed glycosuria.1 This same patient was later given inhaled high-dose budesonide 2 mg daily and he again developed glycosuria and increased glycosylated haemoglobin levels, which improved as the dose was gradually decreased to 800 micrograms daily.2 The adverse effects of systemic corticosteroids on glucose tolerance are well known. Although only one case appears to have been reported, it suggests that high-dose inhaled corticosteroids may have a similar effect. It may be prudent to increase monitoring of diabetic control in patients requiring high-dose corticosteroids and consider reducing the dose of the inhaled corticosteroid if possible, or adjusting the dose of the antidiabetic medication as necessary.
2. Topical. Two patients with an abnormal response to the glucose tolerance test, but without overt signs of diabetes mellitus, developed postprandial hyperglycaemia and one developed glycosuria when they used topical corticosteroids for severe psoriasis. These patients were given 15 g of halcinonide 0.1% or betamethasone 0.1% cream, applied every 12 hours for 15 days under occlusive dressings.2 These cases appear to be rare, and were associated with high doses of potent or very potent corticosteroids, used under occlusive dressings, which increases systemic absorption. No additional special precautions would generally appear to be necessary in diabetics using moderate amounts of topical corticosteroids.

Systemic corticosteroids
Systemic corticosteroids with glucocorticoid activity can raise blood glucose levels and induce diabetes.4 This can oppose the blood glucose-lowering effects of the antidiabetics used in the treatment of diabetes mellitus. For example, a disturbance of the control of diabetes is very briefly described in a patient given with insulin and hydrocortisone.3 A study in 5 patients with type 2 diabetes taking chlorpropamide found that a single 200-mg dose of cortisone modified their glucose tolerance. The blood
glucose levels of 4 of them rose (3 showed an initial fall), whereas in a pre-
vious study assessing the clinical relevance of this.

Antidiabetics + Dextropropoxyphene (Propoxyphene)

Dextropropoxyphene does not appear to affect the pharmacoki-
etics of tolbutamide. Hypoglycaemia was seen in a patient taking an
unnamed sulphonylurea with co-proxamol, and has also been reported
in non-diabetic patients given dextropropoxyphene alone.

Clinical evidence, mechanism, importance and management

After 6 healthy subjects took dextropropoxyphene 65 mg every 8 hours
for 4 days, the clearance of a 500-mg intravenous dose of tolbuta-
damide was not affected.1 There is an isolated case of hypoglycaemia in a patient
taking an unnamed sulphonylurea with co-proxamol (dextropropoxy-
phene with paracetamol (acetaminophen)).2 There are also several reports
of hypoglycaemia in non-diabetic patients taking dextropropoxyphene alone,3–7
sometimes associated with renal failure,4,5 advanced age,5 or with
high doses or in overdose.6 The general importance of these isolated re-
ports is uncertain, and there would normally seem to be little reason for
avoiding the concurrent use of antidiabetics and dextropropoxyphene,
for taking particular precautions.

Antidiabetics + Danazol

Danazol causes insulin resistance. Therefore, on theoretical grounds, danazol would be expected to oppose the effects of anti-
diabetics, but the practical clinical importance of this is uncer-
tain.

Clinical evidence, mechanism, importance and management

Danazol can disturb glucose metabolism. A study in 14 non-diabetic sub-
jects found that 3 months of treatment with danazol 600 mg daily caused a
mild but definite deterioration in glucose tolerance, associated with high
insulin levels. Insulin resistance was also seen in 5 subjects taking danazol
when they were given intravenous tolbutamide.1 Similarly, another study in
9 non-diabetic women found that danazol 600 mg daily raised insulin
levels in response to glucose or intravenous tolbutamide.2 A further study in
9 non-diabetic women also found that danazol caused a mild deteriora-
tion in glucose tolerance and a marked increase in the insulin response to
insulin during treatment with danazol in women with endometriosis.3
4

Clinical evidence, mechanism, importance and management

Disopyramide occasionally causes hypoglycaemia, which may be severe.5,7 Isolated reports describe severe hypoglycaemia when dis-
opyramide was given to diabetic patients taking gliclazide, or
metformin and/or insulin.

Clinical evidence, mechanism, importance and management

Disopyramide occasionally and unpredictably causes hypoglycaemia, which may be severe.1,5 The reasons are not fully understood, but in vitro studies suggest that disopyramide and its main metabolite may enhance in-
sulin release from the pancreas.8 There is a report of severe hypoglyca-
emia in an 82-year-old woman with diabetes who was taking gliclazide,
which occurred 6 months after she started disopyramide 300 mg daily. A further case of hypoglycaemia associated with disopyramide occurred in a 70-year-old woman who had been taking metformin 500 mg twice daily and insulin 62 units daily. Within 3 months of starting disopyramide 250 mg twice daily her insulin dose was reduced to 24 units daily, she stopped taking metformin and was eating ‘substantial snacks’ to avoid hypoglycaemia. The insulin requirements of another patient with type 2 diabetes were markedly reduced when disopyramide was started.11

The manufacturers note that patients at particular risk for hypoglycaemia are the elderly, the malnourished, and diabetics, and that impaired renal function and impaired cardiac function may be predisposing factors.12,13 They advise close monitoring of blood glucose levels12,13 and withdrawal of disopyramide if problems arise.12 This is not simply a problem for diabetics, but certainly within the context of diabetes the blood glucose-lowering effects of disopyramide may possibly cause particular difficulties. Although not strictly an interaction, the concurrent use of disopyramide and antidiabetics should be well monitored because of the potential for severe hypoglycaemia, as the cases show.

### Antidiabetics + Disulfiram

Disulfiram appears not to affect the control of diabetes mellitus. Disulfiram does not appear to affect the pharmacokinetics of tolbutamide and there appears to be no evidence that disulfiram interacts with any other antidiabetics.

#### Clinical evidence, mechanism, importance and management

The manufacturers of disulfiram say that caution should be exercised if it is used in diabetics, but a reviewer who had given disulfiram to over 20 000 alcoholics said that he had prescribed disulfiram for several hundred patients with diabetes mellitus over 20 years without any apparent adverse effects and therefore any theoretical interaction is rarely, if ever, applicable to clinical practice. It would be reasonable to assume that many of these patients were also taking insulin or one of the older oral antidiabetics. There do not appear to be any reported cases in the literature of adverse interactions between disulfiram and any of the antidiabetics. In a study in 5 healthy subjects, disulfiram (400 mg three times daily for one day, then once daily for one day, then 200 mg daily for 2 days) had no significant effect on the half-life or clearance of intravenous tolbutamide 500 mg.2

The conclusion to be drawn from all of this is that any reaction is very rare (if it ever occurs), and no special precautions would normally appear to be necessary.

Clinical evidence

(a) Effects on glucose control

Chlorothiazide, the first of the thiazide diuretics, was found within a year of its introduction in 1958 to have hyperglycaemic effects. Since then, a very large number of reports have described hyperglycaemia, the precipitation of diabetes in prediabetics, and the disturbance of blood sugar control in diabetics taking thiazides. One example from many:

A long-term study in 53 patients with type 2 diabetes found that chlorothiazide 500 mg or 1 g daily or trichlormethiazide 4 or 8 mg daily caused a mean rise in blood glucose levels from about 6.7 to 7.8 mmol/L. Only 7 patients needed a change in their treatment: 4 required more of their oral antidiabetic, 2 an increase in insulin dose, and one was transferred from tolbutamid to insulin. The oral antidiabetics used included tolbutamide, chlorpropamide, acetohexamide and phenformin.7

A rise in blood sugar levels has been observed with bendroflumethiazide,3,4 benzthiazide,5 hydrochlorothiazide 100 to 300 mg daily,5 and chlortalidone 50 to 100 mg daily.6 A study in hypertensive patients found that chlortalidone 50 mg daily increased glucose and insulin levels, but hydrochlorothiazide 50 mg daily alone or as part of a potassium and/or magnesium conserving regimen did not.7

More recent data suggest that the effects of thiazides on blood glucose may be dose related. In a double-blind randomised study comparing the effects of 1.25 or 5 mg of bendroflumethiazide on blood glucose, the lower dose had no effects on insulin action, whereas when the higher dose was given, there was evidence of impaired glucose tolerance.8 A review of the literature on hydrochlorothiazide similarly reports that low doses (6.25 to 12.5 mg) lack significant effects on blood glucose levels.9

A man with type 2 diabetes, stable taking glibenclamide (glyburide) 10 mg daily and hospitalised for congestive heart failure, became clinically hyperglycaemic (blood glucose levels unmeasurable by Labstix) within 40 hours of starting metolazone 5 mg daily. He was treated with intravenous glucose. Although both glibenclamide and metolazone were stopped, he had 4 further hyperglycaemic episodes over the next 30 hours.10 The reasons are not understood. In vitro studies failed to find any evidence that metolazone displaces glibenclamide from its protein binding sites, which might possibly have provided some explanation for what happened.10

The hypoglycaemic responses of 10 healthy subjects were studied following an intravenous infusion of tolbutamide 3 mg/kg, given 3 days before and one hour after the last dose of oral cicletanine 100 mg daily for a week.11 No clinically relevant changes were seen. Note that, studies in animals and in non-diabetic hypertensive patients found that, at therapeutic doses, cicletanine did not affect glycoregulation.12 The conclusion to be drawn is that cicletanine is unlikely to affect the control of diabetes in patients, but this needs confirmation from long-term clinical studies.

(b) Hyponatraemia

A hospital report describes 8 cases of low serum sodium concentrations observed over a 5-year period in patients taking chlorpropamide and Moduretic (hydrochlorothiazide 50 mg with amiloride 5 mg).13

(c) Pharmacokinetics

A study in 12 healthy subjects given a single 25-mg dose of hydrochlorothiazide before and after taking voglibose 5 mg three times daily for 11 days found that the hydrochlorothiazide plasma levels were slightly increased by the voglibose (AUC increased 7.5%, maximum plasma levels increased 15%) but these changes were considered to be clinically irrelevant. The combination was well tolerated and adverse events were unchanged.14

Mechanism

Not understood. One study suggested that the hyperglycaemia is due to the inhibition of insulin release by the pancreas.15 Another suggestion is that the peripheral action of insulin is affected in some way.5,16 There is also evidence that the effects may be related to part to potassium depletion.1

The hyponatraemia appears to be due to the additive sodium-losing effects of chlorpropamide, the thiazide and amiloride. Obese patients may be more sensitive to the effects of hydrochlorothiazide on insulin metabolism.7

Importance and management

The reduction in hypoglycaemic effect is extremely well documented (not all references are given here) but of only moderate practical importance, particularly since much of the data relates to higher doses of thiazides than are now used clinically for hypertension. Low doses of thiazides have a lesser effect on plasma glucose, and recent guidelines on the treatment of hypertension in diabetes recommend the use of thiazides.18 If higher doses are used, increased monitoring of diabetic control would seem prudent. There is evidence that the full effects may take many months to develop in some patients.9 Most patients respond to a modest increase in the dosage of the antidiabetic. This interaction may be expected to occur with all thiazides and possibly related diuretics, such as clopamide and metolazone. Hyponatraemia is a rare but recognised adverse effect of the thiazides and no additional precautions would therefore seem necessary.

Antidiabetics + Fenfluramine

Fenfluramine has inherent blood glucose-lowering activity that can add to, or in some instances replace, the effects of conventional antidiabetic drugs.

Clinical evidence, mechanism, importance and management

A study of the substitution of fenfluramine (initially 40 mg daily, increased to 120 mg daily) for a biguanide antidiabetic found that diabetes was equally well controlled by either drug in 4 of 6 patients.1 This blood glucose-lowering effects of fenfluramine have also been described elsewhere.2,13 It seems that fenfluramine increases the uptake of glucose into skeletal muscle, thereby lowering blood glucose levels.3,4 This is a well established and, on the whole, an advantageous rather than an adverse reaction, but it would be prudent to check on the extent of the response if fenfluramine is added or withdrawn from the treatment being received by diabetics. However, note that fenfluramine was generally withdrawn in 1997 because its use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.1

3. Dykes JRW. The effect of a low-calorie diet with and without fenfluramine, and fenfluramine withdrawal in 1997 because its use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.2,3
A number of reports describe hypoglycaemia and/or an enhancement of the effects of antidiabetic drugs (mostly insulin and sulphonylureas) in patients given fibrates. The combination of gemfibrozil and repaglinide should be avoided, because a marked pharmacokinetic interaction can result in serious hypoglycaemia. Gemfibrozil also causes large increases in the AUCs of pioglitazone and rosiglitazone, and caution is therefore warranted until more is known. Only a modest pharmacokinetic interaction occurs between gemfibrozil and nateglinide. The antiidiuretic effects of clofibrate in the treatment of diabetes insipidus are opposed by glibenclamide (glyburide).

### Clinical evidence

A. Bezafibrate

*(a) Repaglinide*

In a study in healthy subjects bezafibrate 400 mg once daily for 5 days had no effect on the pharmacokinetics of a single 250-microgram dose of repaglinide, and did not alter the glucose-lowering effect of repaglinide.1

*(b) Sulphonylureas and Biguanides*

Three elderly patients with type 2 diabetes and mild renal impairment taking glibenclamide (glyburide) developed hypoglycaemia when they were given bezafibrate: one of them needed a 60% dosage reduction, another was given tolbutamide instead, and the third was able to stop both glibenclamide and buformin.2 The French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia during the period 1985 to 1990, which developed in patients taking unnamed sulphonylureas when they were given fibrates (one case with bezafibrate).3

B. Ciprofibrate

The French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia during the period 1985 to 1990, which developed in patients taking unnamed sulphonylureas when they were given fibrates (3 cases with ciprofibrate).3

C. Clofibrate

*(a) Hypoglycaemia*

Over a 5-day period while taking clofibrate 2 g daily, the control of diabetes was improved in 6 out of 13 patients with type 2 diabetes taking various unnamed sulphonylureas. Hypoglycaemia (blood glucose levels of about 1.7 to 2.2 mmol/L) was seen in 4 patients.4 Other studies confirm that some, but not all, patients have a fall in blood glucose levels while taking clofibrate and the control of the diabetes can improve.4-12 In one study13 the half-life of chlorpropamide ranged from 40 to 62 hours in 5 subjects taking clofibrate compared with a mean of about 36 hours in control subjects.

*(b) Reduced antidiuretic effects*

Clofibrate 2 g daily reduced the volume of urine excreted by 2 patients with pituitary diabetes insipidus, but when glibenclamide was also given the volume increased once again. Without treatment they excreted 5.8 and 6.5 litres of urine daily, and this reduced to only 2.4 and 1.7 litres while taking clofibrate, whereas with glibenclamide and clofibrate they excreted 3.6 and 3.7 litres daily, respectively.14

D. Fenofibrate

*(a) Repaglinide*

In a study in healthy subjects, fenofibrate 200 mg once daily for 5 days had no effect on the pharmacokinetics of a single 250-microgram dose of repaglinide, and did not alter the glucose-lowering effect of repaglinide.1

*(b) Sulphonylureas*

The French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia during the period 1985 to 1990, which developed in patients taking unnamed sulphonylureas when they were given fibrates (3 cases fenofibrate).5

E. Gemfibrozil

*(a) Nateglinide or Repaglinide*

In a randomised crossover study, 12 healthy subjects were given gemfibrozil 600 mg twice daily for 3 days, with a 250-microgram dose of repaglinide on day 3. Gemfibrozil raised the AUC of repaglinide eightfold and increased the plasma levels nearly 29-fold.15 Itraconazole (which may interact, see ‘Antidiabetics + Azoles; Itraconazole or Ketoconazole’, p.479) given with gemfibrozil and repaglinide further increased these effects. The blood glucose-lowering effects of repaglinide were considerably enhanced and prolonged, both by gemfibrozil alone and in combination with itraconazole.13 In 2003, the European Agency for the Evaluation of Medicinal Products had received five reports of serious hypoglycaemic episodes with gemfibrozil and repaglinide.16

In contrast, in a very similar study by the same research group, the combination of gemfibrozil and itraconazole caused only a modest 47% increase in the AUC of a single dose of nateglinide 30 mg, and did not significantly alter the blood glucose response to nateglinide in healthy subjects.17

*(b) Pioglitazone or Rosiglitazone*

Gemfibrozil 600 mg twice daily for 4 days increased the mean AUC of a single dose of rosiglitazone 4 mg by 2.3-fold and the 24-hour plasma level by almost tenfold in a study in healthy subjects.18 In the same way, gemfibrozil increased the mean AUC of a single dose of pioglitazone 3.2-fold without altering its maximum level, but raised the 48-hour plasma level by approximately 15-fold.19 A similar increase in pioglitazone AUC was reported in another study.20 In these studies, the effects of these pharmacokinetic changes on the pharmacodynamics of rosiglitazone or pioglitazone were not assessed.18-20

*(c) Sulphonylureas or Insulin*

Fasting blood glucose levels decreased in 10 diabetic patients, and increased in 4 of 14 diabetic patients receiving insulin, acetohexamide, chlorpropamide or glipizide who were given gemfibrozil (800 mg daily initially, reduced later to 400 to 600 mg daily).21 Another study found that of 20 patients, 9 required a slight increase in the dosage of insulin or sulphonylurea (glibenclamide or chlorpropamide), and one a decreased dosage, when they were given gemfibrozil 800 mg to 1.6 g daily.22 A single report describes hypoglycaemia, which occurred in a diabetic taking glibenclamide when they were given gemfibrozil 1.2 g daily.23 The glibenclamide dosage was reduced from 5 to 1.25 mg daily with satisfactory diabetic control. When the gemfibrozil was later stopped and restarted, the dosage of the glibenclamide had to be increased and then reduced. A placebo-controlled study in 10 healthy subjects found that gemfibrozil 600 mg twice daily for 5 doses increased the AUC of a single 500-microgram dose of glimepiride by 23%, but there were no significant changes in serum insulin or blood glucose.24

### Mechanism

The suggested reasons for the alteration in diabetic control with fibrates include the displacement of the sulphonylureas from their plasma protein binding sites,7 alterations in their renal excretion,13 and a decrease in insulin resistance.6,25 Clofibrate has also been shown to have a blood glucose-lowering action of its own, which improves the glucose tolerance of diabetics.12 It is thought that gemfibrozil inhibits the metabolism of repaglinide by the cytochrome P450 isozyme CYP2C8, and that inhibition of CYP3A4 (its other main route of metabolism) by itraconazole further blocks repaglinide metabolism.15 Gemfibrozil also inhibits the CYP2C8-mediated metabolism of rosiglitazone and pioglitazone.18,19 In addition, gemfibrozil may inhibit CYP2C9-mediated metabolism of glimepiride and other sulphonylureas such as glipizide, glibenclamide or gliclazide,24 and also nateglinide.17 It seems possible that any or all of these mechanisms might contribute towards enhanced hypoglycaemia.

### Importance and management

The interaction between the sulphonylureas and clofibrate is established and well documented. The incidence is uncertain, but what is known suggests that between about one-third and one-half of patients may be affected. Alteration in diabetic control, most usually hypoglycaemia, has been seen in diabetics taking sulphonyluranes with bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil. There would seem to be no good reason for avoiding the concurrent use of sulphonylureas and fibrates, but be aware that the dosage of the antidiabetic may need adjustment. Patients should be warned that excessive hypoglycaemia occurs occasionally and unpredictably.

Note that on the basis of the study,15 and following five reports of serious hypoglycaemic episodes with gemfibrozil and repaglinide, the European
Agency for the Evaluation of Medicinal Products decided to contraindicate concurrent use.16

Marked increases in the AUC of rosiglitazone and pioglitazone have been demonstrated with gemfibrozil, but the clinical relevance of these has not been assessed. Until further experience is gained, caution is warranted. Only modest increases in plasma levels of nateglinide have been demonstrated with gemfibrozil, but the manufacturer recommends caution if nateglinide is given with CYP2C9 inhibitors including gemfibrozil.26

Information about reduced diuretic effects is limited. It would seem prudent to avoid the concurrent use of drugs with actions that are antagonistic; however, in a well controlled study, glucosamine with chondroitin.1 However, in a well controlled study, Cosamin DS (glucosamine hydrochloride 1.5 g daily plus chondroitin sulfate sodium 1.2 g daily for 90 days had no effect on the control of diabe-
te (glycosylated haemoglobin) in 22 patients with type 2 diabetes, 18 of whom were receiving oral antidiabetics [specific drugs not named] and 4 who were diet controlled.2

Endogenous glucosamine has a role in glucose metabolism, and may increase insulin resistance. In one case, glucosamine also reduced hypoglycaemic episodes in a patient with metastatic insulinoma.3

The interaction is not established, and the results of the controlled trial suggest that glucosamine supplements are unlikely to affect diabetes control. However, it has been suggested that the results may not be applicable to patients with later stages of diabetes.4 Therefore, it may be prudent to increase monitoring of blood glucose in these patients if glucosamine supplements are taken. Also, if glucose control unexpectedly deteriorates, bear in mind the possibility of self-medication with supplements such as glucosamine.

Antidiabetics + Guanethidine and related drugs

Limited evidence suggests that guanethidine has blood glucose-lowering activity, which may possibly add to the effects of conventional antidiabetics. One case report suggests soluble insulin may exaggerate the hypotensive effects of debrisoquine.

Clinical evidence

(a) Debrisoquine

An man with type 1 diabetes taking debrisoquine 20 mg twice daily developed severe postural hypotension within an hour of receiving 28 units of a short-acting insulin (soluble insulin) plus 20 units of isophane insulin. He became dizzy and was found to have a standing blood pressure of 97/72 mmHg. The postural fall in systolic pressure was 65 mmHg. He had no evidence of hyperglycaemia and no hypotension when using 48 units of isophane insulin without the soluble insulin.1 Insulin can cause hypoten-
sion but this is only seen in those with an impaired reflex control of blood pressure.1

(b) Guanethidine

A diabetic needed an insulin dose increase from 70 to 94 units daily when guanethidine was withdrawn.2 A later study in 3 patients with type 2 diabetes found that guanethidine 50 to 90 mg daily caused a significant improvement in their glucose tolerance.3 Two other reports also suggest that guanethidine has blood glucose-lowering effects.4 5

Mechanism

It has been suggested that the interaction between insulin and guanethidine occurs because guanethidine can impair the homoeostatic mechanism concerned with raising blood glucose levels, by affecting the release of cate-
cholamines. The balance of the system thus impaired tends to be tipped in favour of a reduced blood glucose level, resulting in a reduced requirement for the antidiabetic. The interaction between debrisoquine and insulin is not understood.

Importance and management

Information about both of these interactions is very limited, and their general importance is uncertain. Increase the frequency of blood glucose monitoring if guanethidine or related drugs are started or stopped. Also check patients given debrisoquine (no longer generally available) and insulin, particularly if they are taking vasodilators, to ensure that excessive hypotension does not develop.1

5. Woebber KA, Arky R, Braverman LE. Reversal by guanethidine of abnormal oral glucose toler-
Guar gum appeared not to affect the absorption of glipizide or glibenclamide (glyburide) to a clinically relevant extent. Although guar gum modestly reduced the absorption of metformin, it enhanced its postprandial hypoglycaemic effect. Gucomannan appeared to reduce the initial absorption of glibenclamide, but also enhanced its hypoglycaemic effect.

Clinical evidence, mechanism, importance and management

(a) Gucomannan

Gucomannan 3.9 g reduced the plasma levels of a single 2.5-mg dose of glibenclamide (glyburide) in 9 healthy subjects. Four samples taken over 30 to 150 minutes found that the plasma levels of glibenclamide were reduced by about 50%. Despite this, plasma glucose levels were lower with glibenclamide alone. Because plasma samples were not taken beyond 150 minutes, it is unclear what effect gucomannan has on the extent of glibenclamide absorption. The clinical relevance of these changes is unclear, but they seem unlikely to be important.

(b) Guar gum

In one study in 10 healthy subjects guar gum was found to have no effect on the AUC or maximum serum levels of a single 2.5-mg dose of glipizide. In this study glipizide was given alone, or 30 minutes before breakfast, and this treatment was compared with guar gum granules (4.75 g guar gum) given either with the breakfast or with the glipizide. In one comparative study, guar gum was found to reduce the AUC of glibenclamide from one formulation (Semi-Euglucon) by about 30%, but not another newer formulation (Semi-Euglucon-N), possibly because the latter preparation is more rapidly and completely absorbed. Similarly, in a double-blind crossover study in 9 patients with type 2 diabetes, guar gum granules 5 g three times daily with meals did not significantly affect the AUC or maximum serum level of glibenclamide 3.5 mg twice daily from the newer formulation. In addition, the combination slightly reduced fasting blood glucose when compared with baseline values.

In a single-dose study, guar gum 10 g reduced the absorption rate of metformin 1.7 g and reduced the AUC by 39% in healthy subjects, but the total reduction in postprandial blood glucose levels was increased. It seems doubtful if any of these modest pharmacokinetic interactions has much, if any, clinical relevance because guar gum can improve the metabolic control and decrease serum lipids in patients with type 2 diabetes.

Clinical evidence

A. Alpha-glucosidase inhibitors

The manufacturer of acarbose notes that it had no effect on the pharmacokinetics or pharmacodynamics of ranitidine in healthy subjects. Conversely, the manufacturer of miglitol notes that it reduced the bioavailability of ranitidine by 60%.

B. Biguanides

Cimetidine 800 mg daily was found to reduce the renal clearance of metformin in 7 healthy subjects by 27% and increase the AUC by 50%. A 59-year-old woman with type 2 diabetes taking long-term metformin 500 mg three times daily developed severe metabolic acidosis with cardiovascular collapse and acute renal failure. Three months previously she had started orlistat 120 mg three times daily, which caused chronic diarrhoea. During the 4 days before hospital admission, she was prescribed cimetidine 400 mg twice daily for her abdominal pain. The metformin-associated lactic acidosis was considered to have been precipitated by the ‘orlistat’, (p.498) and cimetidine.

C. Sulphonylureas

(a) Chlorpropamide

Cimetidine had no effect on the pharmacokinetics of chlorpropamide in healthy subjects, and in another study the blood glucose-lowering effects of chlorpropamide remained unaltered when cimetidine was given.

(b) Glibenclamide (Glyburide)

A study in healthy subjects reported that the blood glucose-lowering effects of glibenclamide were slightly reduced by cimetidine and ranitidine. This occurred despite the fact that cimetidine increased the AUC of glibenclamide by 37% and ranitidine had no significant pharmacokinetic effect on glibenclamide. Marked hypoglycaemia was seen in a patient taking glibenclamide 5 mg daily when ranitidine 150 mg twice daily was also given. Conversely, a study in healthy subjects found that the blood glucose-lowering effects of glibenclamide remained unaltered by cimetidine.

(c)格列美脲

Gliclazide

An elderly type 2 diabetic taking gliclazide 160 mg daily developed very low blood glucose levels (1 mmol/L) after starting to take cimetidine 800 mg daily.

(d) Glimepiride

In a study in healthy subjects no relevant interactions, either pharmacokinetic or pharmacodynamic, were seen when glimepiride was given with either cimetidine or ranitidine.

(e) Glipizide

Six patients with type 2 diabetes were given cimetidine 400 mg one hour before taking a dose of glipizide (average dose 5.8 mg) and then 3 hours later they were given a standard meal with cimetidine 200 mg. The expected rise in blood glucose levels after the meal was reduced by 40% and in two of the patients plasma glucose levels fell to less than 3 mmol/L. Cimetidine increased the glipizide AUC by 23%. However, a study in healthy subjects found that the hypoglycaemic activity of glipizide remained unaltered by cimetidine.

Two studies in type 2 diabetics found that ranitidine 150 mg increased the AUC of glipizide by 29% and 34%, and reduced the expected rise in blood sugar levels after a meal by 22%. However, another study by the same research group reported that ranitidine 300 mg had no significant effects on either the pharmacokinetics or the effects of glipizide, except that the absorption was delayed.

(f) Tolbutamide

The pharmacokinetics of tolbutamide 250 mg daily for 4 days were not significantly changed in 7 healthy subjects when cimetidine 800 mg daily was added for a further 4 days. Other studies also found no pharmacokinetic interaction between tolbutamide and cimetidine, or between tolbutamide and ranitidine, and the hypoglycaemic activity of tolbutamide remained unaltered by cimetidine.

In contrast, in another study in healthy subjects, the AUC of tolbutamide was found to be slightly increased by 20% and the elimination half-life decreased by 17% by cimetidine 1.2 g daily, but plasma glucose levels were not significantly changed. Ranitidine 300 mg had no effect. A later study found effectively the same results.
A study in healthy subjects found that when pioglitazone 45 mg daily was given with ranitidine 150 mg twice daily for 4 days had no effect on the pharmacokinetics of repaglinide of either a single 4-mg oral dose or a single 2-mg intravenous dose of rosiglitazone.23

Mechanism
Where an interaction occurs18 it may be because the cimetidine inhibits the metabolism of the sulphonylurea by the liver, thereby increasing its effects. Cimetidine appears to inhibit the excretion of metformin by the kidneys,3 and this may have contributed to the case of metformin-associated lactic acidosis described.4

Importance and management
The many studies cited here show that cimetidine generally causes no important changes in the pharmacokinetics or pharmacodynamics of the sulphonylureas (chlorpropamide, glimepiride and tolbutamide). Similarly, ranitidine did not interact with glimepiride or tolbutamide. Only a few isolated cases of hypoglycaemia have been reported with ranitidine or cimetidine and sulphonylureas (glibenclamide, glaziclide and unnamed), and only one research group has shown a possible increase in blood glucose lowering effect of glipizide with cimetidine and ranitidine.20 It has been suggested that the dosage of metformin may need to be reduced if cimetidine is used, bearing in mind the possibility of lactic acidosis if levels become too high,3 and there is one case where metformin-associated lactic acidosis described.4

1. Insulin. In one study in 179 diabetic women, 34% needed an increase and 7% needed a decrease in their insulin dose when they were given an oral contraceptive.11 There are also a few scattered reports of individual diabetics who experienced a marked disturbance of their diabetic control when given an oral contraceptive, some of which were low dose.12-15 However, in a study of 38 insulin-dependent diabetics it was found that progesterone-only and combined oral contraceptives had little effect on the control of diabetes,16 and another report17 about women taking Orl-thovanin (norethisterone with mestranol) stated that no insulin dose changes were necessary. Similarly, no change in glycaemic control was found in 22 women with well-regulated insulin-dependent diabetes mellitus who took a monophasic combination of ethinylestradiol and gestodene for 1 year.10

2. Pioglitazone. A randomised double-blind study in 35 healthy women given pioglitazone 45 mg once daily with either a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) or placebo for 21 days found that pioglitazone does not affect systemic exposure to the oral contraceptive, as measured by AUC.18 Similar results were reported in another study.19

3. Repaglinide. A three-period, cross-over, open-label study in healthy subjects found that a combined oral contraceptive (ethinylestradiol/levonorgestrel 35 micrograms/1.5 mg) increased the maximum plasma level of repaglinide 2 mg three times daily by 17%, although the bioavailability of repaglinide was not altered.19 Repaglinide did not significantly alter the bioavailability of ethinylestradiol or leonorgestrel.19

4. Rosiglitazone. Rosiglitazone 8 mg daily, given for the first two weeks of two cycles in 32 women taking an oral contraceptive (ethinylestradiol/norettheristerone 35 micrograms/1 mg, Ortho-Novum), was found to have no effect on the pharmacokinetics of either steroid.20

Mechanism
The reasons for changes in glucose metabolism are not understood. Many mechanisms have been considered including changes in cortisol secretion, alterations in tissue glucose utilisation, production of excessive amounts of growth hormone, and alterations in liver function.21

Importance and management
Moderately well documented. Concurrent use need not be avoided, but some patients may need a small adjustment in their dosage of antidiabetic (increases or decreases). However, it seems likely that routine blood glucose monitoring will identify any problems. Serious disturbances of diabetic control seem extremely rare. Bear in mind that the lowest-strength combined oral contraceptive preparations (20 micrograms of oestrogen) are recommended for patients with risk factors for circulatory disease (such as diabetics), so the potential for interference with their diabetic control will be minimised if this recommendation is followed. The choice of progestogen may also be important, with levonorgestrel having the most detrimental effect. Similarly, irrespective of control of diabetes, menopausal HRT should be used with caution in diabetics because of the increased risk of arterial disease. See also ‘Antidiabetics + Tibolone’, p.509.

**Antidiabetics + Imatinib**

An improvement in diabetic control with a reduction in dose of insulin or oral antidiabetics was seen in 6 of 7 diabetics given imatinib for chronic myelogenous leukaemia. A further patient with type 2 diabetes was able to stop all antidiabetic medication during treatment with imatinib.

Clinical evidence, mechanism, importance and management
Use of imatinib 400 or 600 mg daily for the treatment of chronic myelogenous leukaemia was associated with improved glycaemic control in 6 of 7 diabetic patients. This allowed a reduction in insulin dose in 2 patients and oral antidiabetic drug dosage in 4 patients. A case report describes a 70-year-old woman with type 2 diabetes who needed a reduction in her insulin dose when she was given imatinib for chronic myeloid leukaemia. Later, while still taking imatinib, she was able to stop the insulin completely.2

It was thought that imatinib may have a direct effect on glycaemic control,1,2 rather than an indirect effect via improvement in leukaemia.3 These preliminary findings suggest that diabetic therapy should be well monitored in those given imatinib. Further study is needed.

**Antidiabetics + Isoniazid**

Some reports suggest that isoniazid causes an increase in blood glucose levels in diabetics, whereas another suggests it causes a decrease.

Clinical evidence
A study in 6 diabetics taking insulin found that isoniazid 300 to 400 mg daily increased their fasting blood glucose levels by 40% (from an average of 255 to 357 mg%), and their glucose tolerance curves rose and returned to normal levels more slowly. After 6 days of treatment the average rise was only 20%. Two other patients needed an increased dosage of insulin while taking isoniazid 200 mg daily, but this was reduced again when the isoniazid was withdrawn.1 Another report describes glycosuria and the development of frank diabietes in 3 out of 50 patients given isoniazid 300 mg daily,7 and hyperglycaemia has been seen in cases of isoniazid poisoning.3 In contrast, another study found that isoniazid had a hypoglycaemic effect in 6 out of 8 diabetics.4 A 500-mg dose of isoniazid caused an 18% (range 5 to 34%) reduction in blood glucose levels after 4 hours; 3 g of tolbutamide caused a 28% (19 to 43%) reduction, and together they caused a 35% (17 to 57%) reduction. However, one patient had a 10% increase in blood glucose levels after taking isoniazid, a 41% decrease after tolbutamide, and a 30% decrease after taking both drugs. The diabetic control of another patient was not affected by either drug.5
The blood glucose-lowering effects of chlorpropamide and other antidiabetics can be increased by karela.

Clinical evidence
A report of a patient whose diabetes was poorly controlled on diet and chlorpropamide, but much better controlled when she ate curry containing karela, provides evidence that the blood glucose-lowering effects of karela and conventional oral antidiabetics can be additive.1 Other small non-controlled studies have subsequently shown that karela produces a significant improvement in glucose tolerance in patients with type 2 diabetes, both when they are taking chlorpropamide,2 tolbutamide,3 glibenclamide,4 or metformin,5 and when they are not taking antidiabetics.6,7 In these studies, karela was given orally as a juice from the fruit,8,9 dried powdered fruit,10 and also as aqueous extract.11 Solvent extract from the fruit also produced a significant improvement in glucose tolerance in patients with type 2 diabetes mellitus.12

Hypoglycaemic coma and seizures occurred in two young non-diabetic children after they were given bitter melon (karela) tea.7

Mechanism
Karela (also known as bitter melon, bitter gourd, balsam pear, cundeamor) is the fruit of Momordica charantia which is indigenous to Asia and South America. The blood glucose-lowering effects of karela may be due to its content of polypeptide P, a blood glucose-lowering peptide,13 also known as vegetable insulin (v-insulin).9 This substance is effective when given subcutaneously,14 but its oral activity is uncertain.15 Other blood glucose-lowering compounds isolated from karela include charantin (sterol glucoside mixture in the fruit) and vicine a pyrimidine nucleoside found in the seeds. Karela fruit may have both insulin-like effects and stimulate insulin secretion.16

Importance and management
Karela is available in the UK and elsewhere, and is used to flavour foods such as curries, and also used as a herbal medicine for the treatment of diabetes mellitus. Its blood glucose-lowering activity is clearly established. Health professionals should therefore be aware that patients may possibly be using karela as well as more orthodox drugs to control their diabetes. Irregular consumption of karela as part of the diet could possibly contribute to unexplained fluctuations in diabetic control.

Clinical evidence, mechanism, importance and management
A study in 30 hospitalised diabetics (10 diet controlled, 10 taking unnamed sulphonylureas, 10 taking unnamed biguanides) found that the current use of ketofen 4 mg daily for 14 days was generally well tolerated. However, those taking biguanides had a significant decrease in platelet counts and 3 had a marked fall on day 14 to slightly below 100 × 10^9/L, which returned to normal after a few days.1 This finding underlies the precaution issued by the manufacturers of ketofen,2 that the combination should be avoided until this effect is explained. However, no other studies appear to have confirmed the fall in thrombocyte count so that its importance still remains uncertain.3

Clinical evidence, mechanism, importance and management
The concurrent use of sulphonylureas or biguanides and ketofen appears to be well tolerated, but a fall in the number of platelets has been seen in one study in patients taking biguanides with ketofen.

Clinical evidence, mechanism, importance and management
A study in 30 hospitalised diabetics (10 diet controlled, 10 taking unnamed sulphonylureas, 10 taking unnamed biguanides) found that the concurrent use of ketofen 4 mg daily for 14 days was generally well tolerated. However, no other studies appear to have confirmed the fall in thrombocyte count so that its importance still remains uncertain.3

Clinical evidence, mechanism, importance and management
A study in 30 hospitalised diabetics (10 diet controlled, 10 taking unnamed sulphonylureas, 10 taking unnamed biguanides) found that the concurrent use of ketofen 4 mg daily for 14 days was generally well tolerated. However, those taking biguanides had a significant decrease in platelet counts and 3 had a marked fall on day 14 to slightly below 100 × 10^9/L, which returned to normal after a few days.1 This finding underlies the precaution issued by the manufacturers of ketofen,2 that the combination should be avoided until this effect is explained. However, no other studies appear to have confirmed the fall in thrombocyte count so that its importance still remains uncertain.3

An isolated report describes severe liver damage with prolonged cholestasis in a patient taking chlorpropamide and erythromycin. Isolated cases of hypoglycaemia have been described in patients taking glibenclamide (glyburide) or glipizide with clarithromycin or erythromycin. A study in healthy subjects found that hypoglycaemia may occur if tolbutamide and clarithromycin are given concurrently and another pharmacokinetic study suggests that clarithromycin may enhance the effects of repaglinide.

Clinical evidence, mechanism, importance and management

(a) Effects on the liver

A man with type 2 diabetes taking chlorpropamide was given erythromycin ethylsuccinate 1 g daily for 3 weeks for a respiratory infection. Two weeks later he complained of increasing fatigue and fever. A short episode of purpuric skin rash was followed by the appearance of dark urine, jaundice and hepatomegaly. The picture over the next 2 years was that of profound cholestasis, complicated by steatorrhoea and marked hyperlipidaemia with disappearance of interlobular bile ducts. He died of ischaemic cardiomyopathy. The reasons for this serious reaction are not understood, but the authors point out that liver damage occurs in a very small number of patients given sulphonylureas, such as chlorpropamide, and also with glipizide. They suggest that there may have been an interaction between the two drugs. This case is also complicated by the prior long-term use of phenformin, which is known to be hepatotoxic.4 No general conclusions can be drawn from this unusual case.

(b) Hypoglycaemia

1. Repaglinide. Clarithromycin 250 mg twice daily given to healthy subjects increased the AUC and maximum plasma concentrations of a single 250-microgram dose of repaglinide, given on day 5, by 40% and 67%, respectively. Clarithromycin may inhibit the metabolism of repaglinide by inhibition of cytochrome P450 isozyme CYP3A4. There was a similar corresponding rise in circulating insulin levels. The effect of concurrent administration of these drugs should therefore be monitored. Other macrolides that inhibit CYP3A4 (such as erythromycin) would be expected to interact in a similar manner.

2. Sulphonylureas. Two isolated cases of severe hypoglycaemia occurred in elderly, type 2 diabetic patients, with renal impairment, given glibenclamide or glipizide and clarithromycin.3 A further case of hypoglycaemia occurred when an elderly diabetic patient, with normal renal function, took glibenclamide 5 mg daily also took clarithromycin 1 g daily as part of an Helicobacter pylori eradication regimen. It was thought that the clarithromycin might have displaced glibenclamide and glipizide from protein binding sites.4

A case of hypoglycaemia was reported in a patient taking glibenclamide and erythromycin.5 However, an earlier single-dose study in 12 patients with type 2 diabetes found that erythromycin had little effect on glibenclamide pharmacokinetics or on its blood glucose-lowering effects.6 A placebo-controlled study involving 34 patients with type 2 diabetes (most of whom were treated with glibenclamide or glipizide) found that oral erythromycin 400 mg three times daily for a week reduced fructosamine and fasting blood glucose concentrations and increased insulin secretion. Glycaemic control was also improved in a similar study using oral erythromycin 200 mg three times daily for 4 weeks.7 Further studies have shown that erythromycin increases gastric motility, which results in better control of blood glucose in patients with type 2 diabetes.8

A single-dose study in 9 healthy subjects found that clarithromycin 250 mg increased the rate of absorption of tolbutamide 500 mg by about 20% and increased its bioavailability by 26%. Hypoglycaemia, reported as unescenness and giddiness, occurred on taking the combination.10 The general importance of these cases is uncertain, but some caution may be warranted with concurrent use, and the dose of the sulphonylurea may need to be reduced.

Antidiabetics + MAOIs or RIMAs

The blood glucose-lowering effects of insulin and the oral antidiabetics can be increased by MAOIs. This may improve the control of blood glucose levels in most diabetics, but in a few it may cause undesirable hypoglycaemia. Moclobemide appears not to interact.

Clinical evidence

(a) Moclobemide

A study in healthy subjects given glibenclamide 2.5 mg daily found that moclobemide 200 mg three times daily for a week had no effect on glucose or insulin concentrations after oral glucose tolerance tests.1 In clinical trials, 8 diabetics taking glibenclamide (glyburide), gliclazide, metformin or chlorpropamide received moclobemide, and there was no effect on blood glucose levels or any other evidence of an interaction.1

(b) Non-selective irreversible MAOIs

A diabetic patient receiving insulin experienced postural syncope and hypoglycaemia, which required a reduction in insulin dose, when mebanazine was also taken.2 Other reports in diabetics indicate that mebanazine increases the blood glucose-lowering effects of insulin, tolbutamide and chlorpropamide, and improves diabetic control.3,6

Mechanism

Not fully understood. Mebanazine,4 iproniazid,5 isocarboxazid,6 phenelzine, and tranylcypromine9 have all been shown to reduce blood glucose levels in the absence of conventional antidiabetics, possibly due to some direct action on the pancreas, which causes the release of insulin.9 It would seem that this can be additive with the effects of the conventional hypoglycaemics.

Importance and management

The interaction of the non-selective MAOIs is an established interaction of only moderate clinical importance. It can benefit the control of diabetes in many patients, but some individuals may need a reduction in the dose of their antidiabetic to avoid excessive hypoglycaemia. The effects of concurrent use should be monitored. This interaction would seem possible with any antidiabetic/MAOI combination, but this requires confirmation. No clinically important interaction seems to occur between antidiabetics and moclobemide.

Antidiabetics + Macrolides

An isolated report describes severe liver damage with prolonged cholestasis in a patient taking chlorpropamide and erythromycin. Isolated cases of hypoglycaemia have been described in patients taking glibenclamide (glyburide) or glipizide with clarithromycin or erythromycin. A study in healthy subjects found that hypoglycaemia may occur if tolbutamide and clarithromycin are given concurrently and another pharmacokinetic study suggests that clarithromycin may enhance the effects of repaglinide.
Nicotinic acid causes a deterioration in glucose tolerance, which may be dose-related, and can result in the need for an adjustment in antidiabetic medication. Nevertheless, its benefits on lipids may outweigh its effects on glucose tolerance in some diabetics. Concurrent use should be closely monitored.

Clinical evidence

It is well recognised that nicotinic acid can cause deterioration in blood glucose tolerance. For example, in a small randomised crossover study, immediate-release nicotinic acid 1.5 g three times daily caused a 16% increase in mean plasma glucose and a 21% increase in glycosylated haemoglobin levels in 13 patients with type 2 diabetes. 1 In a retrospective study of patients taking controlled-release nicotinic acid (average dose approximately 1.5 g daily), nicotinic acid was discontinued in 106 out of 160 patients who were diabetics; of these, 43 patients (about 40%) had the nicotinic acid discontinued because of poor glycaemic control. Furthermore, 14 patients required the addition of oral antidiabetic drugs to control their diabetes. 2

In contrast, in another placebo-controlled study including 125 patients with diabetes, immediate-release nicotinic acid 3 g daily (or maximum tolerated dose) only modestly increased plasma glucose levels in patients with diabetes. Moreover, there were no significant differences in antidiabetic medication in diabetics taking nicotinic acid versus placebo, although insulin use was increased by 13% in the nicotinic acid group, when compared with 4% in the placebo group. 3 In a placebo-controlled study in patients with type 2 diabetes taking controlled-release nicotinic acid 1 g or 1.5 g daily, glycosylated haemoglobin marginally increased by 0.29% in the group receiving 1.5 g daily. There was an initial rise in fasting blood glucose between weeks 4 and 8, but this had returned to baseline by week 16. This was probably because some adjustment was made in antidiabetic therapy; 29% of patients taking nicotinic acid 1.5 g required an increase in antidiabetic therapy compared with 16% taking placebo (difference not significant). Only one patient (2%) taking nicotinic acid 1 g and 3 patients (6%) taking nicotinic acid 1.5 g discontinued treatment because of inadequate glucose control. 4 However, it has been noted that patients enrolled in both these studies had good glycaemic control, and that the findings may not be applicable to those with poor glycaemic control. 5

Mechanism

Nicotinic acid reduces glucose tolerance, possibly by causing or aggravating insulin resistance.

Importance and management

It is well known that nicotinic acid can cause deterioration in glycaemic control in patients with diabetes, but the incidence and clinical relevance of this is more controversial. The beneficial lipid-modifying effects of nicotinic acid directly improve the main lipid disorders observed in diabetes. Moreover, there were no significant differences in antidiabetic therapy compared with 16% taking placebo (difference not significant). Only one patient (2%) taking nicotinic acid 1 g and 3 patients (6%) taking nicotinic acid 1.5 g discontinued treatment because of inadequate glucose control. 4 However, it has been noted that patients enrolled in both these studies had good glycaemic control, and that the findings may not be applicable to those with poor glycaemic control. 5

The blood glucose levels of 12 diabetics taking glibenclamide 10 mg daily were unchanged by bromfenac 50 mg three times daily for 3 days, and the pharmacokinetics of glibenclamide were also unaffected.\textsuperscript{9}

The blood glucose levels of 12 diabetics with rheumatic diseases taking glibenclamide were unchanged by diclofenac 150 mg daily for 4 days.\textsuperscript{16}

A study in 6 healthy subjects found that ibuprofen produced no significant changes in the pharmacokinetics of glibenclamide. However, concurrent use significantly increased plasma insulin levels (AUC 47%) and lowered serum glucose levels (8%), but this is probably not clinically important.\textsuperscript{15}

A case of severe hypoglycaemia in a diabetic patient was attributed to the accumulation of glibenclamide and metformin due to deterioration in renal function caused by the concurrent use of ramipril and naproxen.\textsuperscript{16}

Although a preliminary report suggested that nimesulide slightly increased the effects of glibenclamide,\textsuperscript{16} a later study using various [unnamed] sulphonylureas failed to find that it affected fasting blood glucose levels or the glucose tolerance of diabetic patients.\textsuperscript{17}

Valdecoxib, the active metabolite of parecoxib, does not appear to affect either the pharmacokinetics of glibenclamide or its effects on insulin or blood glucose levels.\textsuperscript{18}

Tenoxicam 20 mg daily was found not to affect the glycoregulation of 8 healthy subjects given glibenclamide 2.5 mg daily.\textsuperscript{19}

No changes were seen in the blood glucose levels of 40 diabetics taking glibenclamide when they were given either tolmetin 1.2 g or placebo daily for 5 days.\textsuperscript{20}

A study in 12 healthy subjects found that tenoxicam 20 mg daily did not affect the pharmacokinetics of glibenclamide or its effect on plasma insulin and blood glucose levels.\textsuperscript{21}

In a study in 12 type 2 diabetic patients, salinidac 400 mg daily did not affect the half-life, plasma levels, time-to-peak levels or AUC of tolbutamide. An unimportant reduction in fasting blood glucose levels was seen.\textsuperscript{22}

Naproxen 375 mg every 12 hours for 3 days had no effect on the pharmacokinetics or pharmacological effects of tolbutamide in ten type 2 diabetics.\textsuperscript{23} The pharmacokinetics of a single 500-mg dose of tolbutamide were unaffected in 7 healthy subjects after they took tenoxicam 20 mg daily for 14 days, and blood glucose concentrations were not altered.\textsuperscript{24} No important changes in blood glucose levels occurred in 24 type 2 diabetic patients taking tolbutamide who were given or glipizide when they were given indoprofen 500 mg daily for 5 days.\textsuperscript{25} In other patients taking tolbutamide it was found that ibuprofen lowered fasting blood glucose levels, but not below the lower limits of normal.\textsuperscript{26}

Mechanism, importance and management

The reports briefly quoted here indicate that no adverse or clinically relevant interaction normally occurs between the oral antidiabetics and the NSAIDs cited. The general silence in the literature would seem to add confirmation. Caution is appropriate with pioglitazone or rosiglitazone and NSAIDs, and patients should be monitored for signs of heart failure. Note that the NSAIDs, including coxibs, can cause renal failure, which can precipitate metformin-associated lactic acidosis. In addition, a reduction in the renal clearance of antidiabetic drugs can result in hypoglycaemia. Adverse interactions can certainly occur between antidiabetics and azapropazone, phenylbutazone, oxypHENbutazone and the salicylates; see ‘Antidiabetics + NSAIDs; Phenylbutazone and related drugs’:\textsuperscript{27} p.498 and ‘Antidiabetics + Sulfonylurides’, p.502.

Antidiabetics + NSAIDs; Phenylbutazone and related drugs

The blood glucose-lowering effects of acetohexamide, chlorpropamide, carbutamide, glymidime, glibenclamide (glyburide) and tolbutamide can be increased by phenylbutazone. Severe hypoglycaemia has occurred in a few patients. Similarly, azapropazone can increase the effects of tolbutamide and cause severe hypoglycaemia. Oxyphenbutazone may be expected to behave similarly. Metamizole (dipyrone) and mofebutazone did not interact with glibenclamide.

Clinical evidence

(a) Azapropazone

A woman whose diabetes was well controlled for 3 years with tolbutamide 500 mg twice daily, became confused and semi-comatose 4 days after starting to take azapropazone 900 mg daily. She complained of having felt agitated since starting the azapropazone, so it was withdrawn on suspicion of causing hypoglycaemia. Later that evening she became semi-comatose and was found to have a plasma glucose level of 2 mmol/L.1 A subsequent study in 3 healthy subjects found that azapropazone 900 mg daily increased the plasma half-life of tolbutamide 500 mg threefold (from 7.7 to 25.2 hours) and reduced its clearance accordingly.1 Acute hypoglycaemia occurred in another patient taking tolbutamide 500 mg three times daily, 5.5 hours after a single 600-mg dose of azapropazone was taken.

(b) Metamizole (Dipyrone)

One randomised, placebo-controlled, crossover study in 12 diabetic patients taking glibenclamide, suggested that metamizole 1 g daily for 2 days did not interact with glibenclamide; no relevant alteration in blood glucose levels was found.3

(c) Mofebutazone

Mofebutazone 900 mg daily has not been found to cause any clinically important changes in blood glucose levels in patients taking glibenclamide.4

(d) Oxyphenbutazone

Oxyphenbutazone has been found to alter4 or raise glymidime levels6 and tolbutamide levels.8,9

(e) Phenylbutazone

A man with type 2 diabetes taking tolbutamide experienced an acute hyperglycaemic episode 4 days after starting phenylbutazone 200 mg three times daily, although there was no change in his diet or in the dosage of tolbutamide. He was able to control the hyperglycaemia by eating a large bar of chocolate.9

There are numerous other case reports and studies of this interaction involving phenylbutazone with acetohexamide,9 carbutamide,11 chlorpropamide,12-14 glibenclamide (glyburide),15 glymidime,16 and tolbutamide,13,17-23 some of which describe acute hyperglycaemic episodes.10,12,13,18,20 Several of these interactions have been fatal.13,23 There is a report suggesting that the interaction between glibornuride and phenylbutazone may not be clinically important.24 In contrast to these reports, a single study describes a paradoxical rise in blood glucose levels in 3 African patients taking tolbutamide and phenylbutazone.25 In addition to these reports there is some evidence that tolbutamide increases the metabolism of phenylbutazone by 42%,22 but the extent to which this affects its therapeutic effects is uncertain.

Mechanism

Not fully resolved. Some evidence suggests that phenylbutazone can inhibit the renal excretion of glibenclamide (glyburide),15 tolbutamide,16 and the active metabolite of acetohexamide10 so that they are retained in the body longer and their blood glucose-lowering effects are increased and prolonged. It has also been shown that phenylbutazone can inhibit the metabolism of the sulphonylureas22,23 as well as causing their displacement from protein binding sites.22 Azapropazone also possibly inhibits the metabolism of tolbutamide,1 as well as maybe causing displacement from plasma protein binding sites.1

Importance and management

The interactions between the antidiabetics and phenylbutazone are well documented and potentially clinically important. Blood glucose levels may be lowered, but the number of reports of acute hypoglycaemic episodes seems to be small. Concomitant use should therefore be well monitored. A reduction in the dosage of the sulphonylurea may be necessary if excessive hypoglycaemia is to be avoided. Not all sulphonylureas have been shown to interact (glibornuride probably does not do so) but it would be prudent to assume that they all interact until there is good evidence to suggest otherwise. Oxyphenbutazone may be expected to interact like phenylbutazone (it is a metabolite of phenylbutazone) but, unexpectedly, possibly not mofebutazone although more study would be needed to confirm this.

The information regarding an interaction between azapropazone and the sulphonylureas seems to be limited to the cases and small study involving tolbutamide. Nevertheless, the manufacturers of azapropazone say that the concurrent use of sulphonylureas is not recommended.25

Orlistat improved glycaemic control, which resulted in the need to reduce the dose of glibenclamide (glyburide) or glipizide in almost half the patients in one study. In other studies, orlistat also reduced the dose requirement for metformin and for insulin. Orlistat did not alter the pharmacokinetics of glibenclamide or metformin. Orlistat and miglitol may have contributed to a case of metformin-associated lactic acidosis. The manufacturers recom-
mend avoiding the concurrent use of acarbose and orlistat because of the lack of interaction studies.

Clinical evidence

(a) Acarbose

The manufacturer of orlistat says that in the absence of pharmacokinetic studies its concurrent use with acarbose should be avoided.1

(b) Insulin

In a randomised, placebo-controlled, double-blind study in patients with type 2 diabetes receiving insulin with or without metformin or a sulphonylurea, orlistat 120 mg three times daily for one year combined with a reduced-calorie diet improved glycaemic control and allowed a greater reduction in insulin dose (mean reduction of 8.1 units daily versus 1.6 units daily for placebo). Hypoglycaemic episodes occurred in about 17% of orlistat recipients and about 10% of placebo recipients—three orlistat recipients and one placebo recipient required medical intervention due to hypoglycaemia.2

(c) Metformin

In a randomised study, 21 healthy subjects were given metformin 500 mg daily for 6 days, with or without orlistat 120 mg three times daily. Orlistat had no effect on the pharmacokinetics of metformin, and the combination was well-tolerated.3 In a randomised, placebo-controlled, double-blind study in patients with type 2 diabetes taking metformin with or without a sulphonylurea (mainly glibenclamide (glyburide) or glipizide), orlistat 120 mg three times daily for one year improved glycaemic control and allowed a small reduction in the dose of metformin (mean daily reduction of 16 mg versus a mean increase of 49 mg for placebo). Twice as many patients in the orlistat group either reduced or discontinued one or more antidiabetics (17% versus 8% with placebo). Hypoglycaemic episodes (mild to moderate and not requiring treatment) occurred in 10% of orlistat recipients and 4% of placebo recipients.4 Similarly, improvement in glycaemic control and reduced requirement for oral antidiabetic medication was reported in another study.5

A 59-year-old woman with type 2 diabetes taking long-term metformin 500 mg three times daily, developed severe metabolic acidosis with cardiovascular collapse and acute renal failure. Three months previously she had started orlistat 120 mg three times daily, which caused abdominal pain and chronic diarrhoea. During the 4 days before hospital admission, she was prescribed cetidine 400 mg twice daily for her abdominal pain. The metformin-associated lactic acidosis was considered to have been precipitated by the orlistat and ‘cetidine’, (p.491).

(d) Sulphonylureas

A placebo-controlled study in 12 healthy subjects found that orlistat 80 mg three times daily for a little over 4 days had no effect on the pharmacokinetics of a single 5-mg oral dose of glibenclamide (glyburide) and the blood glucose lowering effects remained unchanged.6 A later 1-year, randomised, placebo-controlled, double-blind trial in obese patients with type 2 diabetes in which 139 patients took orlistat found that orlistat reduced fasting blood glucose and glycosylated haemoglobin levels. In addition, 43% of patients taking orlistat 120 mg three times daily were able to decrease their sulphonylurea dosage ([glibenclamide or glipizide], and 11.7% of them were able to discontinue the sulphonylurea. The average dose decrease was 23% compared with 9% in the placebo group.7

Mechanism

The benefits of orlistat are likely to be as a result of the beneficial effects of weight reduction on glycaemic control, although in some studies the reduction in glycosylated haemoglobin was not entirely dependent on the magnitude of weight loss.8

Importance and management

The benefits of orlistat on glycaemic control in overweight or obese patients with diabetes are established. Antidiabetic treatment should be more closely monitored in patients taking orlistat, and the dose adjusted as necessary.

Antidiabetics + Pentoxifylline

The manufacturer notes that, rarely, high-dose injections of pentoxifylline have intensified the blood glucose-lowering effects of insulin and oral antidiabetic drugs. This effect has not been seen with oral pentoxifylline.9 For example, in one study oral pentoxifylline 600 mg daily for 9 months did not affect glycosylated haemoglobin levels in type 2 diabetic patients.10

Antidiabetics + Phenylephrine

Type 1 (insulin-dependent) diabetes can develop elevated blood pressures if they are given phenylephrine eye drops.

Clinical evidence, mechanism, importance and management

A comparative study of 14 type 1 diabetics, who over a period of 2 hours before ocular surgery were given phenylephrine 10% eye drops (a total of 4 doses of one or two drops), found that they had an average blood pressure rise of 34/17 mmHg, whereas another 176 non-diabetic patients similarly treated had no increases in blood pressure.1 The reason for this pressor reaction is not understood but it would seem that enough phenylephrine is absorbed systemically to stimulate the adrenoceptors of the sympathetic nervous system, which innervates the cardiovascular system. The concentration of phenylephrine in the plasma is a balance between the amount absorbed and rate at which it is then inactivated. The inactivation in diabetics can be reduced (due to sympathetic denervation) so that their phenylephrine levels may rise higher than they would in normal subjects.

The authors of this report say that they readily controlled these hypertensive reactions with halothane and by neuroleptanalgesia accompanying regional block with anaesthesia standby. Strictly speaking this is not a drug interaction, but a drug-disease reaction. The mydriatic dosage of phenylephrine should be reduced in type 1 diabetics but whether this is also true for type 2 diabetics is uncertain.

Antidiabetics + Quinolones

A number of reports describe severe hypoglycaemia in diabetic patients treated with gatifloxacin and various antidiabetics including insulin, metformin, pioglitazone, repaglinide, rosiglitazone, some sulphonylureas, or voglibose. In contrast, another report describes hyperglycaemia when a diabetic taking metformin and glipizide was given gatifloxacin. A retrospective review reported that almost one quarter of adverse events associated with gatifloxacin involved abnormal glucose homeostasis, which was at least tenfold higher than with other quinolones. Interaction studies have shown that gatifloxacin may cause hypoglycaemia and hyperglycaemia, whereas studies using cipro-
gatifloxacin and levofloxacin with glibenclamide suggest plasma glucose levels are not usually affected to a clinically relevant extent. However, isolated reports describe hypoglycaemia in diabetic patients taking glibenclamide, when ciprofloxacin, levofloxacin, or norfloxacin was given, and deaths associated with abnormal glucose homeostasis have been reported in patients taking ciprofloxacin or levofloxacin.

Clinical evidence

A search of the FDA database for adverse drug events associated with gatifloxacin, ciprofloxacin, levofloxacin, and moxifloxacin between November 1997 and September 2003 found 10,025 unique adverse events, including 568 involving glucose homeostasis abnormalities, of which 25 were fatal. Gatifloxacin use was associated with 453 (80%) of the adverse events involving glucose homeostasis, and 17 of these were fatal compared with 3, 5, and 0 fatalities with ciprofloxacin, levofloxacin, and moxifloxacin, respectively. Of all the adverse events associated with gatifloxacin, 24% involved glucose homeostasis, compared with ciprofloxacin (1.3%), levofloxacin (1.6%) and moxifloxacin (1.3%). The risk of adverse events involving glucose homeostasis was higher in older patients, in patients taking medications for diabetes (almost 70% of those taking gatifloxacin were also using insulin or oral antidiabetics) and in patients with renal dysfunction whose dosage had not been appropriately adjusted.1

(a) Ciprofloxacin

A study in 12 patients with type 2 diabetes mellitus taking glibenclamide (glyburide) 10 mg in the morning, plus in some instances 5 mg in the evening, found that ciprofloxacin 1 g daily for a week caused rises in maximum serum glibenclamide levels of 20 to 30%, and a rise in the AUC of 25 to 36%. However, none of these changes were statistically significant, and more importantly blood glucose levels were not altered.2 Nevertheless, an elderly patient who had been taking glibenclamide 5 mg daily for over 2 years was found to be confused, with slurred speech and diaphoresis within a week of starting ciprofloxacin 250 mg twice daily for acute cystitis, and was found to have a serum glucose level several times greater than that normally seen.3 She needed treatment with intravenous glucose to correct the hypoglycaemia. Two further similar cases have been reported, in which hypoglycaemia developed after the first or second dose of ciprofloxacin, for either a wound infection4 or a urinary tract infection.5

(b) Gatifloxacin

In a study in patients with type 2 diabetes controlled by diet and exercise, gatifloxacin 400 mg daily for 10 days had no significant effect on glucose tolerance or most aspects of glucose homeostasis, but did cause a brief increase in serum insulin levels.6 In contrast, the manufacturer of gatifloxacin notes that in another study in patients with type 2 diabetes taking metformin with or without glibenclamide, oral gatifloxacin 400 mg daily for 14 days was associated with initial hypoglycaemia followed by hyperglycaemia.7 Moreover, there is a report of 3 cases of hypoglycaemia in elderly type 2 diabetic patients given gatifloxacin. In one of these cases a patient taking glibenclamide 5 mg daily and pioglitazone 30 mg daily experienced severe, persistent hypoglycaemia within an hour of the first dose of oral gatifloxacin 200 mg. It resolved on withdrawal of all three drugs and she had no further episodes of hypoglycaemia when glibenclamide and pioglitazone were restarted.8 Another case describes a patient taking glimepiride 2 mg before breakfast and 1 mg before dinner who developed severe hypoglycaemia 12 hours after the first dose of intravenous gatifloxacin 400 mg. Both drugs were discontinued and glimepiride was later restarted without further hypoglycaemia.9 In the remaining case, a patient taking repaglinide 500 micrograms every 8 hours was given oral gatifloxacin 400 mg daily for a urinary-tract infection. Repaglinide was discontinued 6 hours after the first dose of gatifloxacin because of the patient’s lack of appetite. Two hours after the second dose of gatifloxacin, he developed severe hypoglycaemia and also experienced a tonic-clonic seizure. Gatifloxacin was discontinued but hypoglycaemia persisted for 32 hours. Repaglinide was restarted 4 days later without further hypoglycaemia.6 Other case reports have described severe hypoglycaemia when gatifloxacin was given to patients with diabetes taking insulin with repaglinide and voglibose.9 glibenclamide,10,12 repaglinide with metformin,13 glibenclamide with rosiglitazone,12 or glipizide.10 In contrast, an 82-year-old woman taking metformin and glipizide who was discharged from hospital taking gatifloxacin 200 mg daily developed severe hyperglycaemia within 48 hours. Her serum glucose rapidly reduced with low-dose intravenous insulin, but increased again the following day after she took oral gatifloxacin while receiving subcutaneous insulin.10 Hyperglycaemia has also been noted in 2 non-diabetic patients within 48 to 72 hours of starting gatifloxacin.10,11 See also the FDA findings, above.

(c) Levofloxacin

A study in 24 healthy subjects found that oral levofloxacin had no effect on the pharmacokinetics of a single oral dose of glibenclamide nor its effect on plasma glucose levels.14 No recurrence of hypoglycaemia occurred in a patient taking glipizide and oral levofloxacin while who had a severe hypoglycaemic episode while receiving glibenclamide and gatifloxacin.11 However, a fatal case of hypoglycaemia related to intravenous levofoxacin occurred in an elderly patient with diabetes who was taking glibenclamide.12

(d) Moxifloxacin

The manufacturer notes that the concurrent use of moxifloxacin and glibenclamide resulted in an approximate 21% decrease in the peak plasma level of glibenclamide in diabetic subjects, but this did not alter blood glucose and endogenous insulin.16 A pooled analysis from clinical and post-marketing studies suggested that moxifloxacin had no clinically relevant effect on blood glucose homeostasis, even in patients with diabetes mellitus.17

(e) Norfloxacin

The manufacturer notes that the concurrent use of norfloxacin with glibenclamide has resulted in severe hypoglycaemia.18

Mechanism

Unknown. The authors of one report suggest that the ciprofloxacin may have inhibited the metabolism of the glibenclamide, thereby raising its serum levels.13 This may possibly be exaggerated in elderly patients whose liver function may be reduced. However, it has also been postulated that quinolones may alter insulin secretion.5,15 Gatifloxacin can cause disturbances in blood glucose levels;12 initiation of treatment with gatifloxacin has been associated with increased insulin release and a decrease in blood glucose levels; but from the third day of treatment, an increase in blood glucose levels has also been reported.17 This severe effect of gatifloxacin on glucose homeostasis does not appear to be a class effect of the quinolones.6

Importance and management

Gatifloxacin has been much more frequently associated with disturbances of blood glucose than other fluoroquinolones. The manufacturer notes that when gatifloxacin is used in diabetic patients, blood glucose should be closely monitored. Signs and symptoms of hypoglycaemia should be monitored, especially in the first 3 days of therapy, and signs and symptoms of hyperglycaemia should be monitored, especially with continued treatment beyond 3 days.7 Alternatives to gatifloxacin should be considered in patients with diabetes.

Isolated cases of hypoglycaemia in patients with diabetes have also been reported for ciprofloxacin, levofloxacin and norfloxacin. The general clinical relevance of these cases is uncertain but probably minor. However, it may be prudent to consider increasing the frequency of blood glucose monitoring in the elderly, who appear more at risk.

References

Rifampicin (rifampin) reduces the serum levels and blood glucose lowering effects of tolbutamide, gliclazide, chlorpropamide (single case) and glibenclamide (glyburide), and to a lesser extent glimepiride, glipizide and glymidine. Rifampicin also reduces the effects of repaglinide, and possibly also nateglinide. Rifampicin reduces the AUC of rosiglitazone, which could be clinically relevant. An isolated report describes an increased insulin requirement in a patient with type 1 diabetes taking rifampicin.

**Clinical evidence**

(a) Insulin

A case report describes a 54-year-old woman with type 1 diabetes whose insulin requirements increased from 36 units to 48 units daily when she took rifampicin. Immediately on discontinuing her antituberculous therapy, she developed frequent hypoglycaemic attacks, which persisted until her insulin dose was reduced back to 36 units daily.1

(b) Nateglinide

In a randomised crossover study, 10 healthy subjects were given a single 60-mg dose of nateglinide the day after a 5-day course of rifampicin 600 mg daily. Rifampicin reduced the AUC_{max} of nateglinide by 24% (range 5 to 53%) and decreased the nateglinide half-life from 1.6 to 1.3 hours. Overall rifampicin did not significantly decrease the blood glucose-lowering effects of nateglinide.2 However, because of the high degree of intersubject variation, the authors suggest that the blood glucose-lowering effects of nateglinide may be reduced in some subjects.2

(c) Repaglinide

In one study in healthy subjects, a single 4-mg dose of repaglinide was given one hour after the final dose of rifampicin 600 mg daily for 7 days. Rifampicin decreased the AUC and the mean maximum plasma concentration of repaglinide by 31% and 26%, respectively, but the blood glucose-lowering effect of repaglinide was not affected.3 In another study,4 pretreatment with rifampicin 600 mg daily for 5 days increased the AUC and maximum level of a single 500-microgram dose of repaglinide given on day 6 by 57% and 41%, respectively. In this study, rifampicin reduced the blood glucose-lowering effect of repaglinide by 35%. A third study investigated the effect of rifampicin 600 mg daily for 7 days on a single 4-mg dose of repaglinide given at the same time as the last rifampicin dose on day 7 or 24 hours later. When rifampicin was given simultaneously, the median AUC of repaglinide was reduced by almost 50%, but when the repaglinide was given 24 hours after the last rifampicin dose, the median AUC was reduced by 80%. The size of the effect of rifampicin on repaglinide may therefore depend on the administration schedule.5

(d) Rosiglitazone

Rifampicin 600 mg daily for 5 days reduced the AUC of a single 4-mg dose of rosiglitazone by 54% and reduced the maximum plasma level by 28%, in a study in healthy subjects. Rifampicin increased the formation of N-desmethylrosiglitazone.5 Very similar findings were reported in a study in healthy Korean subjects.7

**Sulphonylureas**

(a) Chlorpropamide

A single case report describes a man with type 2 diabetes who needed an increase in his dosage of chlorpropamide from 250 to 400 mg daily when he was given rifampicin 600 mg daily. His serum chlorpropamide levels rose dramatically 12 months later when the rifampicin was withdrawn.8

(b) Glibenclamide (Glyburide)

A study in 29 type 2 diabetics, stable taking glibenclamide, found that when they were also given rifampicin 450 or 600 mg daily for 10 days, their blood glucose levels, both fasting and after meals, were raised. Glibenclamide dosage changes were needed in 15 out of 17 patients in whom the diabetes became uncontrolled. Their blood glucose levels normalised 6 days after stopping the rifampicin.9 Another patient with type 2 diabetes taking glibenclamide had a deterioration in diabetic control, over the 8 months after she started rifampicin, which required an increase in glibenclamide dose and the addition of insulin. On stopping rifampicin, she had a marked rise in trough serum glibenclamide levels, from 40 to 200 nanograms/mL, but no appreciable change in blood glucose concentrations.10 A study in 10 healthy subjects found that rifampicin 600 mg daily for 5 days decreased the AUC and peak plasma level of a single 1.75-mg dose of glibenclamide given on day 6 by 39% and 22%, respectively. The elimination half-life was shortened from 2 to 1.7 hours. The maximum reduction in blood glucose level was decreased by 36% by rifampicin.11

(c) Gliclazide

A 65-year-old patient with type 2 diabetes taking gliclazide 80 mg daily for 2 years without problem was given rifampicin 450 mg daily, isoniazid, ethambutol and clarithromycin for an atypical mycobacteriosis. Fasting blood glucose levels became elevated requiring an increase in the dose of gliclazide to 120 mg then 160 mg daily. The plasma level of gliclazide on day 75 was 1.4 micrograms/mL, 2 hours after an 80-mg dose. When rifampicin was discontinued the gliclazide level increased to 4.7 micrograms/mL and the dose was reduced back to 80 mg daily.12 A study in 9 healthy subjects found that pre-treatment with rifampicin 600 mg for 6 days decreased the AUC of a single 80-mg dose of gliclazide given on day 7 by 70%. The mean elimination half-life of gliclazide was reduced from 9.5 to 3.3 hours and the gliclazide oral clearance was increased by about fourfold. The blood glucose-lowering effects of gliclazide were significantly reduced by rifampicin.13

(d) Glimepiride

A placebo-controlled study in 10 healthy subjects found that rifampicin 600 mg daily for 5 days decreased the AUC of a single 1-mg dose of glimepiride given on day 6 by 34%. Rifampicin reduced the elimination half-life of glimepiride by 25%. However, no significant differences in blood glucose were found between the rifampicin and placebo regimens.14

(e) Glipizide

A placebo-controlled study in 10 healthy subjects found that rifampicin 600 mg daily for 5 days decreased the AUC of a single 2.5-mg dose of glipizide given on day 6 by 22%. The elimination half-life was shortened from 3 to 1.9 hours by rifampicin. However, no significant differences in blood glucose concentrations were found.15

(f) Glymidine

In one study the half-life of glymidine was reduced by about one-third by the concurrent use of rifampicin.15

(g) Tolbutamide

After treatment for 4 weeks with rifampicin the half-life of tolbutamide in 9 diabetic patients with tuberculosis was reduced by 43%, and the serum concentrations measured at 6 hours were halved, when compared with other patients not taking rifampicin.16 Similar results have been found in other studies in patients with cirrhosis or cholestasis,17 in healthy subjects18 and in other patients.19

**Mechanism**

Rifampicin is a potent inducer of the liver microsomal enzymes concerned with the metabolism of tolbutamide (cytochrome P450 isoenzyme CYP2C9), which hastens its clearance from the body, thereby reducing its effects.16-18 The interaction between rifampicin and glibenclamide, gliclazide, glimepiride, glipizide, and nateglinide is probably also due to induction of CYP2C9.12,13 Induction of P-glycoprotein may also play a part.11,13 The interaction of rifampicin with repaglinide is probably due to induction of CYP3A4,3,4 and that with rosiglitazone is probably due to induction of CYP2C8 and to a lesser extent CYP2C9.6 The case report with insulin is unexplained.
Importance and management

Information is limited, but the interactions of tolbutamide, glibenclamide (glyburide) and glargide with rifampicin appear to be established. Patients taking these sulphonylureas may need an increase in the dosage while taking rifampicin. This also seems possibly true for chlorpropamide, but the documentation for this interaction is even more limited. The effect of rifampicin on the blood glucose-lowering effects of glimepiride, glipizide or glyburide may be of only limited clinical significance, but it should be noted that these were single-dose studies and it is possible that some effect may occur with multiple dosing. Caution is warranted. Similarly, although the interaction between glibenclamide and repaglinide is significant, a similar interaction is possible, especially with repaglinide, and so an increase in blood glucose monitoring would be prudent. Similarly, the effect on the AUC of rosiglitazone also indicates that diabetic control should be closely monitored if rifampicin is used.

The isolated case of increased insulin requirement suggests that rifampicin may possibly affect the glycaemic control of patients with type 1 diabetes, but this needs further investigation.

There does not seem to be any information regarding the other rifamycins, rifabutin (a weak enzyme inducer) and rifapentine (a moderate enzyme inducer). However, the manufacturers and the UK Committee on Safety of Medicines warn that rifabutin may possibly reduce the effects of a number of drugs, including oral antidiabetics.21,27

When they were given aspirin (patients under 27.2 kg given 1.2 g daily, patients over 27.2 kg given 2.4 g daily) for a week. No significant changes in insulin requirements were necessary.1

Eight patients receiving 12 to 48 units of insulin zinc suspension daily required no insulin when they were treated for 2 to 3 weeks with aspirin in doses of 3.5 to 7.5 g daily, which were large enough to give maximum therapeutic serum sulfonylurea levels of about 2.5 to 3.3 mmol/L. Six other patients were able to reduce their insulin requirements by between about 20 and 65%.2

(b) Chlorpropamide

The blood glucose-lowering effects of chlorpropamide and sodium salicylate may possibly interact in 5 healthy subjects. A further study in 6 healthy subjects found that chlorpropamide 100 mg given with sodium salicylate 1.5 g lowered blood glucose levels by the same amount as either chlorpropamide 200 mg or sodium salicylate 3 g alone.3

The blood glucose levels of a patient taking chlorpropamide 500 mg daily were lowered about two-thirds by aspirin in doses sufficient to give serum sulfonylurea levels of about 1.9 mmol/L.4

(c) Glibenclamide (Glyburide)

Sixteen healthy subjects took a single 5-mg dose of glibenclamide both before and on the fourth day of taking aspirin 975 mg four times daily for 4 days. It was found that the aspirin reduced the AUC₀–₄ of the glibenclamide by 68% and reduced its mean peak serum levels by 35%. The effects of this on glucose tolerance tests and insulin responses were difficult to interpret, but there was no clear evidence that any clinically relevant changes occurred.3

Mechanism

It has been known for over 100 years that aspirin and salicylates have hypoglycaemic properties and in relatively large doses can be used on their own in the treatment of diabetes.6-10 The simplest explanation for this interaction with antidiabetics is that the blood glucose lowering effects are additive,3 but there is some evidence that other mechanisms may come into play.18 In addition aspirin can raise serum chlorpropamide levels, possibly by interfering with renal tubular excretion, and therefore the effects of chlorpropamide are enhanced.4

Importance and management

The interaction between the sulphonylureas or insulin and the salicylates is established but of limited importance. Considering the extremely wide tolerability of the sulfonylureas and insulin, the possibility of a serious interaction would have come to light by now. The data available, coupled with the common experience of diabetes,11 is that excessive and unwanted hypoglycaemia is very unlikely with small to moderate dosages. Some downward readjustment of the dosage of the antidiabetic may be appropriate if large doses of salicylates are used. Information about other antidiabetics and salicylates appears to be lacking, but they are expected to behave similarly.

Antidiabetics + Salicylates

Aspirin and other salicylates can lower blood glucose levels, but small analgesic doses do not normally have an adverse effect on patients taking antidiabetics. Larger doses of salicylates may have a more significant effect, and caution is warranted.

Clinical evidence

(a) Insulin

Twelve children with type 1 diabetes receiving insulin had a reduction in blood glucose levels averaging 15% (from about 10.4 to 8.8 mmol/L) when they were given aspirin (patients under 27.2 kg given 1.2 g daily, patients over 27.2 kg given 2.4 g daily) for a week. No significant changes in insulin requirements were necessary.1

Eight patients receiving 12 to 48 units of insulin zinc suspension daily required no insulin when they were treated for 2 to 3 weeks with aspirin in doses of 3.5 to 7.5 g daily, which were large enough to give maximum therapeutic serum sulfonylurea levels of about 2.5 to 3.3 mmol/L. Six other patients were able to reduce their insulin requirements by between about 20 and 65%.2

The blood glucose-lowering effects of chlorpropamide and sodium salicylate may possibly interact in 5 healthy subjects. A further study in 6 healthy subjects found that chlorpropamide 100 mg given with sodium salicylate 1.5 g lowered blood glucose levels by the same amount as either chlorpropamide 200 mg or sodium salicylate 3 g alone.3

The blood glucose levels of a patient taking chlorpropamide 500 mg daily were lowered about two-thirds by aspirin in doses sufficient to give serum sulfonylurea levels of about 1.9 mmol/L.4

(c) Glibenclamide (Glyburide)

Sixteen healthy subjects took a single 5-mg dose of glibenclamide both before and on the fourth day of taking aspirin 975 mg four times daily for 4 days. It was found that the aspirin reduced the AUC₀–₄ of the glibenclamide by 68% and reduced its mean peak serum levels by 35%. The effects of this on glucose tolerance tests and insulin responses were difficult to interpret, but there was no clear evidence that any clinically relevant changes occurred.3

Mechanism

It has been known for over 100 years that aspirin and salicylates have hypoglycaemic properties and in relatively large doses can be used on their own in the treatment of diabetes.6-10 The simplest explanation for this interaction with antidiabetics is that the blood glucose lowering effects are additive,3 but there is some evidence that other mechanisms may come into play.18 In addition aspirin can raise serum chlorpropamide levels, possibly by interfering with renal tubular excretion, and therefore the effects of chlorpropamide are enhanced.4

Importance and management

The interaction between the sulphonylureas or insulin and the salicylates is established but of limited importance. Considering the extremely wide tolerability of the sulfonylureas and insulin, the possibility of a serious interaction would have come to light by now. The data available, coupled with the common experience of diabetes,11 is that excessive and unwanted hypoglycaemia is very unlikely with small to moderate dosages. Some downward readjustment of the dosage of the antidiabetic may be appropriate if large doses of salicylates are used. Information about other antidiabetics and salicylates appears to be lacking, but they are expected to behave similarly.

Antidiabetics + Somatostatin analogues

Ocotreotide decreases insulin resistance so that the dosage of insulin used by diabetes can be reduced. Fatal diabetic ketoacidosis
occurred in one patient when octreotide was withdrawn. Octreotide appears to have no benefits in those with type 2 diabetes, and it may reduce insulin secretion and affect glucose tolerance in non-diabetic patients. In addition, octreotide has been reported to reduce sulphonylurea-induced hypoglycaemia. Lanreotide may also affect glucose levels in diabetic patients.

Clinical evidence
Changes in glucose tolerance may occur in patients with acromegaly who are given somatostatin analogues. In a prospective study, in 24 acromegalic patients given long-acting octreotide or lanreotide, insulin resistance was reduced, but insulin secretion was impaired resulting in deterioration of glucose homoestasis in non-diabetic patients. Of 16 patients with normal glucose tolerance before octreotide treatment, 4 developed impaired glucose tolerance, and of 7 patients with impaired glucose tolerance, 4 improved, 1 remained stable and 2 deteriorated to diabetes mellitus; the status of one diabetic patient remained the same. In another study in patients with acromegaly given octreotide, impaired glucose tolerance or frank diabetes developed in approximately half of the 55 patients who initially had normal glucose tolerance, but glucose tolerance improved in 3 of the 11 patients who were diabetic.2 Similar results were reported in a further study, although octreotide appeared to be more detrimental to glucose metabolism than lanreotide.5

(a) Insulin
When 7 patients with type 1 diabetes with poor metabolic control were given octreotide 50 micrograms subcutaneously three times daily (at 8, 15 and 23 hours) or by continuous subcutaneous infusion (62.5 or 112.5 micrograms over 24 hours), their blood glucose levels were about 50% lower than when they were given insulin alone. The effects of octreotide on blood glucose levels were virtually the same regardless of route of administration or dose.6 Another study in 6 patients with type 1 diabetes also found that octreotide 50 micrograms subcutaneously before meals reduced their daily insulin requirements by about 50%,7 and other studies confirm that octreotide behaves in this way.6,8 An isolated report describes clinical and biochemical improvement with lanreotide 30 mg intramuscularly every 10 days, in a diabetic acromegalic man whose glucose levels were poorly controlled with insulin. However, he experienced hypoglycaemia when the lanreotide was replaced with intramuscular octreotide 20 mg (deposit preparation) and he had to reduce his insulin dose by 30 to 50% for the first week after each octreotide injection.8 Another report describes deterioration in glucose tolerance leading to death from diabetic ketoacidosis when octreotide was stopped in a patient with acromegaly and insulin-resistant diabetes mellitus.9 Eight obese type 2 diabetic patients whose diabetes was not controlled with oral antidiabetics and who needed insulin, had no significant increases in blood glucose levels following a meal when they were given subcutaneous octreotide 25 micrograms.10 Octreotide reduced insulin requirements in 6 type 2 diabetic patients with chronic renal failure, but did not significantly affect the glycaemic profile of similar diabetic patients with normal renal function. This effect was thought to be due to a greater reduction in glycaemic levels, which are elevated in renal failure.11

(b) Oral antidiabetics
Octreotide does not appear to have a clinically relevant beneficial or harmful effect on the blood glucose-lowering effects of oral antidiabetics such as glibenclamide (glyburide) in patients with type 2 diabetes, although some metabolic changes can occur including suppression of postprandial serum insulin levels.12,13 A retrospective study of 9 patients with hypoglycaemia occurring as a result of a sulphonylurea overdose (with glibenclamide or glipizide) found that there was a dramatic and significant reduction in the number of episodes of hypoglycaemia after octreotide was given (29 episodes before versus 2 episodes after octreotide).14

Mechanism
Octreotide is an analogue of the natural hormone somatostatin, and similarly has blood glucose-lowering effects because it inhibits the actions of glucagon and growth hormone (which raise blood glucose levels), and because it also delays the absorption of carbohydrate from the gut. However, somatostatin is also diabetogenic, because it suppresses insulin release. In type 1 diabetes, because there is no endogenous insulin, the blood glucose-lowering effects predominate. In non-diabetics and type 2 diabetics, the actions may cancel out, or there may be poorer glycaemic control. Octreotide is thought to cause less suppression of insulin release than somatostatin, but this may still be important in those with insulin-secreting reserves.

Lanreotide, like somatostatin and its analogues, may produce a transient inhibition of the secretion of insulin and glucagon,15 but lanreotide may have less affinity for receptors found in the pancreas and so possibly produces a different response to that of octreotide.1,8 Sulphonylureas lower blood glucose levels primarily by facilitating preformed insulin release from pancreatic beta cells, and octreotide may oppose this by directly inhibiting insulin secretion from the pancreas.14

Importance and management
The interaction between insulin and octreotide is established and hypoglycaemia has been reported. If both drugs are used, anticipate the need to reduce the insulin dosage. The studies cited above.4,5 suggest that about a 50% reduction is possible. The manufacturers of octreotide say that octreotide may also reduce the requirements of oral antidiabetics in patients with type 1 diabetes mellitus. However, there do not appear to be any studies on this. Conversely, they state that in patients with type 2 diabetes, octreotide may result in prandial increases in glycaemia,16 but two clinical studies in patients with type 2 diabetes given glibenclamide (glyburide) did not show any deterioration (or benefit) in glycaemia.12,13 However, octreotide has been reported to reduce sulphonylurea-induced hypoglycaemia. Octreotide may affect insulin secretion, and therefore glucose tolerance, and so it would certainly be prudent to monitor the effects of giving octreotide with any of the oral antidiabetics. The manufacturer of lanreotide also recommends that blood glucose levels should be checked in diabetic patients to determine whether antidiabetic treatment needs to be adjusted.15

and increases the maximum plasma levels of glimepiride, but these changes are unlikely to be clinically relevant in most patients. Fluoxetine did not alter the pharmacokinetics of tolbutamide, and sertraline did not significantly affect the pharmacokinetics of glibenclamide (glyburide) or tolbutamide.

Clinical evidence

(a) Fluoxetine

One study found that single, or multiple doses of fluoxetine for 8 days, did not affect the pharmacokinetics or the blood glucose-lowering effects of tolbutamide.1 However, studies in obese patients with type 2 diabetes receiving oral antidiabetics have shown that fluoxetine can cause significant weight loss, reduce fasting plasma glucose levels and improve glycaemic control (decrease in glycosylated haemoglobin levels),2,3 and in those receiving insulin, decrease the daily insulin dose.4 The manufacturers of fluoxetine say that hypoglycaemia has occurred in diabetic patients when they took fluoxetine alone, and hyperglycaemia has developed following discontinuation.5,6

An insulin-dependent diabetic experienced symptoms of hypoglycaemia (nausea, tremor, sweating, lightheadedness) after starting to take fluoxetine 20 mg each night. The symptoms disappeared when the fluoxetine was stopped and reappeared when it was restarted. However, blood glucose levels were found to be normal (9 to 11 mmol/L), so it is likely that the effects were purely adverse effects of fluoxetine that were mistaken for symptoms of hypoglycaemia.7 In contrast, another patient with type 1 diabetes experienced a loss of hypoglycaemic awareness while taking fluoxetine 40 mg daily. Approximately one month after fluoxetine was started, he reported an increased incidence of hypoglycaemia, but these episodes were not accompanied by typical adrenergic symptoms (which he had previously experienced). After 3 grand mal seizures which occurred with blood glucose readings ranging from 1.9 to 2.2 mmol/L, the dose of fluoxetine was gradually decreased. Hypoglycaemic unawareness resolved when the fluoxetine dosage was reduced to 10 mg every second day. Within weeks of discontinuing fluoxetine, blood glucose levels had risen considerably and hypoglycaemia did not recur.8

(b) Fluvoxamine

Hypoglycaemia occurred in a 60-year-old woman with type 2 diabetes controlled with insulin, 5 days after fluvoxamine was started. Blood glucose levels, which had approximately doubled, decreased when the fluvoxamine was stopped, but increased and then decreased again when the fluvoxamine was restarted and then stopped.9

A study in 14 healthy subjects given fluvoxamine 75 or 150 mg daily for 5 days, with a single 500-mg dose of tolbutamide on the third day, found that the clearance of tolbutamide was modestly reduced by 19% by the 75 mg dose and by 33% by the 150 mg dose of fluvoxamine. The clearance of its metabolites (4-hydroxytolbutamide and carboxytolbutamide) was also significantly decreased.10

A randomised, double-blind, crossover study in 12 healthy subjects given fluvoxamine 100 mg or placebo daily for 4 days, with a single 500-microgram dose of glimepiride on the fourth day, found the AUC of glimepiride was not significantly affected by fluvoxamine. Peak plasma levels of glimepiride were increased by 43% and the elimination half-life was prolonged from 2 to 2.3 hours, but there was no significant change in the effects of glimepiride on blood glucose concentrations.11

(c) Sertraline

After taking sertraline 200 mg daily for 22 days the clearance of a single intravenous dose of tolbutamide was decreased by 16% in 25 healthy subjects.12 In another study in 11 healthy subjects, the pharmacokinetics of a single 5-mg dose of glibenclamide (glyburide) were found to be unaffected by sertraline, taken in increasing doses up to 200 mg daily over 15 days. Blood glucose levels were also unchanged.13 However, there is a report of a patient with schizophrenia and type 2 diabetes who developed hypoglycaemia during treatment with sertraline, risperidone and glibenclamide.14 In contrast, another report describes a patient with diet-controlled, type 2 diabetes, whose glucose levels increased after initiation of sertraline treatment.15

Mechanism

Fluvocamine probably decreases the clearance of tolbutamide by inhibition of its metabolism by the cytochrome P450 isoenzyme CYP2C9. This mechanism may also partly explain the increase in plasma levels of glimepiride. However, as the glimepiride AUC was not increased and the half-life was only slightly increased, the increase in plasma levels may also be due to an increased rate of glimepiride absorption caused by the SSRI.10,11 The effects of other SSRIs may also be associated with enzyme inhibition.14

Importance and management

There would seem to be little reason for avoiding concurrent use of fluoxetine, fluvoxamine or sertraline with sulphonylureas, but until more is known it would seem prudent to monitor diabetic control. The manufacturers of fluoxetine, paroxetine and sertraline warn that dosages of insulin or oral antidiabetics may need adjustment during concurrent use.5,6,16,17

Antidiabetics + St John’s wort (Hypericum perforatum)

St John’s wort modestly decreases the AUC of rosiglitazone. Repaglinide is similarly metabolised and may therefore be expected to interact similarly. St John’s wort did not affect the metabolism of tolbutamide.

Clinical evidence

(a) Rosiglitazone

A preliminary report of a pharmacokinetic study1 states that St John’s wort 900 mg daily decreased the AUC of a single dose of rosiglitazone by 26% and increased its clearance by 35%.

(b) Tolbutamide

In a study using tolbutamide as a probe drug for CYP2C9 activity, St John’s wort 900 mg daily had no effect on the metabolism of a single dose of tolbutamide either after one day or after 2 weeks of use.2 Similarly, in another study, a St John’s wort preparation with low hyperforin content (Esbericium) at a dose of 240 mg daily had no effect on tolbutamide metabolism.3

Mechanism

Rosiglitazone is known to be metabolised principally by the cytochrome P450 isoenzyme CYP2C8, and it was therefore concluded that St John’s wort induces CYP2C8. The magnitude of the effect of St John’s wort was
not influenced by CYP2C8 genotype. St John’s wort has no effect on the metabolism of tolbutamide via CYP2C9.

**Importance and management**

The clinical relevance of the modest reduction in rosiglitazone levels has not been assessed, but it would seem unlikely to be important. However, the authors state that St John’s wort use should be monitored when patients are given CYP2C8 substrates. Of the antidiabetics, in addition to rosiglitazone, this would also include repaglinide. Note that repaglinide is also a substrate for CYP3A4, of which St John’s wort is an established inducer. Further study is needed. No special precautions would appear to be necessary if tolbutamide and St John’s wort are used together.

### Antidiabetics + Statins

No clinically relevant adverse interactions appear to have been reported between the statins and the sulphonylureas. One study reported an increased incidence of adverse effects with repaglinide and simvastatin, the clinical relevance of which is unclear. Most studies have shown no pharmacokinetic interaction or increased incidence of adverse effects when pioglitazone or rosiglitazone were used with atorvastatin or simvastatin. Subcutaneous exenatide modestly decreased the AUC of lovastatin, but no clear pattern of altered efficacy of statins was noted in exenatide clinical trials.

#### Clinical evidence

**A. Exenatide**

The manufacturer notes that subcutaneous exenatide 10 micrograms twice daily decreased the AUC of a single dose of lovastatin by 40%, and the maximum level by 28%. However, they also note that in clinical trials of exenatide, the use of exenatide for 30 weeks in patients already taking statins was not associated with consistent changes in lipid profiles.

**B. Repaglinide**

A three-period, crossover, open-label study in healthy subjects found that simvastatin 20 mg daily increased the maximum plasma level of repaglinide 2 mg three times daily by 26%, although there was high variability and the mean bioavailability of repaglinide was increased by 8%. There was a higher incidence of adverse effects during concurrent use.

**C. Sulphonylureas**

**(a) Chlorpropamide**

A study in 7 patients with type 2 diabetes and hypercholesterolaemia, taking chlorpropamide 125 to 750 mg daily, found that lovastatin 20 mg twice daily for 6 weeks reduced low-density lipoprotein cholesterol by 28%, total cholesterol by 24% and apolipoprotein B by 24%. The chlorpropamide plasma levels were unchanged, and the diabetic control remained unaltered.

**(b) Glibenclamide (Gliburide)**

Groups of 16 healthy subjects taking fluvastatin 40 mg or simvastatin 20 mg daily were given single 3.5 mg oral doses of glibenclamide on days 1, 8 and 15. The maximum plasma concentration and the AUC of glibenclamide were increased by about 20% by the statins. The blood glucose-lowering effects of the glibenclamide remained virtually unchanged by both fluvastatin and simvastatin in these subjects, and also when fluvastatin was tested in a group of 32 patients with type 2 diabetes. The manufacturers of fluvastatin report a study in which fluvastatin 40 mg twice daily was given to diabetic patients stable taking glibenclamide 5 to 20 mg daily. Fluvastatin increased the AUC of glibenclamide by 1.7-fold, and increased the maximum serum levels by 1.6-fold, without causing significant changes in glucose levels.

A single 1-g oral dose of tolbutamide was given to two groups of 16 healthy subjects taking fluvastatin 40 mg or simvastatin 20 mg. The pharmacokinetics of the tolbutamide were affected only to a very minor extent, and the blood glucose-lowering effects of the tolbutamide were unchanged.

**D. Thiazolidinediones**

One review reported that patients receiving thiazolidinediones (95% taking troglitazone) were more likely to develop hepatotoxicity if taking atorvastatin than when taking simvastatin. However, troglitazone has now been withdrawn due to its hepatotoxic effects. The same authors more recently conducted a similar study. They analysed the FDA adverse event reporting database for reactions affecting muscle, liver, pancreas, or bone marrow where simvastatin or atorvastatin were implicated. They then looked for events where antidiabetic drugs also featured. Of the 3767 events identified for atorvastatin, 40 also involved rosiglitazone and 20 also involved pioglitazone. Of the 3651 events identified for simvastatin, 10 also involved rosiglitazone and 9 also involved pioglitazone. About half of these events involving pioglitazone or rosiglitazone resulted in hospitalisation or death. Although the data did not allow for an assessment of whether this rate was greater than that expected, the authors say that if simvastatin is used as the control, the data suggest that the number of cases of adverse events with atorvastatin and a thiazolidinedione are greater than would be expected by chance alone.

However, in a study in healthy subjects, pioglitazone 45 mg daily did not significantly affect the pharmacokinetics of simvastatin 80 mg daily and concurrent use was well tolerated. Similarly, there was no pharmacokinetic interaction between pioglitazone 45 mg daily and atorvastatin 80 mg daily. Moreover, clinical use of rosiglitazone with atorvastatin in patients with type 2 diabetes for 16 weeks was well tolerated, as was the clinical use of rosiglitazone or pioglitazone with simvastatin.

#### Mechanism

The small changes in the pharmacokinetics of glibenclamide caused by fluvastatin and simvastatin are not understood, but they do not appear to be clinically significant. The interaction between atorvastatin or simvastatin and the thiazolidinediones is thought to involve the cytochrome P450 isoenzyme CYP3A4, although this is as yet unconfirmed.

#### Importance and management

There is little evidence to suggest that special precautions appear to be needed by diabetic patients taking any of the pairs of sulphonylureas and statins cited here (chlorpropamide with lovastatin, or glibenclamide or tolbutamide with fluvastatin or simvastatin). However, the manufacturers of fluvastatin suggest that a serious interaction cannot be ruled out and therefore advise that the use of glibenclamide should be avoided wherever possible.

The clinical significance of the increased incidence of adverse effects with repaglinide and simvastatin is unclear and so an element of caution would seem prudent.

Most studies have shown no pharmacokinetic interaction or increased incidence of adverse effects when pioglitazone or rosiglitazone were used with atorvastatin or simvastatin. The clinical relevance of the apparent increased incidence of adverse muscle and liver effects with the use of pioglitazone or rosiglitazone together with atorvastatin is unclear. Further study is needed. The clinical relevance of the decrease in lovastatin levels with exenatide is also unclear. But experience in clinical studies suggests that it is unlikely to be significant.

Note that a number of the large-scale trials of the use of lipid-regulating drugs in primary or secondary prevention of cardiovascular events included patients with diabetes. A review of these subgroups concluded that statins were the drug of choice for lipid-lowering therapy in patients with type 2 diabetes and known coronary artery disease or other cardiovascular risk factors. There was no evidence to recommend one statin over another.

Antidiabetics + Sulfinpyrazone

Sulfinpyrazone has no effect on the insulin requirements of diabetics, nor does it affect the control of diabetes in patients taking glibenclamide (glyburide). Increased blood glucose-lowering effects might occur if sulfinpyrazone is given with tolbutamide, but as yet there appear to be no case reports of this interaction. Sulfinpyrazone modestly increased the AUC of nateglinide, but this is unlikely to be clinically relevant.

Clinical evidence

(a) Insulin
A double-blind study in 41 adult diabetics found that sulfinpyrazone 600 to 800 mg daily had no clinically significant effects on insulin requirements over a 12-month period.1

(b) Nateglinide
In a crossover study in healthy subjects, sulfinpyrazone 200 mg twice daily for 7 days increased the mean AUC of a single 120-mg dose of nateglinide by 28%, but did not change the mean maximum plasma level.2

(c) Sulphonylureas
A study in 19 type 2 diabetics taking glibenclamide found that sulfinpyrazone 800 mg daily did not affect diabetic control.3

A detailed study of the pharmacokinetics of tolbutamide in 6 healthy subjects found that sulfinpyrazone 200 mg every 6 hours for a week, almost doubled the half-life of a 500-mg intravenous dose of tolbutamide, from 7.3 to 13.2 hours, and reduced the plasma clearance by 40%.4

Mechanism
Sulfinpyrazone is an inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which tolbutamide and nateglinide are metabolised.

Importance and management
Information about an interaction between tolbutamide and sulfinpyrazone appears to be limited to the report cited. So far there appear to be no reports of adverse interactions in patients, but what is known suggests that increased blood glucose-lowering effects, and possibly hypoglycaemia could occur if the dosage of tolbutamide is not reduced. Such an interaction has been described with phenylbutazone, which has a close structural similarity to sulfinpyrazone (see ‘Antidiabetics + NSAIDs; Phenylbuta-zone and related drugs’, p.498). Patients should be warned if sulfinpyrazone is added to established treatment with tolbutamide. The modest increase in nateglinide exposure when given with sulfinpyrazone has not been assessed in diabetics, but it seems unlikely to be clinically relevant. There seems to be nothing documented about any other clinically important interactions between antidiabetics and sulfinpyrazone.

Antidiabetics + Sugar-containing pharmaceuticals

Some pharmaceutical preparations may contain sufficient amounts of sugar to affect the control of diabetes. Diabetics should be warned and advised of sugar-free alternatives wherever appropriate.

Clinical evidence, mechanism, importance and management
Pharmaceuticals, especially liquid formulations, may contain sugar in significant amounts. The extent to which the use of preparations like these will affect the control of diabetes clearly depends upon the amounts ingested, but the problem is by no means merely theoretical. One report describes the loss of diabetic control (glycosuria) in a woman with type 1 diabetes receiving insulin when given psyllium effervescent powder (Metamucil instant-mix), which contains sugar.1

The range of other sugar-containing preparations is far too extensive to be listed here. Because of concerns over sugar-containing medicines and dental caries, in children in particular, the number of sugar-free preparations has grown considerably over recent years. In the UK the BNF and MIMS provide guidance as to which preparations are sugar-free. Diabetics should be warned about sugar-containing medicines, and given guidance about the terminology used in labelling. Sweetening agents of note to diabetics include: invert sugar (dextrose and fructose), invert syrup (67% w/w invert sugar), syrup BP (66% w/w sucrose), glucose liquid (dextrose content 10 to 20%), glucose syrup (33.3% liquid glucose in syrup) and honey (70 to 80% glucose and fructose).2

Antidiabetics + Sulfinpyrazone

Sulfinpyrazone has no effect on the insulin requirements of diabetics, nor does it affect the control of diabetes in patients taking glibenclamide (glyburide). Increased blood glucose-lowering effects might occur if sulfinpyrazone is given with tolbutamide, but as yet there appear to be no case reports of this interaction. Sulfinpyrazone modestly increased the AUC of nateglinide, but this is unlikely to be clinically relevant.

bly acute hypoglycaemia has occurred in individual patients taking various combinations of sulfonamides and sulphonylureas. There appear to be no reports of a serious adverse interaction between insulin and the sulfonamides. Co-trimoxazole alone may rarely cause hypoglycaemia.

**Clinical evidence**

‘Table 13.3’, (p.508) summarises the information on the interactions between sulphonylureas and sulfonamides. For a report of the combined use of co-trimoxazole and fluconazole causing hypoglycaemia with glucidaze, see ‘Antidiabetics + Azoles; Fluconazole’, p.479.

**Mechanism**

The sulfonamides may inhibit the metabolism of the sulphonylureas so that they accumulate in the body. In this way their serum levels and blood glucose-lowering effects are enhanced.1-4 Greater understanding of metabolic mechanisms has led to the realisation that some sulfonamides are inhibitors of the cytochrome P450 isoezyme CYP2C9 by which many of the sulphonylureas are metabolised. Tolbutamide, in particular, is now recognised as an important substrate of CYP2C9.5,6 Of the sulfonamides, in vitro data suggest that sulfaphenazole is a potent inhibitor of CYP2C9, with sulfadimethoxine, sulfamethoxazole, sulfafluroxazole (sulfisoxazole) and sulfaflumethoxine being moderate to minor inhibitors, and sulfapyridine, sulfadimethoxine and sulfamonomethoxine having little inhibitory activity.6 CYP2C9 shows genetic polymorphism, therefore any interaction might only be clinically relevant in a subgroup of the population. There is also some evidence that the sulfonamides can displace the sulphonylureas from their protein binding sites.5 Where some of the cases of hypoglycaemia cannot be predicted on pharmacokinetic grounds, it is worth noting that hypoglycaemia induced by co-trimoxazole, in the absence of a conventional antidiabetic,3,11 and sometimes associated with renal failure,9 high dose of sulfonamide,7,11 advanced age,5,10 or malnutrition,7 has been described. Note that trimethoprim alone may cause interactions mediated via inhibition of CYP2C8 and CYP2C9, see ‘Antidiabetics + Trimethoprim’, p.510.

**Importance and management**

Information is very patchy and incomplete. Most sulfonamides seem to have caused marked problems (acute hypoglycaemia) in only a few patients and serious interactions are uncommon. When a sulfonamide is first added to established treatment with a sulphonylurea, warn the patient that increased blood glucose-lowering effects, sometimes excessive, are a possibility, but that problems appear to be uncommon or rare. Nevertheless, the cautious approach would be to increase the frequency of blood glucose monitoring. In one study, co-trimoxazole did not appear to cause any significant changes in blood glucose or insulin concentrations in patients receiving insulin.12 However, note that co-trimoxazole alone may rarely cause hypoglycaemia (see Mechanism above). For the interactions of trimethoprim alone, see ‘Antidiabetics + Trimethoprim’, p.510.

**Antidiabetics + Terbinafine**

Terbinafine is reported not to interact with tolbutamide, and did not affect glucose control in a study in patients treated with insulin or oral antidiabetics.

**Clinical evidence**

A large-scale post-marketing survey did not find any interaction in patients taking terbinafine with tolbutamide [number unknown].1 In a 154 patient subgroup of this survey no additional risk was noted in patients taking antidiabetics with terbinafine.2 In a clinical trial in 89 patients with diabetes and toenail fungal infections, oral terbinafine 250 mg daily for 12 weeks had no effect on blood glucose levels in 83% of patients. Eleven (12.4%) of the patients had an elevated blood glucose level at baseline, which was normal at the end of the study, and 4 patients had a normal baseline blood glucose, which became elevated at the end of the study. No episodes of hypoglycaemia were reported. Patients in this study were treated with insulin or oral antidiabetics (not specified).3

**Mechanism**

On the basis of studies with human liver microsomes, terbinafine is unlikely to alter the metabolism of tolbutamide.4

**Antidiabetics + Tetracyclines**

A few early reports indicated that the blood glucose-lowering effects of insulin and the sulphonylureas may sometimes be increased by oxytetracycline. There is also a case of hypoglycaemia involving insulin and doxycycline. Phenformin-induced lactic acidosis may be precipitated by tetracyclines.

**Clinical evidence**

(a) **Insulin**

A diabetic with poorly controlled blood glucose levels needed a marked reduction in his insulin dosage from 208 to 64 units daily in order to control the hypoglycaemia that developed when oxytetracycline 250 mg four times daily was given. This reaction was also seen when the patient was given a second course of antibacterials, and in another patient.1 A report briefly lists a case of hypoglycaemia when a patient receiving insulin was given doxycycline;2 and another case describes doxycycline-induced hypoglycaemia in an elderly diabetic patient treated by diet alone.3

(b) **Phenformin**

There are now at least 6 cases on record of lactic-acidosis in patients taking phenformin that were apparently precipitated by the concurrent use of tetracycline.4,7

(c) **Sulphonylureas**

Marked hypoglycaemia occurred in an elderly patient taking tolbutamide when oxytetracycline was given,3 and another study in diabetic patients similarly found that oxytetracycline could reduce blood glucose levels.9 The half-life of glymidine has been found to be prolonged from 4.6 to 7.6 hours by doxycycline,10 whereas a brief comment in another report...

Continued
suggested that **demeclcycline** and **doxycycline** may not affect **chlorpropamide** disposition.\(^\text{11}\)

**Mechanism**

Not understood. Several mechanisms have been suggested including prolongation of the half-life of insulin and interference with adrenaline-induced glycaemia.\(^\text{3}\)

### Importance and management

Information about the interactions between the sulphonylureas or insulin and the tetracyclines is very limited indeed, and clinically important interactions appear to be very uncommon. Concurrent use need not be avoided, but be aware of this interaction in case of an unexpected response to treatment.

Phenformin was withdrawn in some countries because it was associated with a high incidence of lactic acidosis; where available, concurrent use with tetracyclines should be avoided. However, there is nothing to suggest that there is an increased risk if tetracyclines are given with metformin.\(^\text{1}\)

</tr>
</thead>
<tbody>
<tr>
<td>Antidiabetics + Thiocyclic acid</td>
<td>Thiocic acid is reported not to interact with acarbose, metformin or glibenclamide (glyburide).</td>
</tr>
</tbody>
</table>

#### Clinical evidence, mechanism, importance and management

A study in 24 healthy subjects given tablets containing thiocic acid 200 mg and metformin 500 mg found that the pharmacokinetics of the metformin were unchanged by the presence of the thiocic acid, and the authors of the report say that there was also no pharmacodynamic interaction.\(^\text{1}\) The report gives very few details. A further study in 24 healthy subjects found that a single 600-mg dose of thiocic acid given with glibenclamide (glyburide) 3.5 mg did not result in any clinically relevant pharmacokinetic interaction, and thiocic acid did not alter the effect of glibenclamide on glucose or insulin levels.\(^\text{2}\) Similarly, there was no evidence of a change in thiocic acid pharmacokinetics or pharmacodynamics when it was given to healthy subjects with acarbose.\(^\text{2}\)

No special precautions seem to be required if thioctic acid is given to patients taking acarbose, metformin or glibenclamide.\(^\text{1}\)

### Antidiabetics + Tibolone

**Tibolone may slightly impair glucose tolerance and therefore possibly reduce the effects of the antidiabetics.**

**Clinical evidence, mechanism, importance and management**

One woman developed diabetes 14 weeks after starting tibolone 2.5 mg daily. However, she had a high normal fasting blood glucose level before starting tibolone, and the diabetes did not resolve on withdrawing the drug.\(^\text{1}\) The manufacturers of tibolone noted that on their adverse drug event database they had only 3 cases of diabetes occurring during the use of tibolone, and 3 cases of aggravation of diabetes during its use, which they considered a very low number in relation to the extent of tibolone use.\(^\text{2}\)

A metabolic study in 10 women with type 2 diabetes given tibolone 2.5 mg daily and stabilised with diet and oral antidiabetics found there were no changes in glycaemic control, as measured by glycosylated hagemoglobin levels.\(^\text{3}\) Conversely, a longer 12-month study in 14 women with type 2 diabetes given tibolone found a slight deterioration in glycaemic control (as measured by serum fructosamine),\(^\text{4}\) and an early study found that tibolone caused a slight decrease in glucose tolerance in non-diabetic patients.\(^\text{5}\)

The manufacturers of tibolone say that patients with diabetes should be closely supervised.\(^\text{6,7}\) It would therefore seem prudent to increase the frequency of blood glucose monitoring if tibolone is started or stopped.

### Antidiabetics + Tobacco or Nicotine

Diabetics who smoke tobacco may need more subcutaneous insulin than non-smokers. Smoking or, to a lesser extent, nicotine patches may increase insulin resistance, and stopping smoking can improve glycaemic control in both type 1 and type 2 diabetes. However, the effects of smoking on diabetes appear to be complex, as some studies have reported that smoking does not affect insulin sensitivity or glycaemic control. Preliminary evidence shows that smoking increases the absorption of inhaled insulin.
Clinical evidence, mechanism, importance and management

A study in 163 patients with type 1 diabetes found that, on average, the 114 who smoked needed to 15%–20% more subcutaneous insulin than the non-smokers, and up to 30% more insulin if they smoked heavily.1 Possible mechanisms include decreased absorption of insulin from the subcutaneous tissue because of peripheral vasoconstriction,2 and a significant rise (40% to 100%) in the levels of the hormones that oppose the actions of insulin.3,4

Serum insulin levels during the first 6 hours after smoking were 58% higher in smokers than in non-smokers, and peak insulin levels were about threefold higher. Minor hypoglycaemia requiring a glucose infusion occurred in 12 smokers but not in only one non-smoker. The increased absorption was possibly due to cigarette smoke increasing the permeability of the alveolar-capillary barrier.3 It should be noted that use of inhaled insulin is contraindicated in patients who smoke, or have smoked within the past 6 months.6

In a double-blind, crossover study in 12 smokers with type 2 diabetes, stabilised with diet alone or with oral antidiabetics, the effect of smoking one cigarette every hour for 6 hours compared with transdermal nicotine (30 cm² patch) or a placebo patch. Cigarette smoking and the nicotine patch did not affect endogenous insulin secretion, when compared with placebo, but smoking impaired peripheral insulin action, and resulted in lower rates of glucose utilisation and greater hepatic glucose production. The nicotine patch similarly impaired insulin action, but this was much less pronounced than after cigarette smoking, possibly due to the lower plasma levels of nicotine attained with the patch.7

In another study, glycaemic control (as measured by glycosylated haemoglobin) was modestly improved in 7 subjects with type 1 diabetes and 27 subjects with type 2 diabetes, one year after they had stopped smoking. This improved control was considered clinically significant.8 In a study in patients with type 2 diabetes stabilised with diet alone or diet plus sulphonylureas with or without metformin, insulin resistance was higher in the 28 smokers than the 12 non-smokers.9 Further studies have reported that smoking in diabetics is associated with poor glycaemic control,10 microalbuminuria,10 and impaired insulin clearance.11 However, other studies have suggested that smoking does not affect insulin requirement in type 1 diabetes12 or have a significant effect on glycaemic control in type 1 or type 2 diabetes.13,14 There are numerous other studies on the relationship between smoking and diabetes or insulin resistance in non-diabetics, and only a few are cited here as examples. Some studies have indicated that smoking could increase the risk of type 2 diabetes (relative risk of 2.6), and that tobacco use is associated with a low insulin response.15 However, other studies suggest that a causal relationship between smoking and insulin resistance is unlikely,15,16 although in one of the studies16 exposure to environmental tobacco smoke was associated with lower insulin sensitivity. Glycaemic control is not the only factor of importance with smoking in diabetics. Cigarette smoking may also accelerate progression of atherosclerosis, increase blood pressure, and increase macrovascular complications.17 Diabetics who smoke should be given all the help they need to stop smoking.10,17

• A patient taking tolvazamide became hypoglycaemic 11 days after starting to take doxepin 250mg daily. The patient was eventually stabilised on a daily dose of tolazamide that was only 10% of that used before the doxepin was given.1
• A patient taking chlorpropamide (initially 25mg increased to 75mg daily) developed marked hypoglycaemia 3 days after starting nortriptyline 125mg daily. The chlorpropamide was stopped.5
• A patient receiving insulin developed violent and agitated behaviour (but no adrenergic symptoms) and hypoglycaemia when she started to take amitriptyline 25mg at bedtime.6
• An elderly diabetic woman taking gliclazidamide (glyburide) and phenformin developed hypoglycaemia when given maprotiline. She was stabilised on half the dose of gliclazidamide and phenformin.7

Apart from these isolated cases3–5 the literature seems to be silent about interactions between these antidiabetics and the tricyclic or tetracyclic antidepressants. Bearing in mind the length of time these groups of drugs have been available, the risk of a clinically important interaction would seem to be very small.

Antidiabetics + Trimethoprim

Clinical evidence, mechanism, importance and management

A study in 4 patients suggested that amitriptyline 75 mg daily for 9 days did not affect the half-life of a single 500-mg dose of tolbutamide.1 Although there is some evidence of a change in glucose metabolism during treatment with mianserin,2,4 the alteration failed to affect the control of diabetes in a study in 10 patients and there appear to be no reports of adverse effects caused by concurrent use.3 In contrast there are four case reports describing interactions:

• A patient taking tolazamide became hypoglycaemic 11 days after starting to take doxepin 250 mg daily. The patient was eventually stabilised on a daily dose of tolazamide that was only 10% of that used before the doxepin was given.1
• A patient taking chlorpropamide (initially 25 mg increased to 75 mg daily) developed marked hypoglycaemia 3 days after starting nortriptyline 125 mg daily. The chlorpropamide was stopped.5
• A patient receiving insulin developed violent and agitated behaviour (but no adrenergic symptoms) and hypoglycaemia when she started to take amitriptyline 25 mg at bedtime.6

Antidiabetics + Trimethoprim

Trimethoprim increases the AUC of repaglinide and would be expected to interact with its effects in some patients. The effect of trimethoprim on the AUC of rosiglitazone is more modest and less likely to be clinically relevant. Trimethoprim does not appear to significantly affect the pharmacokinetics of intravenous tolbutamide.

Clinical evidence

(a) Repaglinide

In a study in 9 healthy subjects trimethoprim 160 mg twice daily for 3 days increased the AUC and the maximum plasma level of a single 250-microgram dose of repaglinide by 61% and 41%, respectively. However, the blood glucose-lowering effect of repaglinide was unchanged.1
In a study to 10 healthy subjects trimethoprim 160 mg twice daily for 4 days increased the AUC of a single 4-mg dose of rosiglitazone given on day 3 by 37%. The half-life of rosiglitazone was increased by 26% but the peak plasma level was only slightly affected (14% increase). Similarly, in another study, trimethoprim 200 mg twice daily for 5 days increased the AUC of a single 8-mg dose of rosiglitazone by 31% and increased the half-life by 27%.

Mechanism

Data suggest that trimethoprim inhibits the metabolism of repaglinide and rosiglitazone by the cytochrome P450 isoenzyme CYP2C8. Tolbutamide is metabolised by CYP2C9, and it is thought possible that trimethoprim may have a slight inhibitory effect on this isoenzyme, although there is very little information about this.

Importance and management

The clinical relevance of the pharmacokinetic changes have not been assessed. However, the changes seen with repaglinide suggest that some patients might experience an increase in the effects of this drug. The UK manufacturers of repaglinide suggest that the concurrent use of trimethoprim should be avoided as the effect of larger doses of both drugs are unknown. The US manufacturers suggest that trimethoprim dosage adjustments may be necessary. If both drugs are used it would seem prudent to increase the frequency of blood glucose monitoring until the effects are known.

The more modest increase in AUC of rosiglitazone is less likely to be clinically important, but, until more experience is gained, some caution is warranted. No interaction would be expected between trimethoprim and tolbutamide, although note that co-trimoxazole has rarely caused hypoglycaemia alone or combined with various sulphonylureas, see ‘Antidiabetics + Sulfonylamides’, p.506.

**Insulin + Naltrexone**

The insulin requirements of a patient rose by about 30% when naltrexone was given.

Clinical evidence, mechanism, importance and management

A patient with type 1 diabetes was given naltrexone in an experimental study of the treatment of anorexia nervosa. During two periods of 5 days while taking the naltrexone (dosage not stated), the blood glucose levels of the patient remained unchanged but the insulin dosage requirements rose from 52.8 and 61.4 units daily to 71.4 and 76 units daily (a rise of about 30%). The reason is not known but the authors of this report point out that this apparent interaction must have been due to the actions of insulin rather than on its release because this patient had no endogenous insulin.

The general clinical importance of this interaction is not known but it would be prudent to be alert for any evidence of increased insulin requirements if naltrexone is used in any patient.

**Metformin + Cefalexin**

Cefalexin modestly increased the serum levels of metformin in a single-dose study.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 12 healthy subjects cefalexin 500 mg increased the AUC and maximum serum levels of a single 500-mg dose of metformin by 24% and 34%, respectively. Cefalexin reduced the renal clearance of metformin by 14% by inhibiting metformin tubular secretion via the organic cation system. The clinical relevance of these small changes is uncertain, but they could be greater with longer-term use. The authors recommend that patients receiving metformin with cefalexin should have metformin levels monitored or an alternative antibacterial to cefalexin should be considered. However, based on the available evidence this seems somewhat overcautious.

**Metformin + Iodinated contrast media**

Parenteral administration of iodinated contrast media may cause renal failure, which could result in lactic acidosis in patients taking metformin.

Clinical evidence, mechanism, importance and management

Parenteral administration of iodinated contrast media to patients taking metformin may result in lactic acidosis. However, the problem is reported to occur only if the contrast media causes renal failure and metformin use is continued. This is because metformin is mainly excreted by the kidneys and in renal failure toxic levels may accumulate, which may result in lactic acidosis. A literature search identified 18 cases of lactic acidosis after the use of contrast media in patients taking metformin. Of these 18 cases, 14 or 15 were associated with pre-existing renal impairment and 2 cases with other contraindications to metformin (sepsis and cirrhosis). The remaining case was in an elderly woman with neurological disease. The manufacturers of metformin say that it should be stopped before, or at the time of giving the contrast media and not restarted until 48 hours later, and then only after renal function has been re-checked and found to be normal. Guidelines issued by the Royal College of Radiologists are based on this statement and they say that referring clinicians should assess renal function before the test. Similar guidelines have been issued by the European Society for Urogenital Radiology. Nevertheless, some consider that metformin need not be stopped for 48 hours in those patients with normal renal function. However, a more recent analysis supports the guidelines. Of 97 patients taking metformin who were given intravenous contrast media, 4 developed contrast media-associated nephropathy (all 4 had baseline normal renal function). These patients could have been at increased risk of metformin-associated lactic acidosis had the metformin not been stopped and withheld, as suggested by the guidelines.

Pioglitazone + Fexofenadine

A study in healthy subjects indicated that the pharmacokinetics of pioglitazone 45 mg daily are not significantly affected by fexofenadine 60 mg twice daily, and that pioglitazone does not affect the pharmacokinetics of fexofenadine.

Pioglitazone or Rosiglitazone + Insulin

Pioglitazone and rosiglitazone may cause fluid retention and peripheral oedema, which can worsen or cause heart failure. There is evidence that the incidence of these effects is higher when combined with insulin. The incidence of hypoglycaemia may also be increased.

Clinical evidence

(a) Pioglitazone

It has been noted that in patients receiving insulin the dose may need to be reduced by 10 to 25% if pioglitazone 15 or 30 mg daily is given. In one 16-week, randomised, double-blind, placebo-controlled study, pioglitazone 15 or 30 mg with insulin was compared with insulin alone in 566 patients with long-standing diabetes. Oedema was reported in 15.3% of the patients receiving pioglitazone plus insulin (12.6% and 17.6% with pioglitazone 15 mg and 30 mg, respectively) compared with 7% when insulin was given alone. Four of the 379 patients given with pioglitazone and insulin developed congestive heart failure compared with none of the 187 patients given insulin alone; all 4 had a history of cardiovascular disease. Analysis of this study did not identify specific factors that predict this possible increased risk of congestive heart failure. One case report describes a 57-year-old obese man with type 2 diabetes, no history of heart failure and excellent exercise tolerance, who was given insulin and pioglitazone 30 mg daily. Over the first 4 weeks after starting pioglitazone he developed significant weight gain and subsequently developed heart failure and pulmonary oedema.

(b) Rosiglitazone

A randomised, double-blind, placebo-controlled study in patients with poorly-controlled type 2 diabetes receiving insulin twice daily found that the addition of rosiglitazone 2 or 4 mg twice daily for 26 weeks improved the control of their blood glucose levels and they needed less insulin. Mean total daily insulin reductions were 12% for the 4 mg dose, 5.6% for the 2 mg dose, and 0.6% for placebo. Symptoms consistent with hypoglycaemia also occurred more frequently with the combination; 67% with the 4 mg rosiglitazone dose, 53% with the 2 mg dose, and 38% with placebo. The incidence of oedema was about threefold higher in those patients given insulin and rosiglitazone; 16.2% with the 4 mg dose, and 13.1% with the 2 mg dose, compared with 4.7% in those given placebo. Congestive heart failure occurred in 4 of 209 patients receiving the combination compared with 1 of 104 receiving placebo. However, 2 of the patients receiving rosiglitazone had a prior history of coronary heart disease.

From results of clinical studies, the UK manufacturer has reported an incidence of heart failure of 1.1% with insulin monotherapy and 2.4% when combined with rosiglitazone. In a pilot study in 8 massively obese patients with type 2 diabetes, taking large doses of insulin, the use of rosiglitazone 8 mg daily allowed a 22% reduction in the median insulin dose, and improved glycaemic control. However, 5 of the 8 patients (63%) developed peripheral oedema. One case report described 2 patients receiving insulin who developed congestive heart failure 6 to 12 months after starting rosiglitazone. They recovered when rosiglitazone was withdrawn and diuretic doses increased. Another patient taking metformin, glimepiride, rosiglitazone and insulin unusually developed unilateral oedema 2 years after starting rosiglitazone, which resolved on stopping the rosiglitazone, and reappeared within 5 days of restarting it.

Mechanism

Pioglitazone or rosiglitazone alone can exacerbate or precipitate heart failure because they can cause fluid retention and weight gain. Fluid retention and tissue oedema appear to be part of a vascular ‘leak’ syndrome but, additionally, thiazolidinediones may potentiate the renal effects of insulin on sodium and water retention. It is conceivable that increased fluid retention caused by thiazolidinediones may alter the already precarious volume status in patients with underlying cardiac or renal dysfunction thus leading to congestive heart failure. However, congestive heart failure has been estimated to occur in as many as 12% of patients who have type 2 diabetes and whether the incidence of heart failure in patients given thiazolidinediones and insulin is simply a reflection of other factors that increase the risk in these patients, or due to some specific interaction with insulin, remains to be established.

Importance and management

The fact that rosiglitazone and pioglitazone can cause weight gain and peripheral oedema, and that the incidence of this is greater in patients who are also receiving insulin. An estimated 2 to 5% of patients receiving thiazolidinedione monotherapy and 5 to 15% receiving concurrent insulin therapy experience peripheral oedema. Fluid retention and tissue oedema appear to be part of a vascular ‘leak’ syndrome but, additionally, thiazolidinediones may potentiate the renal effects of insulin on sodium and water retention. It is conceivable that increased fluid retention caused by thiazolidinediones may alter the already precarious volume status in patients with underlying cardiac or renal dysfunction thus leading to congestive heart failure. However, congestive heart failure has been estimated to occur in as many as 12% of patients who have type 2 diabetes and whether the incidence of heart failure in patients given thiazolidinediones and insulin is simply a reflection of other factors that increase the risk in these patients, or due to some specific interaction with insulin, remains to be established.
The pharmacokinetics of metformin are not altered by pioglitazone or rosiglitazone. Pioglitazone does not alter glipizide pharmacokinetics. Rosiglitazone does not have an important effect on glibenclamide (glyburide) pharmacokinetics, and does not alter glimepiride pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Metformin

In healthy subjects, pioglitazone 45 mg daily for 7 days did not alter the pharmacokinetics of a single 1-g dose of metformin.1,2 The steady-state pharmacokinetics of metformin 500 mg twice daily and rosiglitazone 2 mg twice daily were not affected when they were given to healthy subjects for 4 days.3,4 No special precautions appear to be needed if metformin is used with the thiazolidinediones.

(b) Sulphonylureas

In healthy subjects, pioglitazone 45 mg daily for 7 days did not alter the steady-state pharmacokinetics of glipizide 5 mg daily.1,2 Rosiglitazone 2 mg twice daily for 7 days did not alter the mean steady-state 24-hour plasma glucose levels in diabetes taking glibenclamide (glyburide) 3.75 to 10 mg daily. However, rosiglitazone 8 mg daily for 8 days caused a decrease of about 20% in the AUC of glibenclamide in healthy Caucasian subjects, and a slight increase in the AUC of glibenclamide in Japanese subjects.3,5 These changes are not considered clinically relevant.3,5 No pharmacokinetic interaction appears to occur between glimepiride and rosiglitazone.3

No special precautions appear to be needed if these sulphonylureas are used with the thiazolidinediones.

Sitagliptin + Miscellaneous

Single-dose ciclosporin slightly increased the absorption of sitagliptin, although this was not considered clinically relevant. Sitagliptin does not have a clinically relevant effect on the pharmacokinetics of digoxin, oral contraceptives, simvastatin or warfarin.

Clinical evidence, mechanism, importance and management

(a) Cyclosporin

A crossover study in 8 healthy subjects found that when a single 100-mg dose of sitagliptin was given with a single 600-mg dose of ciclosporin there was a 68% increase in the maximum plasma levels of sitagliptin, with a slight increase in overall exposure to sitagliptin (AUC increased by 28%). It is likely that ciclosporin enhances the absorption of sitagliptin via inhibition of P-glycoprotein. However, these changes were considered unlikely to be clinically meaningful, because of the apparent wide therapeutic index of sitagliptin.1

(b) Digoxin

The manufacturers describe a study in which digoxin 250 micrograms daily was given with sitagliptin 100 g daily for 10 days. The AUC and maximum plasma levels of digoxin were increased by 11% and 18%, respectively, which was not considered to be clinically significant.2,3 Therefore it is unlikely that the dose of digoxin will need to be altered on concurrent use.

(c) Hormonal contraceptives

Sitagliptin did not appear to alter the pharmacokinetics of norethisterone (norethindrone) or ethinylestradiol given as part of an oral contraceptive.2,3

(d) Simvastatin

Sitagliptin did not appear to alter the pharmacokinetics of a single dose of simvastatin.2,3

(e) Warfarin

Sitagliptin did not appear to affect the pharmacokinetics or either S- or R-warfarin, or the INR in response to warfarin.2,3

The blood glucose-lowering effects of tolbutamide and chlorpropamide can be increased by chloramphenicol and acute hypoglycaemia can occur.

Clinical evidence
A man taking chloramphenicol 2 g daily started taking tolbutamide 2 g daily. Three days later he had a typical hypoglycaemic collapse and was found to have serum tolbutamide levels three to fourfold higher than expected.1 Studies in diabetics have shown that chloramphenicol 2 g daily can increase the serum level and half-life of tolbutamide twofold, and two to threefold, respectively.1,2 Blood glucose levels were reduced by about 25 to 30%.2-3 Hypoglycaemia, acute in one case, developed in two other patients taking tolbutamide with chloramphenicol.4,5 In another study chloramphenicol 1 to 2 g daily caused an average twofold increase in the half-life of chlorpropamide.6

Mechanism
Chloramphenicol inhibits the liver enzymes concerned with the metabolism of tolbutamide, and probably chlorpropamide as well, leading to their accumulation in the body. This is reflected in prolonged half-lives, reduced blood glucose levels and occasionally acute hypoglycaemia.1,4,6

Importance and management
The interaction between tolbutamide and chloramphenicol is well established and of clinical importance. The incidence is uncertain, but increased blood glucose-lowering effects should be expected if both drugs are given. The interaction between chlorpropamide and chloramphenicol is less well documented. Nevertheless, monitor concurrent use carefully and reduce the dosage of the sulphonylureas as necessary. Some patients may show a particularly exaggerated response. The manufacturers of other sulphonylurea often list chloramphenicol as an interacting drug, based on its interactions with tolbutamide and chlorpropamide, but direct information of an interaction does not appear to be available. No interaction would be expected with chloramphenicol eye drops, because the systemic absorption is likely to be small.1

Sulphonylureas + Heparin
Isolated reports describe hypoglycaemia in two diabetic patients, one taking glipizide, the other taking glibenclamide (glyburide). The effects were attributed to the concurrent use of heparin.1

Clinical evidence, mechanism, importance and management
A diabetic, taking glipizide 5 mg daily for 6 months, with fair control was hospitalised for the treatment of a foot ulcer. Over a period of 4 days he experienced recurring episodes of hypoglycaemia after taking a routine 5-mg dose of glipizide. It was suggested that this might possibly have been due to an interaction with subcutaneous heparin calcium 5000 units every 12 hours which was suggested, might have displaced the glipizide from its protein binding sites.1 Another report mentions that hypoglycaemia developed in a patient taking glibenclamide (glyburide) and heparin.2 No other information seems to be available. The general importance of these reports is unknown, but seems likely to be small.1

Sulphonylureas + Methysergide
A preliminary study indicated that methysergide may enhance the effects of tolbutamide.

Clinical evidence, mechanism, importance and management
Pretreatment with methysergide 2 mg every 6 hours for 2 days increased the amount of insulin secreted in response to a 1-g intravenous dose of tolbutamide by almost 40% in 8 patients with type 2 diabetes.1 Whether in practice the addition or withdrawal of methysergide adversely affects the control of diabetes is uncertain, but the possibility should be borne in mind.

Sulphonylureas + Chlorpropamide + Urinary acidifiers or alkalinisers
On theoretical grounds the response to chlorpropamide may be decreased if the urine is made alkaline, and increased if urine is acidified.

Clinical evidence, mechanism, importance and management
A study in 6 healthy subjects given a 250-mg oral dose of chlorpropamide found that when the urine was made alkaline (pH 7.1 to 8.2) with sodium bicarbonate, the half-life of the chlorpropamide was reduced from 50 to 13 hours, and the 72-hour clearance was increased fourfold. In contrast, when the urine was acidified (pH 5.5 to 4.7) with ammonium chloride, the chlorpropamide half-life was increased from 50 to 69 hours and the 72-hour urinary clearance was decreased to 5%, and non-renal (i.e. metabolic) clearance predominated.1 Another study found that the renal clearance of chlorpropamide was almost 100 times greater at pH 7 than at pH 5.2 The reasons are that changes in urinary pH affect the ionisation of the chlorpropamide, and this affects the ability of the kidney to reabsorb it from the kidney filtrate (see more details under ‘Drug excretion interac-
tions’, (p. 7)). Thus, urinary pH determines the relative contribution of renal and metabolic clearance.

There appear to be no reports of adverse interactions between chlorpropamide and drugs that can alter urinary pH, but prescribers should be aware of the possibilities: a reduced response if the pH is raised significantly and renal clearance predominates (e.g. with sodium bicarbonate, acetazolamide, some antacids); an increased response if the pH is made more acid than usual and metabolic clearance predominates (e.g. with ammonium chloride). Perhaps more importantly, the effects of drugs that alter the hepatic clearance of chlorpropamide are likely to be more significant when its renal clearance is low (i.e. when the urine is acid).2

Sułphonylureas; Glibenclamide (Glyburide) + Bosentan

There appears to be an increased risk of liver toxicity if bosentan is given with glibenclamide, and the combination should probably be avoided. Glibenclamide modestly reduces the plasma levels of bosentan, and bosentan reduces the plasma levels of glibenclamide.

Clinical evidence, mechanism, importance and management

In clinical studies, bosentan was noted to be associated with dose-related asymptomatic elevations in liver enzymes in some patients, and these elevations were higher in patients also receiving glibenclamide.1 Study in rats confirmed that combined use of bosentan and glibenclamide caused increases in serum bile salt levels that were greater than with either drug alone.1 In addition, in vitro study showed bosentan inhibits the bile salt export pump.2 Glibenclamide also inhibits this pump. Because of the possibility that there may be a pharmacokinetic component to the interaction, the pharmacokinetics of both bosentan and glibenclamide were determined in a crossover study in 12 healthy subjects. However, glibenclamide actually reduced the maximum plasma levels and AUC of bosentan by 24 and 29%, respectively, while bosentan reduced the maximum plasma levels and AUC of glibenclamide by 22 and 40%, respectively. Two subjects had asymptomatic elevated liver enzyme levels while taking bosentan with glibenclamide.2

Based on the limited evidence available about the increased risk of liver toxicity, the UK manufacturer of bosentan recommends that it should not be used with drugs that are inhibitors of the bile salt export pump, such as glibenclamide. They suggest that an alternative antidiabetic drug should be avoided. Glibenclamide modestly reduces the plasma levels of bosentan, and bosentan reduces the plasma levels of glibenclamide.

Sułphonylureas; Glymidine + Phenobarbital

A study in 18 elderly patients with type 2 diabetes and symptoms of dementia, taking glibenclamide (glyburide), found that 4 days of treatment with vinpocetine 10 mg three times daily did not affect either the pharmacokinetics of the glibenclamide or the control of blood glucose levels.1 There would seem to be no reason for avoiding concurrent use.

Sułphonylureas; Tolbutamide + Aprepitant

Aprepitant slightly reduces tolbutamide levels.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects aprepitant (125 mg on day one, then 80 mg daily on days 2 and 3) decreased the AUC of a single 500-mg dose of tolbutamide by 23%, 28%, 15%, when given on days 4, 8, and 15, respectively, when compared with 12 subjects not given aprepitant.1 Aprepitant is an inducer of the cytochrome P450 isoenzyme CYP2C9 by which tolbutamide is metabolised. It therefore increases tolbutamide metabolism, which leads to a reduction in tolbutamide levels. However, the clinical relevance of these small changes has not been assessed. The manufacturer recommends caution when both drugs are given.

Echinacea does not have a clinically relevant effect on the pharmacokinetics of tolbutamide.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 12 healthy subjects were given *Echinacea purpurea* root 400 mg four times daily for 8 days with a single 500-mg dose of tolbutamide on day 6. The AUC of tolbutamide was increased by 14%, and the time to maximum levels was increased from 4 to 6 hours. The oral clearance was decreased by a mean of 11%, although 2 subjects had a 25% or greater reduction. These minor to modest changes are unlikely to be clinically relevant.

Tolcapone did not alter tolbutamide pharmacokinetics in a single-dose study.

Clinical evidence, mechanism, importance and management

In a single-dose study in 12 healthy subjects, tolcapone 200 mg had no effect on the pharmacokinetics of tolbutamide 500 mg, and did not alter the glucose-lowering effect of tolbutamide. This study was conducted since *in vitro* evidence showed that tolcapone inhibits the cytochrome P450 isoenzyme CYP2C9, by which tolbutamide is metabolised. However, the findings in healthy subjects suggest that no clinically relevant changes in pharmacokinetics of tolbutamide are likely.

The antiepileptic drugs find their major application in the treatment of various kinds of epilepsy, although some of them are also used for other conditions, such as pain management.

**Drug interactions**

The drugs used as antiepileptics are a disparate group, and their interactions need to be considered individually. Carbamazepine and phenytoin have established ranges of therapeutic plasma levels and these are typically fairly narrow. Modest changes in plasma levels may therefore be clinically important.

(a) **Carbamazepine or oxcarbazepine**

Carbamazepine is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 to the active metabolite, carbamazepine-10,11-epoxide, which is then further metabolised. Concurrent use of CYP3A4 inhibitors or inducers may therefore lead to toxicity or reduced efficacy. However, importantly, carbamazepine also induces CYP3A4 and so induces its own metabolism (autoinduction). Because of this, it is important that drug interaction studies are multiple-dose and carried out at steady state. Auto-induction also means that moderate inducers of CYP3A4 may have less of an effect on steady-state carbamazepine levels than expected. Oxcarbazepine is a derivative of carbamazepine, but has a lesser effect on CYP3A4. However, both carbamazepine and oxcarbazepine can act as inhibitors of CYP2C19, see ‘Phenytoin + Carbamazepine’, p.554.

(b) **Phenobarbital**

Phenobarbital is an inducer of a wide range of cytochrome P450 isoenzymes, and may increase the metabolism of a variety of drugs. It may, itself, also be affected by some enzyme inducers or inhibitors, although these interactions are less established.

(c) **Phenytoin**

Phenytoin is extensively metabolised by hydroxylation, principally by CYP2C9, although CYP2C19 also plays a role. These isoenzymes show ‘genetic polymorphism’, (p.4), and CYP2C19 may assume a greater role in individuals who have a poor metaboliser phenotype of CYP2C9. The concurrent use of inhibitors of CYP2C9, and sometimes also CYP2C19, can lead to phenytoin toxicity. In addition, phenytoin metabolism is saturable (it shows non-linear pharmacokinetics), and therefore small changes in metabolism or phenytoin dose can result in marked changes in plasma levels. Moreover, phenytoin is highly protein bound, and drugs that alter its protein binding may alter its levels. Although protein binding interactions are usually not clinically relevant (unless metabolism is also inhibited, see ‘Phenytoin + Valproate’, p.568), they can be important in interpreting drug levels.

(d) **Valproate**

Valproate is a generic name that is applied in this section to cover valproic acid and its salts and esters. Valproate undergoes glucuronidation and β-oxidation, and possibly also some metabolism via CYP2C isoenzymes. It can therefore undergo drug interactions via a variety of mechanisms. It acts as an inhibitor of glucuronidation and so may affect other drugs that undergo glucuronidation. Valproate also has non-linear pharmacokinetics due to saturation of plasma protein binding, and so may interact with drugs that alter its protein binding. However, note that, although protein binding interactions are usually not clinically relevant unless metabolism is also inhibited, they can be important in interpreting drug levels.

(e) **Newer antiepileptics**

Of the newer antiepileptics, both felbamate and topiramate are weak inducers of CYP3A4. They may also inhibit CYP2C19. They are also partially metabolised by the cytochrome P450 isoenzyme system, so may have their metabolism altered by other drugs such as the older enzyme-inducing antiepileptics.

Gabapentin, lamotrigine, levetiracetam, tiagabine, vigabatrin, and zonisamide do not appear to act as inhibitors or inducers of cytochrome P450 isoenzymes, and so appear to cause less drug interactions than the older antiepileptics. Moreover, gabapentin, levetiracetam, and vigabatrin do not appear to be metabolised by the cytochrome P450 system, so appear to be little affected by drug interactions that result from this mechanism. Tiagabine and zonisamide are metabolised by the cytochrome P450 system, so may have their metabolism altered by other drugs such as the older enzyme-inducing antiepileptics. Lamotrigine is metabolised by glucuronidation, and may be affected by inhibitors (e.g. valproate) or inducers (e.g. the older enzyme-inducing antiepileptics) of this process. Lamotrigine may also act as an inducer of glucuronidation.
Antiepileptics + Acetazolamide

Severe osteomalacia and rickets have been seen in a few patients taking phenytoin, phenobarbital, or primidone with acetazolamide. A marked reduction in serum primidone levels with a loss in seizure control, rises in serum carbamazepine levels with toxicity, and rises in phenytoin levels have also been described in a very small number of patients given acetazolamide.

Clinical evidence

(a) Osteomalacia

Severe osteomalacia developed in 2 women taking phenytoin or primidone and phenobarbital when they were given acetazolamide 750 mg daily, despite a normal intake of calcium. When the acetazolamide was withdrawn, the hyperchloraeic acidosis that had been seen in both patients abated and their high urinary excretion of calcium fell by 50%. Similar cases have been described in 3 children given acetazolamide, phenytoin and primidone, with phenobarbital and/or metharbital, who developed rickets.

(b) Reduced serum primidone levels

A patient taking primidone had an increase in seizure-frequency and a virtual absence of primidone (or phenobarbital) in the serum while taking acetazolamide 250 mg daily. Primidone levels rose when the acetazolamide was withdrawn, probably due to improved absorption. A subsequent study in 2 other patients found that acetazolamide had a small effect on primidone absorption in one, and no effect in the other.

(c) Increased serum carbamazepine levels

A 9-year-old girl and two teenage boys, all of them taking the highest dosages of carbamazepine tolerable (without adverse effects), developed signs of toxicity after taking acetazolamide 250 to 750 mg daily. Their serum carbamazepine levels were found to have increased by about 25 to 50%. In one instance toxicity appeared within 48 hours.

The seizure control of 54 children with grand mal and temporal lobe epilepsy was improved when acetazolamide 10 mg/kg daily was added to the carbamazepine. Serum carbamazepine levels rose by 1 to 6 mg/L in 60% of the patients.

(d) Increased serum phenytoin levels

When acetazolamide was added to phenytoin treatment in 6 children, 5 of them had an increase in the phenytoin level (range 20 to 132%), representing an increase of 3 to 12.5 mg/L, and one had a slight decrease (20% or 3 mg/L) [values estimated from figure].

Mechanism

Uncertain. Mild osteomalacia induced by antiepileptics is a recognised phenomenon (see also ‘Vitamin D substances + Phenytoin and Barbiturates’, p.1291). It seems that this is exaggerated by acetazolamide, which increases urinary calcium excretion, possibly by causing systemic acidosis, which results from the reduced absorption of bicarbonate by the kidney. The changes in the antiepileptic levels are not understood.

Importance and management

The documentation of all of these interactions is very limited, and their incidence is uncertain. Concurrent use should be monitored for the possible development of osteomalacia or altered antiepileptic levels and steps taken to accommodate them. Withdraw the acetazolamide if necessary, or adjust the dosage of the antiepileptic appropriately. In the case of the children with rickets the acetazolamide was withdrawn and high doses of vitamin D was given. It seems possible that other carbonic anhydrase inhibitors may behave like acetazolamide.

Antiepileptics + Aciclovir

Isolated reports describe a marked reduction in serum phenytoin and valproate levels in two children given aciclovir. Seizure frequency increased.

Clinical evidence, mechanism, importance and management

A 7-year-old boy with epilepsy taking phenytoin, valproate and ni-trazepam was given oral aciclovir 1 g daily for 6 days. After 4 days his trough serum phenytoin levels had fallen from 17 to 5 micrograms/mL, and his trough valproate levels similarly fell, from 32 to 22 micrograms/mL. When the aciclovir was stopped the serum levels of both antiepileptics rose over a period of 3 to 6 days. During the period when the antiepileptic levels were restabilising, the seizure frequency markedly increased and his EEG worsened. The reason for this apparent interaction is not known, but the authors of the report suggest that the aciclovir may possibly have reduced the absorption of the antiepileptics, in some way not understood. Reduced phenytoin and valproate levels during treatment with aciclovir have been reported in another child.

There appears to be only these isolated reports of an interaction between these drugs. Its general clinical importance is not known. More study is needed.

Antiepileptics + Antineoplastics; Cytotoxic

Carbamazepine, phenytoin and valproate serum levels can be reduced by several antineoplastic drug regimens and seizures can occur if the antiepileptic dosages are not raised appropriately. In contrast, phenytoin toxicity has occurred when fluorouracil and fluorouracil prodrugs, such as capecitabine, doxifluridine and tegafur, were given. The effects of many antineoplasics are reduced or changed by enzyme-inducing antiepileptics. Increased haematological toxicity may occur if valproate is given with folinic acid.

Clinical evidence

(a) Antiepileptic levels reduced

There are a number of reports (mainly case reports) that implicate a variety of types of chemotherapy in reducing the levels of carbamazepine, phenytoin, and valproate. See ‘Table 14.1’, (p.519) for details.

(b) Antiepileptic levels raised

Two epileptic patients taking phenytoin developed phenytoin toxicity when they were given fluorouracil to treat colon cancer. Three patients with malignant brain tumours developed acute phenytoin toxicity associated with raised serum phenytoin levels when they were given UFT (uracil and tegafur, a prodrug of fluorouracil). Another case of phenytoin toxicity has been reported with UFT. Phenytoin toxicity was also seen in a woman treated with combination therapy that included the fluorouracil prodrug doxifluridine. Similarly, phenytoin toxicity has occurred in a patient given capecitabine (another prodrug of fluorouracil). Although in one report, no interaction occurred in one of the patients when the UFT was replaced by fluorouracil, cases of phenytoin toxicity have been reported in 3 patients receiving fluorouracil with folinic acid.

Antineoplastic serum valproate levels reduced by 50% after the first cycle and generalised tonic-clonic seizures occurred. There was no effect on phenytoin levels.

Methotrexate CSF valproic acid levels reduced by 70% during the perfusion, but returned to normal when the chemotherapy had finished, with levels returning to normal 2 to 3 weeks later.

Methotrexate (high dose) A child had a seizure a few hours after methotrexate. Serum valproate levels reduced by 75%. The valproate dose was increased by 50% and clonazepam added.

Cisplatin Carboplatin Vincristine Acute lymphoblastic leukaemia Phenyltoin levels dropped from 19.8 micrograms/mL on the day before chemotherapy to 3.6 micrograms/mL on the 6th day of chemotherapy.

Cisplatin Carboplatin Vincristine Stage IV T-cell lymphoma Phenyltoin failed to reach therapeutic levels and so was substituted with carbamazepine. Chemotherapy caused carbamazepine levels to drop below therapeutic levels resulting in seizures. Increasing the dose from 30 to 50 mg/kg per day prevented subtherapeutic levels.

Carboplatin Vinblastine Bleomycin Lung cancer with brain metastases Phenyltoin levels fell from 9.4 to 5.6 micrograms/mL 24 hours after vinblastine. Patient fitted. Phenyltoin levels returned to normal 2 weeks after chemotherapy. Phenobarbital levels unaffected.

Carboplatin Allretamine Small cell lung cancer with brain metastases Phenyltoin level dropped from 9.7 to 4.6 micrograms/mL 10 days into chemotherapy, resulting in seizures. Phenyltoin dose had to be increased by 35% to achieve a level of 10.7 micrograms/mL.

Doxorubicin Cisplatin Cyclophosphamide Alretamine Papillary adenocarcinoma of the ovaries Seizures occurred 2 to 3 days after starting chemotherapy. All drug levels dropped to one-third or lower. Doses increased to compensate, which led to phenytoin toxicity when the chemotherapy finished.

Cisplatin Vinblastine Bleomycin Metastatic germ cell tumour Phenyltoin 800 mg daily gave a level of 15 micrograms/mL whilst receiving chemotherapy. After chemotherapy the same dose produced a toxic level of 42.8 micrograms/mL. Phenobarbital levels unaffected.

Cisplatin Vinblastine Bleomycin Metastatic embryonal cell cancer Phenyltoin levels returned to normal 2 to 3 weeks after chemotherapy.

Vinblastine Carmustine Methotrexate Lung cancer with brain metastases Phenyltoin levels fell from 9.4 to 5.6 micrograms/mL 24 hours after vinblastine. Patient fitted. Phenyltoin levels returned to normal 2 weeks after chemotherapy. Phenobarbital levels unaffected.

Cetuximab Cetuximab Metastatic embryonal cell cancer Phenyltoin levels returned to normal 2 weeks after chemotherapy.

Carmustine Cisplatin Sodium valproate Small cell lung cancer with brain metastases Phenyltoin level dropped from 9.7 to 4.6 micrograms/mL 10 days into chemotherapy, resulting in seizures. Phenyltoin dose had to be increased by 35% to achieve a level of 10.7 micrograms/mL.

Sodium valproate Carboplatin Vincristine Malignant melanoma with brain metastases Phenyltoin level of only 2.5 micrograms/mL despite a loading 1-g dose and a daily dose of 500 mg phenytoin.

Sodium valproate Carboplatin Vinblastine Bleomycin Small cell lung cancer with brain metastases Phenyltoin level dropped from 9.7 to 4.6 micrograms/mL 10 days into chemotherapy, resulting in seizures. Phenyltoin dose had to be increased by 35% to achieve a level of 10.7 micrograms/mL.

Continued
Antiepileptics + Calcium carbimide or Disulfiram

Phenytoin serum levels are markedly and rapidly increased by disulfiram. Phenytoin toxicity can develop. There is evidence that phenobarbital and carbamazepine are not affected by disulfiram, and that phenytoin is not affected by calcium carbimide.

Clinical evidence

The serum phenytoin levels of 4 patients rose by 100 to 500% over a 9-day period when they were given disulfiram 400 mg daily. Phenytoin levels were still rising even 3 to 4 days after the disulfiram was withdrawn, and had still not returned to normal after 14 days. Two patients developed signs of mild phenytoin toxicity. In a follow-up study in two of the patients, one developed ataxia and both had a rise in serum phenytoin levels, of 25% and 50%, respectively, during 5 days of disulfiram treatment.

Disulfiram increased the half-life of phenytoin from 11 to 19 hours in 10 healthy subjects. There are also other case reports describing this interaction.

Phenobarbital levels (from primidone in 3 patients and phenobarbital in one patient) fluctuated by about 10% (which is unlikely to be clinically significant) when disulfiram was given for 9 days.

A case report suggested that carbamazepine did not interact with disulfiram, and this has been confirmed in a study of 5 epileptic, non-alcoholic patients.

A study in 4 patients found that calcium carbimide 50 mg daily for a week followed by 100 mg daily for 2 weeks had no effect on serum phenytoin levels.

Mechanism

Disulfiram inhibits the liver enzymes concerned with the metabolism of phenytoin (possibly the cytochrome P450 isoenzyme CYP2C9) thereby prolonging its stay in the body and resulting in a rise in its serum levels, to toxic concentrations in some instances. One study concluded that the inhibition was non-competitive.

Importance and management

The interaction between phenytoin and disulfiram is established, moderately well documented, clinically important and potentially serious. It seems to occur in most patients and develops rapidly. Recovery may take 2 to 3 weeks after the disulfiram is withdrawn. It has been suggested that the dosage of phenytoin could be reduced to accommodate the interaction, but it may be difficult to maintain the balance required. Monitor very closely if both drugs are given.

Carbamazepine and phenobarbital do not appear to interact with disulfiram and calcium carbimide does not appear to interact with phenytoin.

Antiepileptics + Chinese herbal medicines

A study in epileptics found that Saiko-ka-ryukotsu-borei-to enhanced the antiepileptic effects of carbamazepine. Paeoniae Radix does not appear to affect the pharmacokinetics of valproic acid.

Clinical evidence

(a) Carbamazepine

A study in epileptic patients found the antiepileptic effects of carbamazepine were enhanced by concurrent Saiko-ka-ryukotsu-borei-to; patients experienced fewer seizures and improved neurological symptoms.

(b) Valproate

The pharmacokinetics of a single 200-mg dose of valproic acid were unaffected by 1.2 g of a powder extract of Paeoniae Radix daily for 7 days in 6 healthy subjects.

Mechanism

Not fully understood. As a pharmacokinetic interaction has not been found between Saiko-ka-ryukotsu-borei-to and carbamazepine, the enhanced effects found in the patients with epilepsy may therefore have been due to a pharmacodynamic interaction.

Paeaniae Radix (the dried root of Paeonia lactiflora) is reported to reduce the rate of gastric emptying. However, this does not appear to affect the rate of absorption of valproate.

Importance and management

Evidence is limited, but there appears to be no evidence of an adverse effect when using Paeoniae radix with valproate, or Saiko-ka-ryukotsu-borei-to with carbamazepine; concurrent use may even be beneficial.

Importance and management

Evidence is limited, but there appears to be no evidence of an adverse effect when using Paeoniae radix with valproate, or Saiko-ka-ryukotsu-borei-to with carbamazepine; concurrent use may even be beneficial.

If folate supplements are given to treat folate deficiency, which can be caused by the use of antiepileptics (phenytoin, phenobarbital, primidone and possibly pheneturide), the serum antiepileptic levels may fall, leading to decreased seizure control in some patients.

Clinical evidence

A study in 50 folate-deficient epileptics (taking phenytoin, phenobarbital and primidone in various combinations) found that after one month of treatment with folic acid 5 mg daily, the plasma phenytoin levels of one group of 10 patients had fallen from 20 to 10 micrograms/mL. In another group of patients taking folic acid 15 mg daily the levels of phenytoin fell from 14 to 11 micrograms/mL. Only one patient (in the 5-mg folic acid group) had a marked increase in seizure frequency and severity. No alterations were seen in the phenobarbital levels.

Another long-term study was conducted in 26 patients with folic acid deficiency (serum folate less than 5 nanograms/mL, and treated with two or more drugs (phenytoin, phenobarbital, primidone). The mental state of 22 of them (as shown by increased alertness, concentration, sociability etc.) improved to a variable degree when they were given folic acid 5 mg three times daily. However, the frequency and severity of seizures in 13 patients (50%) increased to such an extent that the vitamin had to be withdrawn from 9 of them.

Similar results, both of increased seizure activity and decreased serum folate levels, have been described in other studies and reports in patients taking phenytoin, phenobarbital, primidone and pheneturide.

Another report describes lack of phenytoin efficacy in a patient receiving UFT with folic acid, which was attributed to the effect of the folic acid on phenytoin levels.

Mechanism

Patients taking antiepileptics may have subnormal serum folic acid levels. Frequencies of 27 to 76% have been reported for phenobarbital, primidone, and phenytoin alone in various combinations. One possible explanation is that this is due to the enzyme-inducing characteristics of these antiepileptics, which makes excessive demands on folate for the synthesis of the enzymes concerned with drug metabolism. Ultimately drug metabolism becomes limited by the lack of folate, and patients may also develop a reduction in their general mental health and even frank megaloblastic anaemia. If folic acid is then given to treat this deficiency, the metabolism of the antiepileptic increases once again, resulting in a reduction in serum antiepileptic levels, which in some instances may become so low that seizure control is partially or totally lost.

Importance and management

A very well documented and clinically important interaction, which has been the subject of review. Reductions in serum phenytoin levels of 16 to 50% have been described in patients taking 5 to 15 mg folic acid daily for 2 to 4 weeks. If folic acid supplements are given to folate-deficient epileptics taking phenytoin, phenobarbital, primidone and possibly pheneturide, their serum antiepileptic levels should be well monitored so that suitable dosage increases can be made.

Clinical evidence, mechanism, importance and management

An isolated report describes a 20-year-old woman, with a 7-year history of epilepsy (bilateral myoclonus and generalised tonic-clonic seizures) controlled with sodium valproate 1.3 g daily, who developed tonic-clonic seizures 8 hours after taking the second of 3 prophylactic doses of mefloquine 250 mg.1 It is not clear whether this resulted from a drug-drug or a drug-disease interaction. The manufacturers of mefloquine advise its avoidance in those with a history of convulsions as it may increase the risk of convulsions. In these patients mefloquine should be used only for curative treatment if compelling reasons exist.2

Antiepileptics + Quinoline

Preliminary evidence suggests that the effects of carbamazepine and phenobarbital may be increased by quinine, possibly leading to toxicity. An isolated report suggests that phenytoin may reduce the levels of quinine but the levels of phenytoin do not appear to be affected by quinine.

Clinical evidence, mechanism, importance and management

Single doses of carbamazepine 200 mg, phenobarbital 120 mg or phenytoin 200 mg were given to 3 groups of 6 healthy subjects with and without a single 600-mg dose of quinine sulfate. The AUC of carbamazepine and phenobarbital were increased by 104% and 57%, respectively, and the peak plasma levels were increased by 81% and 53%, respectively. Phenytoin was not significantly affected. The reasons for these effects are not known but the authors suggest that quinine inhibits the metabolism of carbamazepine and phenobarbital (but not phenytoin) by the liver, so that their levels become raised.

In an earlier study, phenobarbital 125 mg daily for 4 days caused only a small reduction in the plasma half-life of quinine in 2 healthy subjects.3

Information seems to be limited to these studies. The importance of the interactions with either carbamazepine and phenobarbital awaits as- sessment in a clinically realistic situation (i.e. in patients taking multiple doses) but in the meantime it would seem prudent to monitor the effects of carbamazepine or phenobarbital for evidence of increased effects and possible toxicity if quinine is also taken.

An isolated report describes a 22-month-old girl treated with phenytoin, sodium valproate and topiramate for epilepsy and then with quinine sul- fate (initially intravenously, then orally) followed by a single dose of sul- fadoxine/pyrimethamine for malaria. Her malaria film became negative after 4 days of the 7-day quinine course. About 1 month later she was fainted to have recrudescent falciparum malaria, which was treated with quinine sulfate and then atovaquone/proguanil. Although it is possible that quinine resistance may have occurred, the authors also considered that en- zyme induction by phenytoin may have led to suboptimal quinine levels.4

Although quinine does not appear to affect phenytoin levels, the isolated case report suggests that levels of quinine may be reduced in the presence of phenytoin and it would seem prudent to monitor carefully concurrent use.

Antiepileptics + Quinolones

Studies suggest that ciprofloxacin, clinafloxacin, and enoxacin do not usually have a clinically significant effect on phenytoin levels. However, case reports describe both a rise and a fall in phenytoin levels in patients given ciprofloxacin. Quinolones alone very occa- sionally cause convulsions, therefore they should be used with caution in patients with epilepsy.

Clinical evidence

(a) Ciprofloxacin

In a study in 4 healthy subjects there was no difference in the pharmacokinetics of phenytoin 200 mg daily when it was given with ciprofloxacin 500 mg twice daily. However, one of the 4 subjects experienced a 30% decrease in the phenytoin maximum serum levels when ciprofloxacin was added.1 In another study in 7 patients taking phenytoin, ciprofloxacin 500 mg twice daily for 10 days caused no significant change in phenytoin levels, although there was a tendency for an increase (mean 24% rise).2 Four case reports describe falls of 50% or more in phenytoin serum levels when ciprofloxacin was added, accompanied by seizures in 3 instances.3,6

Another report describes unexpectedly low phento- in levels (measured after a loading dose) in a woman taking ciprofloxacin.7 Conversely, phenytoin levels rose in an elderly woman, possibly as a result of the cip- rofloxacin she was taking.8 In one report, blood levels of phenytoin and valproic acid were not affected by ciprofloxacin although a seizure occurred on the fourth day of therapy.9 Other cases describe seizures in pa- tients taking phenytoin when given ciprofloxacin, but with little or no information on phenytoin levels.10

(b) Clinafloxacin

Phenytoin 300 mg daily was given to healthy subjects for 10 days, then clinafloxacin 400 mg twice daily was added for a further 2 weeks. The maximum serum phenytoin levels rose by 18%, from 6.74 to 7.95 mg/L, the AUC rose by 20% and the clearance fell by 17%.11

(c) Enoxacin

In a study in healthy subjects, enoxacin did not appear to alter phenytoin serum levels, nor were multiple-dose serum enoxacin levels significantly altered by phenytoin.12

Mechanism

Fluoroquinolones alone rarely cause convulsions both in patients with and without a history of seizures. The mechanism for the effect of cipro- floxacin on phenytoin levels is unknown, and is unlikely to be due to ef- fects on hepatic metabolism or oral absorption.13,14 However, ciprofloxacin decreased phenytoin levels in an animal study, and a sug- gested reason for this was increased urinary excretion.15

Importance and management

The known potential for quinolones to induce seizures suggests that these antibacterials should either be avoided in epileptics, or only used when the benefits of treatment outweigh the potential risks of seizures. Some of the reactions seem to be drug-disease interactions rather than drug-drug inter- actions, the usual outcome being that the control of epilepsy is worsened. However, it appears that ciprofloxacin may also alter (usually decrease) phenytoin levels, and if this combination is used it would be prudent to consider monitoring phenytoin levels. Enoxacin appears not to alter phenytoin levels.

Antiepileptics + St John’s wort (Hypericum perforatum)

St John’s wort modestly increased the clearance of single-dose carbamazepine, but had no effect on multiple-dose carbamazepine pharmacokinetics. Carbamazepine does not appear to significantly affect the pharmacokinetics of hypericin or pseudohypericin (constituents of St John’s wort). St John’s wort is predicted to reduce the blood levels of phenytoin and phenobarbital, but this awaits clinical confirmation.

Clinical evidence, mechanism, importance and management

In a multiple-dose study, St John’s wort had no effect on the pharmacokinetics of carbamazepine or its metabolite (carbamazepine-10,11-epoxide) in 8 healthy subjects. In this study, subjects took carbamazepine 200 mg increased to 400 mg daily alone for 20 days, then with St John’s wort 300 mg (standardised to 0.3% hypericin) three times daily for a further 14 days. In contrast, the AUC of a single 400-mg dose of carbamazepine was reduced by 21% after St John’s wort 300 mg was given three times daily for 14 days, and the AUC of the 10,11-epoxide metabolite was increased by 26%. St John’s wort is a known enzyme inducer, and the results with single-dose carbamazepine are as predicted. However, carbamazepine is also an enzyme inducer, which induces its own metabolism (autoinduction). It is suggested that St John’s wort is not sufficiently potent an inducer to further induce carbamazepine metabolism when autoinduction has occurred,1 and therefore a small interaction is seen with single doses but no interaction is seen with multiple doses.

A double-blind, placebo-controlled study in healthy subjects found that, apart from a modest 29% decrease in the AUC of pseudohypericin, carbamazepine did not significantly affect the pharmacokinetics of either hypericin or pseudohypericin, which are both constituents of St John’s wort.2 The available evidence therefore suggests that a clinically significant interaction between carbamazepine and St John’s wort is unlikely. Prior to the publication of the above reports, the CSM in the UK had advised that patients taking a number of drugs including the antiepileptics carbamazepine, phenytoin and phenobarbital should not take St John’s wort.3 This advice was based on predicted pharmacokinetic interactions. In the light of the above studies, this advice no longer applies to carbamazepine, but until more is known, it should probably still apply to phenytoin and phenobarbital.

4. Committee on the Safety of Medicines (UK). Message from Professor A Breckenridge (Chairman of CSM) and Fact Sheet for Health Care Professionals, 29th February 2000.

Antiepileptics + Tobacco

Smoking tobacco appears to have no important effect on the serum levels of phenytoin, phenobarbital or carbamazepine.

Clinical evidence, mechanism, importance and management

A comparative study in 88 epileptic patients taking antiepileptics (phenobarbital, phenytoin and carbamazepine alone or in combination) found that although smoking had a tendency to lower the steady-state serum levels of these drugs, a statistically significant effect on the concentration–dose ratios was only found in the patients taking phenobarbital.1 However, in another study in healthy subjects, there was no difference in the pharmacokinetics of a single 60-mg dose of phenobarbital between smokers and non-smokers.2 In practical terms smoking appears to have only a negligible effect on the serum levels of these antiepileptics and epileptics who smoke are unlikely to need higher doses than non-smokers.

Antiepileptics + Vitamin B substances

High daily doses of pyridoxine can cause 35% reductions in phenytoin levels and 50% reductions in phenobarbital levels in some patients. Some evidence suggests that high doses of nicotinamide reduce the conversion of primidone to phenobarbital, and increase carbamazepine levels.

Clinical evidence

(a) Nicotinamide

Nicotinamide 41 to 178 mg/kg daily increased the levels of primidone and decreased the levels of primidone-derived phenobarbital in 3 children. Although two of the children had refractory seizures, seizure frequency decreased while on nicotinamide. Two of the children on carbamazepine had increases in their carbamazepine levels.1

(b) Pyridoxine

Pyridoxine 200 mg daily for 4 weeks reduced the phenobarbital serum levels of 5 epileptics by about 50%. Reductions in serum phenytoin levels of about 35% (range 17 to 70%) were also seen when patients were given pyridoxine 80 to 400 mg daily for 2 to 4 weeks. However, no interaction occurred in a number of other patients taking these drugs.2

Mechanism

It is suggested that the pyridoxine increases and nicotinamide decreases the activity of the liver enzymes concerned with the metabolism of these antiepileptics.1,2

Importance and management

Information seems to be limited, but what is known suggests that concurrent use should be monitored if large doses of pyridoxine or nicotinamide are used, being alert for the need to modify the antiepileptic dosage. It seems unlikely that small doses (as in multivitamin preparations) will interact to any great extent.

Antiepileptics + Terbinafine

An isolated report describes the development of fatal toxic epidermal necrosis shortly after a patient taking phenobarbital and carbamazepine started taking terbinafine.

Clinical evidence, mechanism, importance and management

An isolated report describes a 26-year-old woman with cerebral palsy who had been taking phenobarbital 15 mg with carbamazepine 400 mg daily for 12 years to control epilepsy, and who developed fatal toxic epidermal necrosis 2 weeks after starting oral terbinafine 250 mg daily for tinea corporis. The reasons are not understood, but the authors point out that all three drugs can cause adverse skin reactions (erythema multiforme) and suggest that some synergism may have occurred.1 It is uncertain whether this was a true interaction or a terbinafine adverse effect.

Carbamazepine + Allopurinol

There is some evidence to suggest that high-dose allopurinol (15 mg/kg or 600 mg daily) can gradually raise serum carbamazepine levels by about a third. It appears that allopurinol 300 mg daily has no effect on carbamazepine levels.
Clinical evidence
In a 6-month study, 7 epileptic patients taking antiepileptics, which included carbamazepine, were also given allopurinol 100 mg three times daily for 3 months then 200 mg three times daily for 3 months. The mean trough steady-state serum carbamazepine levels of 6 of the patients rose by 30% or more and the carbamazepine clearance fell by 32% during the second 3-month period. A reduction in the carbamazepine dosage was needed in 3 patients because of the symptoms that developed.1 Similarly, in another study allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks increased carbamazepine levels by 29% in 11 patients taking antiepileptics, which included carbamazepine.2 Conversely, in another study, allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months had no effect on carbamazepine levels in 53 patients taking antiepileptics, which included carbamazepine.3

Mechanism
Uncertain. A possible explanation is that allopurinol can act as a liver enzyme inhibitor, which reduces the metabolism and clearance of carbamazepine.

Importance and management
Information is limited to these studies, but be alert for the need to reduce the dosage of carbamazepine if high doses of allopurinol are used long-term. This interaction apparently takes several weeks or even months to develop fully. More study is needed.

1. Mikati M, Erba G, Skouteli H, Gadia C. Pharmacokinetic study of allopurinol in resistant epileptics, which included carbamazepine. 2 Conversely, in another study, allopurinol (100 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months had no effect on carbamazepine levels in 53 patients taking antiepileptics, which included carbamazepine.3

Carbamazepine + Antiepileptics

Clinical evidence, mechanism, importance and management
A single 400-mg dose of carbamazepine was given to 9 patients with cardiac disease (premature ventricular contractions, supraventricular tachycardia, sinus arrhythmia) before and after they took amiodarone 200 mg twice daily for a month. The pharmacokinetics of carbamazepine were found to be unchanged by the amiodarone. This certainly suggests that no clinically important interaction occurs, but it needs confirmation in patients who are given both drugs long term. Furthermore, the authors postulate that a higher amiodarone dose may inhibit the metabolism of the carbamazepine by the liver.1

Clinical evidence, mechanism, importance and management (g) Raised carbamazepine or carbamazepine-10,11-epoxide levels
Two patients, one taking loxapine 500 mg daily and the other taking chlorpromazine 350 mg and amoxapine 300 mg daily, developed toxicity (ataxia, nausea, anxiety) when given carbamazepine 600 to 900 mg daily, even though their serum carbamazepine levels were low to normal.1 In another case, neurotoxicity (ataxia, lethargy, visual disturbances) developed in a man given carbamazepine and lopinavir.2 In all 3 cases, the toxicity appeared to be due to elevated carbamazepine-10,11-epoxide levels (the metabolite of carbamazepine).1,2 The problem resolved when the carbamazepine dosages were reduced. Raised carbamazepine-10,11-epoxide levels have also been reported in 2 patients after they were given quetiapine, with toxicity in one of the patients.3 Risperidone 1 mg daily for 2 weeks raised carbamazepine levels by about 20% in 8 patients.4 Raised serum carbamazepine levels have also been seen with ‘haloperidol’, (p.707).

It is relatively well documented that carbamazepine can reduce the levels of many of the antipsychotics (discussed in individual monographs elsewhere). The above reports show that the effect of the antipsychotic on carbamazepine should also be considered. The levels of both carbamazepine and its metabolite should be monitored if toxicity develops.

(b) No changes to carbamazepine-10,11-epoxide levels
Thioridazine 100 to 200 mg daily was found to have no effect on the steady-state levels of carbamazepine or carbamazepine-10,11-epoxide in 8 epileptic patients,2 and also carbamazepine had no significant effect on thioridazine plasma levels in 6 patients.3

(c) Stevens-Johnson syndrome
Three patients treated with various antipsychotics (fluphenazine, haloperidol, trifluoperazine, chlorpromazine) developed Stevens-Johnson syndrome within 8 to 14 days of starting to take carbamazepine. All 3 had erythema multiforme skin lesions and at least two mucous membranes were affected. After treatment, all 3 were restarted on all their previous drugs, except carbamazepine, without problems.4 Another case of Stevens-Johnson syndrome has been reported in a patient taking carbamazepine, lithium carbonate, haloperidol and trihexyphenidyl.5 The reasons are not understood. Stevens-Johnson syndrome with carbamazepine alone is rare, and the risk appears to be mostly confined to the first 8 weeks of treatment.6 It may be more common in patients being treated for conditions other than epilepsy.7 It is not possible to say whether the concurrent use of antipsychotics increases the risk of its development, but until more is known it would be prudent to monitor the outcome, particularly during the first 2 weeks of combined use.

(d) Neuroleptic malignant syndrome
A 54-year old man living in a psychiatric hospital, who had been taking haloperidol, levomepromazine, sultopride, and metoxene long-term was prescribed carbamazepine 400 mg daily for impulsive behaviour. The following day he became unstable on his feet, and after 3 days could no longer walk by himself. He had a fever of 40°C, muscle rigidity, diaphoresis, and blood creatine phosphokinase was elevated to 923 units/L. He was diagnosed as having neuroleptic malignant syndrome (NMS), and recovered after body cooling and administration of fluids, with symptoms resolving over 12 days. Before carbamazepine was given, his haloperidol level was 19 nanograms/mL and after 3 days of carbamazepine it was reduced to 10.9 nanograms/mL.8 Carbamazepine alone is not associated with NMS. It was suggested that carbamazepine may have reduced levels of the antimuscarinic (anticholinergic) antipsychotics (levomepromazine and sultopride), resulting in cholinergic rebound, and inducing NMS.9 The general applicability of this case is unknown.

**Carbamazepine + Aspirin or NSAIDs**

Carbamazepine levels are unaffected by aspirin or tolfenamic acid.

**Clinical evidence, mechanism, importance and management**

No changes in carbamazepine serum levels were seen in 10 patients who took aspirin 1.5 g daily for 3 days.1 It would appear that no precautions are necessary if aspirin is used in patients on carbamazepine.

Tolfenamic acid 300 mg for 3 days had no significant effect on the serum levels of carbamazepine in 11 patients.3 No special precautions seem necessary if these drugs are taken concurrently.

**Carbamazepine + Azoles**

Ketoconazole causes a small to moderate rise in serum carbamazepine levels. A marked rise in carbamazepine levels has been seen in two patients taking fluconazole, with toxicity in one. Adverse effects were seen in another patient when carbamazepine was given with miconazole. Carbamazepine may markedly reduce the levels of itraconazole and possibly voriconazole, and is predicted to lower the levels of posaconazole.

**Clinical evidence**

(a) Fluconazole

A 33-year-old man whose seizures were stabilised by carbamazepine became extremely lethargic after taking fluconazole 150 mg daily for 3 days. His carbamazepine level was found to have risen from 11.1 to 24.5 micrograms/mL. Symptoms resolved when both drugs were stopped, and carbamazepine was later re-introduced without problem.1 Another well-documented case report describes a threefold increase in carbamazepine levels (without any signs of toxicity) 10 days after fluconazole 400 mg daily was started.2

(b) Itraconazole

About 14 days after starting carbamazepine 400 mg daily, a patient taking itraconazole 200 mg daily was noted to have low itraconazole levels (0.15 mg/L), and about 2 months later they were undetectable. About 3 weeks after stopping the carbamazepine, itraconazole levels had reached the therapeutic range (0.36 mg/L).3 For mention of 2 patients taking carbamazepine with phenytoin, who had undetectable or very low itraconazole levels, and who relapsed or did not respond to itraconazole therapy, see ‘Phenytoin + Azoles’, p.552.

(c) Ketoconazole

A study in 8 patients with epilepsy taking carbamazepine found that oral ketoconazole 200 mg daily for 10 days increased their serum carbamazepine levels by 28.6% (from 5.6 to 7.2 micrograms/mL) without affecting carbamazepine-10,11-epoxide levels. When the ketoconazole was stopped the serum carbamazepine levels returned to their former levels.4

(d) Miconazole

A patient receiving long-term treatment with carbamazepine 400 mg daily developed malaise, myoclonia and tremor within 3 days of being given oral miconazole 1.125 g. The same reaction occurred on each subsequent occasion that miconazole was given. These toxic effects disappeared when the miconazole was withdrawn.5

**Mechanism**

Carbamazepine levels are thought to rise because azole antifungals inhibit the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of carbamazepine. Different azoles affect CYP3A4 to varying degrees, see ‘azole antifungals’, (p.207). Carbamazepine is an enzyme inducer, and appears to decrease the levels of azole antifungals by increasing their metabolism.

**Importance and management**

Evidence for these interactions is limited and in some cases the effects are only modest. Nevertheless, it would seem prudent to monitor the outcome of adding azole antifungals to established carbamazepine treatment, being alert for any evidence of increased carbamazepine adverse effects.

Note also that carbamazepine may reduce the levels of azole antifungals: a marked reduction in itraconazole levels has been reported, and some manufacturers of itraconazole consequently say that concurrent use of potent enzyme inducers such as carbamazepine is not recommended.6,7 Based on the interaction with ‘phenytoin’, (p.552), which results in reduced posaconazole levels, the manufacturer of posaconazole suggests that concurrent use of posaconazole and carbamazepine should be avoided, unless the benefits outweigh the risks.8 If both drugs are given it would seem sensible to consider increasing the posaconazole dose, and increase monitoring of carbamazepine levels. Based on the interaction with ‘phenytoin’, (p.552), the manufacturers of voriconazole also contra-indicate the concurrent use of carbamazepine and voriconazole.9,10

**Carbamazepine + Bile-acid binding resins**

Colestyramine 8 g did not affect the absorption of carbamazepine 400 mg in 6 healthy subjects, whereas colestipol 10 g reduced it by 10%. Both colestyramine and colestipol were given as a single dose 5 minutes after the carbamazepine.1 This small reduction is unlikely to be clinically important.

**Carbamazepine or Oxcarbazepine + Calcium-channel blockers**

Both diltiazem and verapamil can increase serum carbamazepine levels causing toxicity. Limited evidence suggests that amlodipine and nifedipine do not affect carbamazepine levels. A single case report describes neurological toxicity in a patient taking phenytoin and carbamazepine with isradipine.

The plasma levels of felodipine, nifedipine, nilvadipine, and nimodipine are reduced by carbamazepine. Felodipine levels are modestly reduced by oxcarbazepine.

**Clinical evidence**

(a) Diltiazem

An epileptic patient taking carbamazepine 400 mg in the morning and 600 mg in the evening developed symptoms of toxicity (dizziness, nausea, ataxia and diplopia) within 2 days of starting to take diltiazem 60 mg three times daily. His serum carbamazepine levels had risen by about 40% to 21 mg/L, but fell once again when the diltiazem was stopped. No interaction occurred when the diltiazem was replaced by nifedipine 20 mg three times daily.1 Other case reports describe carbamazepine toxicity and a rise in serum levels of up to fourfold in a total of 11 patients given diltiazem.2–7 One patient required a 62% reduction in the carbamazepine dose.2 Another patient had a marked fall in serum carbamazepine levels of 54% when diltiazem was stopped.8 For a further case report involving diltiazem, see Nifedipine, below.
**Carbamazepine + Danazol**

Serum carbamazepine levels can be doubly elevated by danazol and carbamazepine toxicity may occur.

**Clinical evidence**

The serum carbamazepine levels of 6 epileptic patients approximately doubled within 7 to 30 days of taking danazol 400 to 600 mg daily. Acute carbamazepine toxicity (dizziness, drowsiness, blurred vision, ataxia, nausea) was experienced by 5 out of the 6 patients.

**Other reports**

Other reports similarly describe rises in serum carbamazepine levels of 50 to 100% (with toxicity seen in some instances) when danazol was given.

**Mechanism**

It would appear that diltiazem and verapamil inhibit the metabolism of carbamazepine by the cytochrome P450 isoenzyme CYP3A4, thereby reducing its loss from the body and increasing serum levels. In contrast, carbamazepine is an enzyme inducer, which increases the metabolism of the calcium-channel blockers by the liver, resulting in a very rapid loss from the body.

**Importance and management**

Information about the effects of calcium-channel blockers on carbamazepine is limited, but what is known indicates that if carbamazepine is given with verapamil or diltiazem, the carbamazepine dosage may possibly need to be reduced to avoid toxicity. A 50% reduction in the dose of carbamazepine has been suggested if diltiazem is to be used. Nifedipine and amloclipine normally appear to be non-interacting alternatives. Oxcarbazepine appears to be a non-interacting alternative for carbamazepine.

Carbamazepine has been shown to lower the levels of a number of calcium-channel blockers. Given that the majority are metabolised by CYP3A4 (see ‘calcium-channel blockers’, p.860) most calcium-channel blockers would be expected to interact similar. If a calcium-channel blocker is given to a patient taking carbamazepine expect to need to use a larger dose. If carbamazepine is added to existing treatment with a calcium-channel blocker monitor the blood pressure and expect to need to increase the dose. Note that the manufacturer of nimodipine contraindicates its use with carbamazepine.

Oxcarbazepine interacts to a lesser extent than carbamazepine and it may therefore be a suitable alternative in some patients.
Carbamazepine + Dantrolene and Oxybutynin

Carbamazepine toxicity has been reported in a patient given oxybutynin and dantrolene.

Clinical evidence

A woman with incomplete tetraplegia who had taken carbamazepine 1 g daily for neuropathic pain for 2 years was given dantrolene in a gradually increasing dose and oxybutynin 5 mg twice daily. Two weeks after starting oxybutynin and while receiving dantrolene 125 mg daily, she experienced dizziness and vomiting, drowsiness, confusion, slurred speech, and nystagmus, and was found to have a raised carbamazepine level of 16 micrograms/mL. All drugs were stopped and the plasma carbamazepine level fell to 8.3 micrograms/mL (therapeutic range 4 to 12 micrograms/mL). Because of pain, urinary frequency and spasticity, daily doses of carbamazepine 600 mg, oxybutynin 10 mg and dantrolene 100 mg were restarted which resulted in a carbamazepine level of 9.2 micrograms/mL. The dantrolene dosage was increased to 125 mg daily because of continuing spasticity, but after one day, symptoms of carbamazepine toxicity occurred and the carbamazepine plasma level was 29 micrograms/mL. Carbamazepine and oxybutynin were discontinued and the dantrolene dose was reduced to 25 mg. In order to relieve the patient’s symptoms of pain and spasticity, carbamazepine 400 mg daily and dantrolene 25 mg daily were given (carbamazepine levels of 8.4 micrograms/mL at 7 days). The addition of oxybutynin 5 mg daily was associated with an increase in the carbamazepine level to 32 micrograms/mL and symptoms of toxicity. Carbamazepine was replaced by valproate 600 mg daily, which appeared to be beneficial and without an interaction with dantrolene or oxybutynin.1

Mechanism, importance and management

In the reported case, oxybutynin was being taken on each occasion when carbamazepine levels increased. This increase was probably due to the inhibition of oxybutynin by the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of carbamazepine. Dantrolene was also being taken and the second episode of carbamazepine toxicity occurred after the dantrolene dose was increased. The exact mechanism of dantrolene metabolism is not known but it may decrease the activity of cytochrome P450 isoenzymes in a dose-dependent manner. Valproate, which is mainly metabolised by glucuronide conjugation, was not affected by concurrent oxybutynin or dantrolene. The authors recommend careful monitoring and, if necessary, dose adjustments if carbamazepine is given with dantrolene and/or oxybutynin.1

Carbamazepine or Oxcarbazepine + Dextropropoxyphene (Propoxyphene)

Carbamazepine serum levels can be raised by dextropropoxyphene. Toxicity may develop unless suitable dosage reductions are made. Oxcarbazepine appears not to interact with dextropropoxyphene.

Clinical evidence

(a) Carbamazepine

The observation of toxicity (headache, dizziness, ataxia, nausea, tiredness) in patients taking both carbamazepine and dextropropoxyphene prompted further study. Five carbamazepine-treated patients given dextropropoxyphene 65 mg three times daily had a mean rise in serum carbamazepine levels of 65%, and 3 showed evidence of carbamazepine toxicity. Carbamazepine levels were not taken in a further 2 patients because they withdrew from the study after 2 days of treatment due to adverse effects.1,2 In a further study a 66% rise in carbamazepine levels was seen after 6 days of treatment with dextropropoxyphene.3 Carbamazepine toxicity due to this interaction is reported elsewhere.4,7 and rises in trough serum carbamazepine levels of 69% to 600% have been described.5 A study in the elderly compared groups of patients taking either carbamazepine or dextropropoxyphene alone, with patients taking both drugs (21 subjects). The carbamazepine dose was about a third lower in those receiving combined treatment, yet the mean serum carbamazepine levels were still 25% higher than in the patients not taking dextropropoxyphene. The prevalence of adverse effects was also higher in patients taking both drugs.6

(b) Oxcarbazepine

Dextropropoxyphene 65 mg three times daily for 7 days did not affect the steady-state levels of the active metabolite of oxcarbazepine in 7 patients with epilepsy or trigeminal neuralgia.10

Mechanism

Uncertain. It is suggested that dextropropoxyphene inhibits the metabolism of carbamazepine by the liver, leading to its accumulation in the body.1,2

Dextromethorphan appears not to affect the serum levels of carbamazepine.
Carbamazepine + Diuretics

Two patients taking carbamazepine developed hyponatraemia when they were also given hydrochlorothiazide or furosemide. Another patient developed hyponatraemia while taking carbamazepine, hydrochlorothiazide and paroxetine.

Clinical evidence, mechanism, importance and management

Two epileptic patients taking carbamazepine developed symptomatic hyponatraemia while also taking hydrochlorothiazide or furosemide. Another case has been described in a patient taking carbamazepine when also given hydrochlorothiazide and paroxetine. The reasons are uncertain but all these drugs can cause sodium to be lost from the body. This seems to be an uncommon interaction, but be aware that it can occur.

Carbamazepine + Felbamate

Felbamate modestly reduces serum carbamazepine levels but increases the levels of the active metabolite, carbamazepine-10,11-epoxide. Carbamazepine may reduce felbamate levels. The importance of these changes is uncertain but it is likely to be small.

Clinical evidence

The serum carbamazepine levels of 22 patients, with doses adjusted to keep levels in the range of 4 to 12 micrograms/mL, fell by 25% (range 10 to 42%) when they were given felbamate 3 g daily. The decrease occurred within a week, reaching a plateau after 2 to 4 weeks, and returning to the original levels within 2 to 3 weeks of stopping the felbamate. Other studies in epileptics have found reductions in carbamazepine levels of between 18% and 31% when felbamate was given. Some of these studies also found that the serum levels of the active carbamazepine metabolite carbamazepine-10,11-epoxide rose by 33% to 57%.

Carbamazepine increases the clearance of felbamate by up to 49%, 6,7

Mechanism

Not established. Felbamate does not induce the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of carbamazepine, but appears to alter the interaction of carbamazepine with CYP3A4.

Importance and management

This interaction is established, but its clinical importance is uncertain because the modest fall in serum carbamazepine levels would seem to be offset by the rise in levels of its metabolite, carbamazepine-10,11-epoxide, which also has anticonvulsant activity. However, monitor carbamazepine levels carefully, reducing the dose as necessary, and be alert for any changes in the anticonvulsant control. The importance of the increased felbamate clearance is uncertain. More study is needed.

Carbamazepine + Grapefruit and other fruit juices

Grapefruit juice increases carbamazepine levels. A case of possible carbamazepine toxicity has been seen when a man taking carbamazepine started to eat grapefruit.

Clinical evidence

A 58-year-old man, taking carbamazepine 1 g daily for epilepsy developed visual disturbances with diplopia, and was found to have a carbamazepine level of 11 micrograms/mL (therapeutic range 4 to 10 micrograms/mL). Previous levels had not exceeded 5.4 micrograms/mL. The patient said that one month previously he had started to eat one whole grapefruit each day. The levels stabilised at 5.1 micrograms/mL after the carbamazepine dose was reduced to 800 mg daily.

A randomised, crossover study in 10 epileptic patients taking carbamazepine 200 mg three times daily found that a single 300-mL drink of grapefruit juice increased the plasma levels and AUC of carbamazepine by about 40%.

Mechanism

The cytochrome P450 isoenzyme CYP3A4 is the main enzyme involved in the metabolism of carbamazepine. Components of grapefruit juice are known to inhibit CYP3A4, which in this case would lead to a reduction in the metabolism of carbamazepine, and therefore an increase in levels.

Importance and management

Although the information is sparse, the interaction has been predicted, demonstrated in a study, and has also occurred in practice. The authors of the study suggest that grapefruit juice should be avoided in patients taking carbamazepine. In the case report, the patient continued to eat grapefruit, and this was successfully managed by a reduction in the
carbamazepine dose. However, it should be noted that intake of a set amount of grapefruit would need to be maintained for this approach to work. The manufacturers advise carbamazepine dosage adjustment and monitoring of carbamazepine levels in patients taking substances that may raise carbamazepine levels, such as grapefruit juice. If monitoring is not practical, or regular intake of grapefruit is not desired, it would seem prudent to avoid grapefruit/grapefruit juice.

What is of particular interest in the case cited is that the interaction apparently occurred with whole grapefruit, which is not usually considered to be a problem, although it is known that the fruit content of possible active components (e.g. flavonoids) do vary considerably. The juice (as opposed to the whole fruit) more commonly interacts, as thejuicing process can increase the flavonoid content. The evidence with pomegranate juice is currently too sparse to predict its effects in practice.

The serum levels of those taking long-term carbamazepine may transiently increase, possibly accompanied by an increase in adverse effects, for the first few days after starting to take cimetidine, but these adverse effects rapidly disappear. Cimetidine does not appear to have this effect on oxcarbazepine levels. Ranitidine appears not to interact with carbamazepine.

**Clinical evidence**

**(a) Carbamazepine**

The steady-state carbamazepine levels of 8 healthy subjects taking carbamazepine 300 mg twice daily were increased by 17% within 2 days of them starting to take cimetidine 400 mg three times daily. Adverse effects occurred in 6 patients, but after 7 days of treatment the carbamazepine levels had fallen again and the adverse effects disappeared. Conversely, the steady-state carbamazepine levels of 7 epileptic patients receiving long-term treatment remained unaltered when they were given cimetidine 1 g daily for a week. Another study also showed a lack of an interaction in 11 epileptic patients. However, an 89-year-old woman taking carbamazepine 600 mg daily developed symptoms of carbamazepine toxicity within 2 days of starting to take cimetidine 400 mg daily, and had a rise in serum carbamazepine levels, which fell when the cimetidine was withdrawn. The effects of cimetidine may be additive with those of isoniazid, see ‘Carbamazepine + Isoniazid or Rifampicin (Rifampin)’, below.

The results of these studies in patients and subjects taking carbamazepine long term differ from single-dose studies and short-term studies in healthy subjects. For example, a 33% rise in serum carbamazepine levels, a 20% fall in clearance, and a 26% increase in the AUC have been reported, which would indicate that there is some potential for a clinically significant interaction (see ‘Mechanism’ below).

In 8 healthy subjects ranitidine 300 mg daily did not affect the pharmacokinetics of a single 600-mg dose of carbamazepine.

**(b) Oxcarbazepine**

No changes in the pharmacokinetics of a single 600-mg oral dose of oxcarbazepine were seen in 8 healthy subjects who took cimetidine 400 mg twice daily for 7 days.

**Mechanism**

Not fully understood. It is thought that cimetidine can inhibit the activity of the liver enzymes concerned with the metabolism of carbamazepine (such as the cytochrome P450 isozyme CYP3A4), resulting in its reduced clearance from the body, but the effect is short-lived because the auto-inducing effects of the carbamazepine oppose it. This would possibly explain why the single-dose and short-term studies in healthy subjects suggest that a clinically important interaction could occur, but in practice the combination causes few problems in patients receiving long-term treatment.

**Importance and management**

The interaction between carbamazepine and cimetidine is established but of minimal importance. Patients receiving long-term treatment with carbamazepine should be warned that for the first few days after starting to take cimetidine they may possibly experience some increase in carbamazepine adverse effects (nausea, headache, dizziness, fatigue, drowsiness, ataxia, an inability to concentrate, a bitter taste). However, because the serum levels are only transiently increased, these effects should subside and disappear by the end of a week. Ranitidine appears to be a non-interacting alternative to cimetidine.

In one study carbamazepine levels rose modestly 14 days after an influenza vaccine was given. A case report describes carbamazepine toxicity and markedly increased carbamazepine levels in a teenager 13 days after she was given an influenza vaccine.

**Clinical evidence, mechanism, importance and management**

The serum carbamazepine levels of 20 children rose by 47% from 6.17 to 9.04 micrograms/mL 14 days after they were given 0.5 mL of influenza vaccine USP, types A and B, whole virus (Squibb). Levels remained elevated on day 28. A teenager taking carbamazepine 400 mg in the morning and 600 mg at night with gabapentin 600 mg three times daily developed signs of carbamazepine toxicity (unsteady, lethargic, slurred speech) 13 days after she was given an influenza vaccination (Fluzone, Aventis Pasteur). Her serum carbamazepine level was 27.5 micrograms/mL (previous levels 8.2 to 12.4 micrograms/mL), and she required ventilation for 19 hours. A urine drug screen was positive for tricyclic antidepressants and cocaine, but it was eventually concluded that these were likely to represent false-positive results.

It has been suggested that the vaccine inhibits the liver enzymes concerned with the metabolism of carbamazepine, and therefore raising its levels. The moderate increase in serum carbamazepine levels seen in the first study is unlikely to have much clinical relevance. However, the case report of markedly increased carbamazepine levels introduces a note of caution. Further study is needed.

**Carbamazepine + Isoniazid or Rifampicin (Rifampin)**

Carbamazepine serum levels are markedly and very rapidly increased by isoniazid and toxicity can occur. Rifampicin has been reported both to augment and negate this interaction. There is evidence to suggest that carbamazepine may potentiate isoniazid hepatotoxicity.
Clinical evidence

Disorientation, listlessness, aggression, lethargy and, in one case, extreme drowsiness developed in 10 out of 13 patients taking carbamazepine when they were given isoniazid 200 mg daily. Serum carbamazepine levels were measured in 3 of the patients and they were found to have risen above the normal therapeutic range (initial level not stated). 1

Carbamazepine toxicity, associated with marked rises in serum carbamazepine levels, has been described in other reports. 2-6 Some of the patients were also taking sodium valproate, which does not seem to be implicated in the interaction, and in one case cimetidine, which was thought to have potentiated the interaction. 6 See also ‘Carbamazepine or Oxcarbazepine + H2-receptor antagonists’, p.529.

One report describes carbamazepine toxicity in a patient given isoniazid, but only when rifampicin was present as well. Usually the enzyme-inducing effects of rifampicin would be expected to counteract any enzyme inhibition by isoniazid, so this report is somewhat inexplicable. 7 Conversely, a case report describes reduced carbamazepine levels in a woman given rifampicin and isoniazid, which resulted in reduced carbamazepine efficacy (symptoms of hypomania). 8

Isoniazid-induced fulminant liver failure occurred in a 16-year-old girl taking carbamazepine and clonazepam, within 5 days of starting isoniazid, rifampicin and pyrazinamide. She recovered with supportive measures and later tolerated the antiepileptics with concurrent rifampicin and pyrazinamide. 9 Isoniazid hepatotoxicity has also occurred in a 74-year-old woman 10 and a 10-year-old boy 11 taking carbamazepine, shortly after treatment with isoniazid, rifampicin, and ethambutol, with or without pyrazinamide, was started.

Mechanism

It seems probable that isoniazid inhibits the activity of the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of carbamazepine, causing it to accumulate in the body. 12 Rifampicin is a potent enzyme inducer, and would be expected to negate the effects of isoniazid, and to induce the metabolism of carbamazepine. This is supported by one report, but not another.

Importance and management

The documentation is limited, but a clinically important and potentially serious interaction is established between isoniazid and carbamazepine. Toxicity can develop quickly (within 1 to 5 days) and also seems to disappear quickly if the isoniazid is withdrawn. Concurrent use should not be undertaken unless the effects can be closely monitored and suitable downward dosage adjustments made (a reduction to between one-half or one-third was effective in 3 patients). 1 It seems probable that those who are ‘slow’ metabolisers of isoniazid may show this interaction more quickly and to a greater extent than fast metabolisers. 1

The effect of concurrent rifampicin on the interaction between isoniazid and carbamazepine is unclear. One report showed negation of the interaction, whereas another showed potential augmentation. Limited evidence suggests that carbamazepine may potentiate isoniazid hepatotoxicity.

Carbamazepine + Isotretinoin

A study in one patient found that isotretinoin modestly reduced the serum levels of both carbamazepine and its active metabolite.

Clinical evidence, mechanism, importance and management

The carbamazepine AUC in an epileptic patient taking carbamazepine 600 mg daily was reduced by 11% when isotretinoin 500 micrograms/kg daily, was taken, and by 24% when 1 mg/kg daily was taken. The AUC of carbamazepine-10,11-epoxide (the active metabolite of carbamazepine) was reduced by 21 and 44% by the small and large doses of isotretinoin, respectively. The patient had no adverse effects. 1 Although the author of the report suggests that monitoring may be necessary in patients given both drugs changes of this magnitude, especially those seen with the lower dose, are not usually clinically significant.

Carbamazepine + Lamotrigine

Most studies have found that lamotrigine has no effect on the pharmacokinetics of carbamazepine or its epoxide metabolite. However, some studies have found that lamotrigine raises the serum levels of carbamazepine-10,11-epoxide. Carbamazepine reduces lamotrigine levels. Symptoms of toxicity have been seen irrespective of changes in levels.

Clinical evidence

(a) Effects on carbamazepine

The addition of lamotrigine increased the serum levels of carbamazepine-10,11-epoxide, the active metabolite of carbamazepine, in 3 epileptic patients, but carbamazepine levels remained unchanged. One of the patients had carbamazepine-10,11-epoxide serum levels of 2 to 2.2 micrograms/mL while taking carbamazepine 1.1 g daily. The levels rose to 4.7 to 8.7 micrograms/mL when lamotrigine was added. Symptoms of toxicity occurred in 2 patients (dizziness, double vision, sleepiness, nausea). 1 In another study in 9 patients, the addition of lamotrigine 200 mg increased the mean serum carbamazepine-10,11-epoxide levels by 45%. Toxicity was seen in 4 patients (dizziness, nausea, diplopia). 2 The addition of lamotrigine resulted in cerebellar toxicity (nausea, vertigo, nystagmus, ataxia) in 6 out of 9 patients taking subtoxic and just-tolerated doses of carbamazepine when lamotrigine was added. Analysis showed that in all 8 cases at least one of the levels of carbamazepine, carbamazepine-10,11-epoxide or lamotrigine had become unusually high, but the authors concluded the interaction was likely to be pharmacodynamic rather than pharmacokinetic. 3

In contrast other studies have found that the concurrent use of lamotrigine and carbamazepine does not result in any clinically significant pharmacokinetic changes. Lamotrigine caused no changes in carbamazepine levels in two clinical studies, 4,5 and another pharmacokinetic study found that lamotrigine 200 to 300 mg daily had no effect on the disposition of a single dose of oral carbamazepine-epoxide. 6 Another study in 47 patients taking carbamazepine, to which lamotrigine was added, found no significant changes in carbamazepine or carbamazepine-10,11-epoxide levels. Despite this 9 cases of diplopia or dizziness were recorded, predominantly in those whose carbamazepine levels were already high before the lamotrigine was added, even though there was no change in carbamazepine or carbamazepine-10,11-epoxide levels. 7 A further well-designed study in healthy subjects found that lamotrigine 100 mg twice daily for a week had no effect on the pharmacokinetics of carbamazepine or carbamazepine-10,11-epoxide after a single 200-mg dose of carbamazepine. 8 Similarly, lamotrigine had no effect on mean carbamazepine levels, and actually decreased mean carbamazepine-10,11-epoxide levels by 23% in a study in 14 children. Two children developed diplopia, which was unrelated to drug levels, but responded to a reduction in lamotrigine dose in one, and a reduction in carbamazepine dose in the other. 9

(b) Effects on lamotrigine

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was much lower in patients also taking carbamazepine than in those taking...
lamotrigine monotherapy (0.38 versus 0.84). Other studies have reported similar findings. In another study, mean increases in lamotrigine levels of about 60% occurred in patients taking lamotrigine with carbamazepine when the carbamazepine was withdrawn. Similarly, a case report describes a rapid increase in lamotrigine levels when carbamazepine was withdrawn. A review of patients taking antiepileptics found that carbamazepine increased the clearance of lamotrigine by 30 to 50%.

Mechanism

The apparent contradiction in the results described is not understood. One suggestion to account for the toxic symptoms seen in some patients is that it occurs at the site of action (a pharmacodynamic interaction) rather than because lamotrigine increases the carbamazepine-10,11-epoxide level. Carbamazepine may induce the glucuronidation of lamotrigine.

Importance and management

Overall lamotrigine does not appear to significantly alter carbamazepine levels. However, toxicity has occurred, and therefore patients should be well monitored if lamotrigine is added, and the carbamazepine dose reduced if CNS adverse effects occur. Carbamazepine induces the metabolism of lamotrigine, and the recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking carbamazepine is twice that of patients taking lamotrigine monotherapy. However, if they are also taking valproate in addition to carbamazepine, the lamotrigine dose should be reduced. See ‘Lamotrigine + Valproate’, p.542.

Clinical evidence

(a) Azithromycin

Azithromycin 500 mg once for 3 days had no effect on the pharmacokinetics of carbamazepine 200 mg twice daily or its active metabolite, carbamazepine-10,11-epoxide, in healthy subjects.

(b) Clarithromycin

A pharmacokinetic study in healthy subjects found that clarithromycin 500 mg every 12 hours for 5 days increased the AUC of a single 400-mg dose of carbamazepine by 26%. A retrospective study of 5 epileptic patients found that when they were given clarithromycin (dosage not stated) their serum carbamazepine levels rose by 20 to 50% within 3 to 5 days, despite 30 to 40% reductions in the carbamazepine dosage in 4 of them. Carbamazepine levels in the toxic range were seen in 3 of them, and their carbamazepine dosages were then even further reduced. A number of case reports have described carbamazepine toxicity following the addition of clarithromycin in adults and children. Two other epileptic patients had marked rises in serum carbamazepine levels when they were given clarithromycin 500 mg three times daily and omeprazole. It is not clear whether the omeprazole also had some part to play. See also ‘Carbamazepine + Proton pump inhibitors’, p.534.

(c) Erythromycin

An 8-year-old girl taking phenobarbital 50 mg and carbamazepine 800 mg daily was given 500 mg, then later 1 g of erythromycin daily. Within 2 days she began to experience balancing difficulties and ataxia, which were eventually attributed to carbamazepine toxicity. Her serum carbamazepine levels were found to have risen from a little below 10 micrograms/mL to over 25 micrograms/mL (therapeutic range 2 to 10 micrograms/mL). The levels rapidly returned to normal after carbamazepine was withheld for 24 hours and the erythromycin stopped.

A study in 7 healthy subjects confirmed that erythromycin can cause significant increases in carbamazepine levels, and a study in 8 healthy subjects found that the clearance of carbamazepine is reduced by an average of 20% (range 5 to 41%) by erythromycin 1 g daily for 5 days. Another study, in healthy subjects given erythromycin 500 mg three times daily for 10 days, found that the clearance of a single dose of carbamazepine was reduced by about 20% and the maximum serum levels of carbamazepine-10,11-epoxide were reduced by about 40% by erythromycin.

Marked rises in serum carbamazepine levels (up to fivefold in some cases) and/or toxicity (including cases of hepatorenal failure and AV block as well as more typical signs of carbamazepine toxicity) have been described in over 30 cases involving both children and adults. Symptoms commonly began within 24 to 72 hours of starting erythromycin, although in some cases it was as early as 8 hours. In most cases toxicity resolved within 3 to 5 days of stopping the erythromycin.

(d) Fluoroxythymiclin

Fluoroxythymiclin 500 mg three times daily for a week increased the AUC of a single 400-mg dose of carbamazepine by about 20% and moderately reduced the production of carbamazepine-10,11-epoxide in healthy subjects.

(e) Josamycin

Josamycin 1 g twice daily for a week reduced the clearance of carbamazepine by about 20% in healthy subjects and in patients.

(f) Midecamycin acetate

A single-dose study in 14 subjects found that after taking midecamycin acetate 800 mg twice daily for 8 days the AUC of a single 200-mg dose of carbamazepine was increased by 15%, and the AUC of its active metabolite (carbamazepine-10,11-epoxide) was reduced by 26%. Another study in patients taking carbamazepine found that the addition of midecamycin acetate 600 mg twice daily caused a small increase in the trough serum levels of carbamazepine, and only an 11% increase in the AUC.

(g) Roxithromycin

Roxithromycin 150 mg twice daily for 8 days did not affect the pharmacokinetics of a single 200-mg dose of carbamazepine in healthy subjects. However, there is an isolated report of carbamazepine toxicity (levels increased to 21.7 mg/L) in a patient taking carbamazepine and atorvastatin the day after she started to take roxithromycin 150 mg twice daily. Roxithromycin and atorvastatin were stopped and carbamazepine levels fell to 12.5 mg/L within a day. The increased carbamazepine levels were attributed to the concurrent use of roxithromycin.

Carbamazepine + Macrolides

Carbamazepine serum levels are markedly and rapidly increased by erythromycin or troleandomycin, and toxicity can often develop within 1 to 3 days. Telithromycin is predicted to interact similarly. Clarithromycin also raises carbamazepine levels, but to a lesser extent. Studies suggest that azithromycin, fluorothymiclin, josamycin, midecamycin, and roxithromycin have no interaction or no clinically significant interaction, with carbamazepine, but note that a case of carbamazepine toxicity has been reported in a patient given roxithromycin.
532

Chapter 14

(h) Telithromycin
The manufacturer predicts that carbamazepine will reduce the levels of telithromycin, with possible loss of efficacy, because carbamazepine induces the cytochrome P450 isoenzyme CYP3A4. Telithromycin is an
inhibitor of CYP3A4, and may therefore raise carbamazepine levels.43
(i) Troleandomycin
Symptoms of carbamazepine toxicity (dizziness, nausea, vomiting, excessive drowsiness) developed in 8 epileptic patients taking carbamazepine
within 24 hours of starting to take troleandomycin. The 2 patients available for examination had a sharp rise in serum carbamazepine levels, from
about 5 to 28 micrograms/mL over 3 days, and a rapid fall following withdrawal of the troleandomycin.44,45
Another report by the same authors describes a total of 17 similar cases
of carbamazepine toxicity caused by troleandomycin.16 Some of the patients had three or fourfold increases in serum carbamazepine levels. Another case has been described elsewhere.12 In most instances the serum
carbamazepine levels returned to normal within about 3 to 5 days of withdrawing the macrolide.16
Mechanism
It seems probable that clarithromycin, erythromycin and troleandomycin,
and to a lesser extent some of the other macrolides, slow the rate of metabolism of the carbamazepine by the cytochrome P450 isoenzyme
CYP3A4 so that the anticonvulsant accumulates within the body.46,47 Telithromycin is predicted to interact similarly.43 It was suggested that the
carbamazepine toxicity seen with roxithromycin may have been mediated
by P-glycoprotein inhibition, which occurred as a result of an interaction
between roxithromycin and atorvastatin.
Importance and management
The interaction between carbamazepine and troleandomycin is established, clinically important and potentially serious. The incidence is high.
The rapidity of its development (within 24 hours in some cases) and the
extent of the rise in serum carbamazepine levels suggest that it would be
difficult to control carbamazepine levels by reducing the dosage. Concurrent use should probably be avoided.
The interaction between carbamazepine and erythromycin is also very
well documented, well established and of clinical importance. Concurrent
use should be avoided unless the effects can be very closely monitored by
measurement of serum carbamazepine levels and suitable dosage reductions made. Toxic symptoms (ataxia, vertigo, drowsiness, lethargy, confusion, diplopia) can develop within 24 hours, but serum carbamazepine
levels can return to normal within 8 to 12 hours of withdrawing the antibacterial.36
The interaction between carbamazepine and clarithromycin is also established, clinically important and potentially serious. However, the extent of
the interaction is less with clarithromycin than with erythromycin or troleandomycin (i.e. the rise in carbamazepine levels is less).48 It has been recommended that carbamazepine dosages should be reduced by 30 to 50%
during treatment with clarithromycin, with monitoring within 3 to 5 days,
and patients should be told to tell their doctor of any symptoms of toxicity
(dizziness, diplopia, ataxia, mental confusion).
Analysis of the macrolide/carbamazepine interactions has shown that
patients requiring high doses of carbamazepine to reach therapeutic levels
are likely to have a greater rise in their carbamazepine levels.48 The extent
of the interactions is also correlated with the macrolide dose.48
Josamycin, flurithromycin and midecamycin acetate appear to be safer
alternatives to either clarithromycin, erythromycin or troleandomycin.
Nevertheless a small or moderate reduction in the dosage of the carbamazepine may be needed, with subsequent good monitoring. Pharmacokinetic data suggest that azithromycin and roxithromycin do not
interact. However, there is an isolated report of carbamazepine toxicity in
a patient taking roxithromycin, but this was complicated by the presence
of atorvastatin. Telithromycin is predicted to interact, and the manufacturer advises avoidance of the combination, and suggests that telithromycin
should not be used within 2 weeks of stopping carbamazepine.43

Phenelzine, moclobemide and tranylcypromine appear not to interact adversely with carbamazepine.

Clinical evidence, mechanism, importance and management

There appear to be no reports of adverse reactions during the concurrent use of MAOIs and carbamazepine. However, the manufacturers of carbamazepine\(^1\) say that concurrent use should be avoided because of the close structural similarity between carbamazepine and the tricyclic antidepressants (and therefore the theoretical risk of an adverse interaction). They suggest that MAOIs should be discontinued at least 2 weeks before carbamazepine is started. Several reports describe successful use of carbamazepine and MAOIs, namely tranylcypromine,\(^2,3\) phenelzine,\(^4\) and moclobemide.\(^5\) Bearing in mind that the MAOIs and the tricyclics can be given together under certain well controlled conditions (e.g. MAOAs or RIMAs + Tricyclic and related antidepressants’, p.1149), the warning about the risks may possibly prove to be overcautious. That note, rarely, the MAOIs have been seen to cause convulsions.

1. Gupta M, Gupta YK, Agarwal S, Aneja S, Kalaivani M, Kohli K. Effects of add-on melatonin on antioxidant enzymes, melatonin 6 to 9 mg/kg daily for 14 days was given with carbamazepine to children with epilepsy. The addition of melatonin increased the antioxidant activity of glutathione reductase, compared with a decrease in the placebo group; similar trends which did not reach statistical significance were found with glutathione peroxidase. Carbamazepine may cause reactive oxygen species (ROS) accumulation and the effect may be antagonised by melatonin. ROS can interact with other molecules within the body, causing damage to cell structures. This results in oxidative stress, which may vary depending on the development of some disease states. Serum levels of carbamazepine and its metabolite carbamazepine-10,11-epoxide were not affected by concurrent melatonin which suggests a pharmacokinetic interaction is unlikely.\(^1\)

Carbamazepine + Melatonin

Melatonin does not affect the serum levels of carbamazepine or its 10,11-epoxide metabolite.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study on the effects of melatonin on antioxidant enzymes, melatonin 6 to 9 mg/kg daily for 14 days was given with carbamazepine to children with epilepsy. The addition of melatonin increased the antioxidant activity of glutathione reductase, compared with a decrease in the placebo group; similar trends which did not reach statistical significance were found with glutathione peroxidase. Carbamazepine may cause reactive oxygen species (ROS) accumulation and the effect may be antagonised by melatonin. ROS can interact with other molecules within the body, causing damage to cell structures. This results in oxidative stress, which may vary depending on the development of some disease states. Serum levels of carbamazepine and its metabolite carbamazepine-10,11-epoxide were not affected by concurrent melatonin which suggests a pharmacokinetic interaction is unlikely.\(^1\)

Carbamazepine + Nefazodone

Five patients developed elevated serum carbamazepine levels and toxicity when nefazodone was given. A study in healthy subjects using lower carbamazepine doses found only modest increases in carbamazepine levels, and no evidence of toxicity when nefazodone was given. Carbamazepine markedly reduces nefazodone levels.

Clinical evidence

A patient taking carbamazepine 1 g daily developed evidence of toxicity (light-headedness, ataxia) within 15 days of starting to take nefazodone (initially 100 mg twice daily increasing to 150 mg twice daily after a week). Her serum carbamazepine levels had risen from below 8.3 micrograms/mL up to 10.8 micrograms/mL. It was found necessary to reduce the carbamazepine dosage to 600 mg daily to eliminate these adverse effects and to achieve a serum level of 7.4 micrograms/mL.\(^1\) In 4 other patients taking carbamazepine 800 mg or 1 g daily the addition of nefazodone caused up to threefold rises in carbamazepine levels. The carbamazepine dose was reduced by 25 to 60%.\(^1,2\) In a study in 12 healthy subjects no evidence of toxicity was seen when carbamazepine 200 mg twice daily was given with nefazodone 200 mg twice daily for 5 days. However, the levels of carbamazepine were slightly increased (23% increase in AUC) and the levels of nefazodone markedly decreased (93% decrease in AUC). The authors suggest that there may be a greater effect with higher doses of carbamazepine.\(^3\)

Mechanism

Both drugs are metabolised by the cytochrome P450 isoenzyme CYP3A4. Nefazodone is known to inhibit CYP3A4, whereas carbamazepine is a potent inducer of CYP3A4. Hence concurrent use reduces carbamazepine metabolism, leading to raised levels, and increases nefazodone levels, leading to lowered levels.

Importance and management

Information is limited, but it would seem prudent to monitor for signs of carbamazepine toxicity if nefazodone is added to established treatment, especially with doses of carbamazepine above 800 mg. The nefazodone dosage may need to be increased in the presence of carbamazepine, so be alert for a reduced effect. Nefazodone has largely been withdrawn, but the US manufacturer of nefazodone did contraindicate its concurrent use with carbamazepine.\(^4\)

Carbamazepine + Phenobarbital

Carbamazepine serum levels are reduced to some extent by phenobarbital, and carbamazepine-10,11-epoxide levels are raised. In children, phenobarbital clearance is decreased by carbamazepine.

Clinical evidence

A comparative study found that on average patients taking both carbamazepine and phenobarbital (44 patients) had carbamazepine serum levels that were 18% lower than those taking carbamazepine alone (43 patients).\(^1\) Similar results were found in other studies in both adult and paediatric patients taking both drugs.\(^2,5\) Levels of the active metabolite, carbamazepine-10,11-epoxide, were increased.\(^3,6\) However, one study
found that the clearance of a single dose of carbamazepine-10,11-epoxide was higher and the plasma half-life shorter in epileptic patients taking phenobarbital when compared with healthy subjects not taking phenobarbital. In a prospective study the clearance of phenobarbital in 222 patients receiving monotherapy was compared to that in 63 patients who were also taking carbamazepine. During phenobarbital monotherapy, clearance was highest in the very young, decreased with increasing weight, and was lowest in adults. The pattern was similar for carbamazepine, except that its clearance was decreased by phenobarbital. Further, the effects of carbamazepine on phenobarbital clearance were maximal in young children (about 54%) and minimal in adults.

### Mechanism
Phenobarbital and carbamazepine are both known enzyme inducers, and may therefore increase each others metabolism. Phenobarbital may also induce the metabolism of carbamazepine-10,11-epoxide.

### Importance and management
An established interaction. It would be prudent to monitor phenobarbital levels in children also given carbamazepine, as changes in clearance may affect dose requirements. The small fall in serum carbamazepine levels probably has little practical importance, especially since the metabolite carbamazepine-10,11-epoxide also has anticonvulsant activity. Consider also ‘Carbamazepine + Primidone’, below.

### Carbamazepine + Primidone

#### Clinical evidence

A 15-year-old boy had complex partial seizures that were not controlled despite treatment with primidone 12 mg/kg daily in three divided doses and carbamazepine 10 mg/kg daily in three divided doses. Even when the carbamazepine dosage was increased to 20 and then 30 mg/kg daily his serum carbamazepine levels only reached 4.8 micrograms/mL, and his sei- zures continued. When the primidone was gradually withdrawn his serum carbamazepine levels increased to 12 micrograms/mL and his seizures completely disappeared.

- **Mechanism**

  When the primidone was stopped, the clearance of the carbamazepine decreased by about 60%. This is consistent with the known enzyme-inducing effects of primidone (converted in the body to phenobarbital), which can increase the metabolism of other drugs by the liver. There is some evidence to suggest that carbamazepine may increase the metabolism of primidone to phenobarbital.

- **Importance and management**

  Direct information seems to be limited to these reports. It may be prudent to monitor combined treatment, and adjust doses if necessary. Consider also ‘Carbamazepine + Phenobarbital’, p.533.

#### Clinical evidence

### Carbamazepine + Proton pump inhibitors

**Omeprazole**

Omeprazole markedly raised the levels of a single dose of carbamazepine, but had no significant effect on carbamazepine taken long-term. Some anecdotal reports suggest that carbamazepine serum levels may possibly be reduced by lansoprazole. Pantoprazole did not affect the pharmacokinetics of carbamazepine in one study.

#### Clinical evidence

(a) **Lansoprazole**

In 2001 the manufacturers of lansoprazole had on record 5 undetailed case reports of apparent interactions between lansoprazole and carbamazepine. One of them describes the development of carbamazepine toxicity when lansoprazole was added, but there is some doubt about this case because it is thought that the patient may have started to take higher doses of carbamazepine.

The other 4 cases are consistent, in that carbamazepine levels fell shortly after lansoprazole was added, and/or the control of seizures suddenly worsened. One patient had a fall in carbamazepine serum levels from 11.5 to 7.7 mg/L. The carbamazepine levels of another patient returned to normal when the lansoprazole was stopped.

(b) **Omeprazole**

Omeprazole 20 mg daily for 14 days was found to increase the AUC of a single 400-mg dose of carbamazepine in 7 patients by 75%. The clearance was reduced by 40% and the elimination half-life was more than doubled (from 17.2 to 37.3 hours). However, a retrospective study of the records of 10 patients who had been taking omeprazole 20 mg daily with long-term carbamazepine (rather than a single dose) found a non-significant re- duction in carbamazepine serum levels.

(c) **Pantoprazole**

Pantoprazole 40 mg daily for 5 days had no effect on the AUC of carbamazepine or carbamazepine-10,11-epoxide after a single 400-mg dose of carbamazepine in healthy subjects.

#### Mechanism

Omeprazole may inhibit the oxidative metabolism of single doses of carbamazepine. However, when carbamazepine is taken continuously it in- duces its own metabolism by the cytochrome P450 isoenzyme CYP3A4, thereby possibly opposing the effects of this interaction.
Importance and management

It seems that in practice no clinically relevant interaction is likely to occur between omeprazole and carbamazepine. For lansoprazole, information seems to be limited to this handful of reports from which no broad general conclusions can be drawn, but they do suggest that this interaction should be considered if lansoprazole is added to established treatment with carbamazepine. Pantoprazole appears not to affect the pharmacokinetics of carbamazepine.

Carbamazepine + SSRIs

Some, but not all, reports indicate that carbamazepine serum levels can be increased by fluoxetine and fluvoxamine. Toxicity may develop. Citalopram, paroxetine and sertraline do not normally affect carbamazepine, but there is an isolated case of raised carbamazepine levels with sertraline. Citalopram, paroxetine and sertraline levels may be reduced by carbamazepine. The use of carbamazepine with an SSRI has, rarely, led to effects such as hypotension, the serotonin syndrome, and parkinsonism. Consideration should be given to the fact that SSRIs have been known to cause seizures.

Clinical evidence

(a) Citalopram

In a study in 12 healthy subjects citalopram 40 mg daily for 2 weeks caused no change in the pharmacokinetics of carbamazepine 400 mg once daily. An approximate 30% decrease in citalopram levels occurred in 6 patients taking citalopram 40 to 60 mg daily when they were given carbamazepine 200 to 400 mg daily for 4 weeks. Despite this decrease, the combination was considered clinically useful. Similarly, two patients with epilepsy, major depression, and panic disorder had increased citalopram levels (one had an improved antidepressant response, but the other patient experienced tremor and increased anxiety) when their treatment with carbamazepine was replaced by oxcarbazepine.

(b) Fluoxetine

Two patients developed carbamazepine toxicity (diplopia, blurred vision, tremor, vertigo, nausea, tinnitus etc.) within 7 and 10 days of starting to take fluoxetine 20 mg daily. Their serum carbamazepine levels were found to have risen by about 33% and 60%, respectively. The problem was resolved in one of them by reducing the carbamazepine dosage from 1 g to 800 mg daily, and in the other by stopping the fluoxetine. The effects seen in these cases are supported by a study in 6 healthy patients, where adding fluoxetine 20 mg daily to steady-state carbamazepine caused a rise in the AUC of carbamazepine and carbamazepine-10,11-epoxide (its active metabolite) of about 25 to 50%.

In contrast, fluoxetine 20 mg daily for 3 weeks was found to have no effect on the serum levels of carbamazepine or carbamazepine-10,11-epoxide in 8 epileptic patients stabilised on carbamazepine.

Aside from these pharmacokinetic changes two cases of parkinsonism developed within 3 and 9 days of adding fluoxetine to carbamazepine treatment. In both cases carbamazepine levels were unaffected. A case of the serotonin syndrome (shivering, agitation, myoclonic-like leg contractions, diaphoresis etc.) has also been seen, in a woman taking carbamazepine 200 mg daily and fluoxetine 20 mg daily.

(c) Fluvoxamine

Increased serum levels and signs of carbamazepine toxicity (nausea, vomiting) were seen in 3 patients taking long-term carbamazepine when they were given fluvoxamine. The carbamazepine level almost doubled in one of them within 10 days of starting fluvoxamine 50 to 100 mg daily. The interaction was accommodated by reducing the carbamazepine dosage by 200 mg daily in all three (from 1 g to 800 mg in one of them, and from 800 to 600 mg daily in the other two). An approximate doubling of carbamazepine levels has also been seen in other patients given fluvoxamine.

In contrast, fluvoxamine 100 mg daily for 3 weeks was found to have no effect on the serum levels of carbamazepine or carbamazepine-10,11-epoxide in 7 epileptic patients stabilised on carbamazepine.

(d) Paroxetine

In epileptic patients, paroxetine 30 mg daily for 16 days caused no changes in the plasma levels or therapeutic effects of carbamazepine. Steady-state paroxetine plasma levels were lower in those taking phenytoin (16 nanograms/mL) than in those taking carbamazepine (27 nanograms/mL) or sodium valproate (73 nanograms/mL). An elderly patient taking carbamazepine 200 mg daily then 400 mg daily for neuropathic pain associated with herpes zoster infection was given paroxetine 20 mg daily to treat depression. He developed vertigo, bradycardia and syncope and his plasma sodium was found to be low (120 mmol/L). Sodium levels returned to normal (135 mmol/L) over several weeks after carbamazepine was withdrawn.

(e) Sertraline

A double blind, placebo-controlled, parallel group study in 13 healthy subjects (7 taking sertraline, 6 taking placebo) found that sertraline 200 mg daily for 17 days had no effect on the pharmacokinetics of carbamazepine 200 mg twice daily, nor on the pharmacokinetics of carbamazepine-10,11-epoxide. In addition, sertraline did not potentiate the cognitive effects of carbamazepine.

However, an isolated report describes a woman who had taken carbamazepine 600 mg and flecainide 100 mg daily for 2 years, who had a rise in her trough serum carbamazepine levels from 4.7 to 8.5 micrograms/mL within 4 weeks of starting sertraline 100 mg daily. After 3 months of treatment, carbamazepine levels were 11.9 micrograms/mL. At the same time she developed pancytopenia (interpreted as a toxic bone marrow reaction to the increased carbamazepine), which improved when the carbamazepine and sertraline were stopped.

An isolated report describes a woman with schizoaffective disorder successfully treated for 3 years with haloperidol and carbamazepine who was given sertraline 50 mg daily for depression. When she failed to respond, the sertraline dosage was progressively increased to 300 mg daily but her sertraline plasma levels remained low (about 17 to 25% of those predicted). Another patient on carbamazepine similarly failed to respond to the addition of sertraline and had low sertraline levels. In an analysis of plasma sertraline levels the concentration to daily dose ratio of sertraline was significantly lower in patients who had taken sertraline with carbamazepine compared with those who had taken sertraline without carbamazepine, suggesting that carbamazepine lowered sertraline levels.

Mechanism

The evidence suggests that fluoxetine and fluvoxamine inhibit the metabolism of carbamazepine by the liver (presumably by inhibiting the cytochrome P450 isozyme CYP3A4) so that its loss from the body is reduced, leading to a rise in its serum levels.

Citalopram, sertraline and possibly paroxetine serum levels may be reduced because carbamazepine induces their metabolism by CYP3A4, which results in lower levels of these SSRIs. Oxcarbazepine appears not to interact. Both carbamazepine and paroxetine may cause hypotension so the reduced sodium levels could be due to the effects of both drugs.

Importance and management

Information for fluoxetine and fluvoxamine appears to be limited to these reports. It is not clear why they are inconsistent, but be alert for an increase in carbamazepine serum levels and toxicity if fluoxetine or fluvoxamine is added. The interaction appears rare. A literature search by the manufacturers of fluvoxamine only identified 8 cases of an interaction between fluvoxamine and carbamazepine up until 1995. However, because of the unpredictability of this interaction it would be prudent to monitor concurrent use, particularly in the early stages, so that any patient affected can be quickly identified. Be alert for the need to reduce the carbamazepine dosage. The manufacturers of fluoxetine suggest that carbamazepine should be started at or adjusted towards the lower end of the dosage range in those taking fluoxetine. They additionally suggest caution if fluoxetine has been taken during the previous 5 weeks.

There would seem to be no particular need to monitor carbamazepine levels in patients taking citalopram, paroxetine, or sertraline. However, be
aware that the SSRIs may be less effective in the presence of carbamazepine. Considering increasing the dose if necessary.

Note that SSRIs may increase seizure frequency and should therefore be used with caution in patients with epilepsy, and avoided in those with unstable epilepsy.

Clinical evidence, mechanism, importance and management

A 67-year-old man taking carbamazepine 600 mg twice daily developed symptoms of carbamazepine toxicity (drowsiness, dizziness, ataxia) within a week of starting to take ticlopidine 250 mg twice daily. His carbamazepine level one week after starting the ticlopidine was 17.7 [micrograms/mL], but it had been only 10.1 [micrograms/mL] five weeks earlier. The carbamazepine dose was reduced to 500 mg twice daily, with resolution of symptoms, and producing a level of 12.5 [micrograms/mL] one week later. After stopping the ticlopidine, carbamazepine levels fell to 9.9 [micrograms/mL]. It was suggested that ticlopidine may interfere with carbamazepine metabolism. However, carbamazepine is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, and ticlopidine is not usually considered an inhibitor of this isoenzyme. This is the only report so far, and its general relevance is uncertain.

Carbamazepine + Trazodone

A single case report describes a moderate rise in serum carbamazepine levels in a patient given trazodone. Carbamazepine may moderately decrease trazodone levels.

Clinical evidence, mechanism, importance and management

A 53-year-old man who had been taking carbamazepine 700 mg daily for 7 months (serum levels 7.2 and 7.9 mg/L) started taking trazodone 100 mg daily. Two months later his serum carbamazepine levels were 10 mg/L and the concentration/dose ratio had increased by about 26%, but no signs or symptoms of carbamazepine toxicity were seen. The reasons for this interaction are not known but the authors suggest that it might occur because trazodone inhibits the cytochrome P450 isoenzyme CYP3A4 resulting in a reduction in the metabolism of the carbamazepine.

This seems to be the first and only report of raised carbamazepine levels with trazodone, and its general importance is unknown. The rise was only moderate and in this case was clinically irrelevant, but a carbamazepine serum rise of 26% might possibly be of importance in those patients with serum levels already near the top end of the therapeutic range.

In 6 patients taking trazodone 150 or 300 mg daily, the addition of carbamazepine 400 mg daily for 4 weeks decreased the plasma levels of trazodone by 24%, and of the active metabolite of trazodone by 40%.

However, the combination was considered clinically useful in three of the cases. In another study, when carbamazepine 400 mg daily was given with trazodone 100 to 300 mg daily, the plasma levels of trazodone and its active metabolite were reduced by 76% and 60%, respectively. The FDA in the US and the manufacturer of trazodone recommend that patients should be closely monitored and trazodone doses increased if necessary when both drugs are given.

Carbamazepine + Valnoctamide

Carbamazepine toxicity may develop if valnoctamide is also taken.

Clinical evidence

A study in 6 epileptic patients taking carbamazepine 800 to 1200 mg daily found that valnoctamide 200 mg three times daily for 7 days caused a 1.5 to 6.5-fold increase in the serum levels of carbamazepine-10,11-epoxide (an active metabolite). Clinical signs of carbamazepine toxicity (drowsiness, ataxia, nystagmus) were seen in 4 of them. Two patients were also taking phenobarbital or phenytoin, and the serum levels of these drugs were unaffected by valnoctamide. A further study in 6 healthy subjects found
that valnoctamide 600 mg daily for 8 days increased the half-life of a single 100-mg dose of carbamazepine-10,11-epoxide threefold, from 6.7 to 19.7 hours, and decreased its oral clearance fourfold.2

**Mechanism**

Valnoctamide inhibits the enzyme epoxide hydrolase, which is concerned with the metabolism and elimination of carbamazepine and its active epoxide metabolite.1,2

**Importance and management**

Information is limited but the interaction appears to be established. Patients taking carbamazepine who also take valnoctamide could rapidly develop carbamazepine toxicity because the metabolism of its major metabolite, carbamazepine-10,11-epoxide, is inhibited. This interaction is very similar to the interaction that occurs between carbamazepine and valpromide (an isomer of valnoctamide), see ‘Carbamazepine + Valproate’, below. Concurrent valnoctamide should be avoided unless the carbamazepine dosage can be reduced appropriately.

**Carbamazepine + Valproate**

The serum levels of carbamazepine are usually only slightly affected by sodium valproate, valproic acid or valpromide but a moderate to marked rise in the levels of its active metabolite, carbamazepine-10,11-epoxide may occur. Carbamazepine may reduce the serum levels of sodium valproate by 60% or more. Concurrent use may possibly increase the incidence of sodium valproate-induced hepatotoxicity.

**Clinical evidence**

(a) **Carbamazepine**

1. Sodium valproate or valproic acid. A study in 7 adult epileptic patients who had been taking carbamazepine 8.3 to 13.5 mg/kg for more than 2 months found that their steady-state serum carbamazepine levels fell by an average of 24% (range 3 to 59%) over a 6-day period when they were given sodium valproate 1 g twice daily. The carbamazepine levels were reduced in 6 of the patients and remained unchanged in one. The levels of the active metabolite, carbamazepine-10,11-epoxide, increased by an amount of 38%, with small decreases or no change in 4 patients and 24 to 150% increases in the remaining 3 patients.1,2

Other reports state that falls,5,4 no changes3,5,7 and even a slight rise4 in carbamazepine levels have been seen in some patients also taking sodium valproate or valproic acid. The serum levels of carbamazepine-10,11-epoxide are reported to be increased by about 50 to 100%.6,8–10 This active metabolite may cause the development of marked adverse effects such as blurred vision, dizziness, vomiting, tiredness and even nystagmus.8,11 Acute psychosis, tentatively attributed to elevated epoxide levels, occurred in one patient when carbamazepine was added to sodium valproate treatment.12

2. Valpromide. Symptoms of carbamazepine toxicity developed in 5 out of 7 epileptic patients taking carbamazepine when concurrent treatment with sodium valproate was replaced by valpromide, despite the fact that their serum carbamazepine levels did not increase.13 The toxicity appeared to be connected with a fourfold increase in the serum levels of the metabolite of carbamazepine, carbamazepine-10,11-epoxide, which rose to 8.5 micrograms/mL.13

In another study in 6 epileptic patients the serum levels of carbamazepine-10,11-epoxide rose by 330% (range 110 to 864%) within a week of starting valpromide, and two of the patients developed confusion, dizziness and vomiting. The symptoms disappeared and serum carbamazepine-10,11-epoxide levels fell when the valpromide dosage was reduced by one-third.6

A study in healthy subjects given a single 100-mg oral dose of carbamazepine-10,11-epoxide confirmed that valpromide 300 mg twice daily for 8 days reduced carbamazepine-10,11-epoxide clearance by 73%, and increased peak levels by 62%.14

(b) **Valproate levels**

A pharmacokinetic study in 6 healthy subjects found that carbamazepine, 200 mg daily, over a 17-day period increased the sodium valproate clearance by 30%.15

Other reports have described reductions in serum sodium valproate levels of 34 to 38% when carbamazepine was added,16,18 and rises of 50 to 65% when the carbamazepine was withdrawn.19,20 The rise appears to reach a plateau after about 4 weeks.20 A pharmacokinetic model has been devised to estimate valproate clearance when given with carbamazepine.21

(c) **Other effects**

Evidence from epidemiological studies suggests that the risk of fatal hepatotoxicity is higher when sodium valproate is given with other antiepileptics than when it is given alone, especially in infants.22,23 A single case report describes hepatocellular and cholestatic jaundice and a reversible Parkinsonian syndrome in a woman taking sodium valproate and carbamazepine, which reversed when the carbamazepine was withdrawn. Levels of both drugs did not exceed the therapeutic range at any stage. The Parkinsonian syndrome was attributed to a drug interaction, whereas the hepatotoxicity was considered most likely to be due to the carbamazepine, although the valproate may have contributed.24

**Mechanism**

The evidence suggests that carbamazepine increases the metabolism of valproate, so that it is cleared from the body more quickly. Carbamazepine may also possibly increase the formation of a minor but hepatotoxic metabolite of sodium valproate (2-propyl-4-pentenoic acid or 4-ene-VPA).25,26

The latter stages of carbamazepine metabolism appear to be inhibited by both valproate and its amide derivative, valpromide.27 The levels of the metabolite carbamazepine-10,11-epoxide increase during concurrent use, probably by inhibition of its metabolism to carbamazepine-10,11-trans-diol.8,10 by epoxide hydrolase. Valpromide was found to be about 100 times more potent an inhibitor of this enzyme than sodium valproate in vitro and caused a threefold higher rise in epoxide levels than valproate in one study.6 The carbamazepine-10,11-epoxide metabolite has anticonvulsant activity, but it may also cause toxicity if its serum levels become excessive.6,32

It has also been suggested that valproate is not a selective inhibitor of epoxide hydrolase but that it inhibits all the steps of the epoxide-diol pathway.33 The trans-diol metabolite is then further converted by glucuronidation, and it seems that this step is also inhibited.30

**Importance and management**

Moderately well documented interactions, which are established. A minor to modest fall in carbamazepine levels may occur, but there may be a moderate to marked rise in the active epoxide metabolite. Therefore, be alert for signs of toxicity, which may indicate high levels of carbamazepine-10,11-epoxide and a need to reduce the carbamazepine dose. Be alert for falls in the serum levels of valproate if carbamazepine is added, and rises if carbamazepine is withdrawn. Sodium valproate has been associated with serious hepatotoxicity, especially in children aged less than 3 years, and this has been more common in those receiving other antiepileptics. Sodium valproate monotherapy is to be preferred in this group.

There is also some debate about whether the combination of valproate (especially valproamide) and carbamazepine should be avoided, not only because of the risk of toxicity but also because inhibition of epoxide hydrolase may be undesirable.13 This enzyme is possibly important for the detoxification of a number of teratogenic, mutagenic and carcinogenic epoxides.8,13 More study is needed.

Ethosuximide + Isoniazid

A single report describes a patient who developed psychotic behaviour and signs of ethosuximide toxicity when given isoniazid.

Clinical evidence, mechanism, importance and management

An epileptic patient, who had been stable taking ethosuximide and sodium valproate for 2 years, developed persistent hiccuping, nausea, vomiting, anorexia and insomnia within a week of starting to take isoniazid 300 mg daily. Psychotic behaviour gradually developed over the next 5 weeks and so the isoniazid was stopped. The appearance of these symptoms appeared to be related to the sharp rise in serum ethosuximide levels (from about 50 up to 198 micrograms/mL). It is suggested that the isoniazid may have inhibited the metabolism of the ethosuximide, leading to accumulation and toxicity. The general importance of this case is uncertain.

Ethosuximide + Other antiepileptics

Minor to modest falls in serum ethosuximide levels may occur if carbamazepine, primidone or phenytoin are also given, whereas methylphenobarbital or sodium valproate may cause a rise in ethosuximide levels. The effect of all these changes on seizure control is uncertain. Lamotrigine appears not to affect ethosuximide levels. Ethosuximide is reported to have caused phenytoin toxicity in a few cases, and it appears that ethosuximide can reduce valproate levels.

Clinical evidence

(a) Barbiturates

In a retrospective analysis, the level to dose ratio of ethosuximide was 33% lower in 29 epileptic patients taking ethosuximide and primidone than in 39 patients taking ethosuximide alone, suggesting that primidone reduces ethosuximide levels. Similarly, in another study, which compared the pharmacokinetics of a single dose of ethosuximide in 10 epileptic patients taking phenobarbital, phenytoin and/or carbamazepine with 12 healthy controls found that the epileptic group had markedly shorter (about halved) ethosuximide half-lives. Conversely, another report stated that ethosuximide levels tended to rise after administration of methylenobarbital, used (the opposite effect to that which would be expected), but did not appear to be affected by phenobarbital or primidone. Phenobarbital levels (from primidone) do not appear to be affected by ethosuximide.

(b) Carbamazepine

A study in 6 healthy subjects taking ethosuximide 500 mg daily found that the mean plasma levels of ethosuximide were reduced by 17%, from 32 to 27 mg/mL by carbamazepine 200 mg daily for 18 days. One individual had a 35% reduction in ethosuximide levels. Another study, which compared 10 epileptic patients (taking enzyme-inducing antiepileptic drugs, including 4 taking carbamazepine) with 12 healthy controls found that the epileptic group had markedly shorter (about halved) ethosuximide half-lives.

In contrast, the concurrent use of carbamazepine did not affect the correlation between ethosuximide dose and levels in another study.

(c) Lamotrigine

Five children taking ethosuximide and various other antiepileptics had no change in their plasma ethosuximide levels when lamotrigine was also given.

(d) Phenytoin

A study compared the pharmacokinetics of a single dose of ethosuximide in 10 epileptic patients taking phenobarbital, phenytoin and/or carbamazepine with 12 healthy controls. The epileptic group had markedly shorter (about halved) ethosuximide half-lives. In contrast, the concurrent use of phenytoin did not affect the correlation between ethosuximide levels and dose in another study.

Three cases have occurred in which ethosuximide appeared to have been responsible for increasing phenytoin levels, leading to the development of phenytoin toxicity in 2 patients.

(e) Sodium valproate

Four out of 5 patients taking ethosuximide (average dose 27 mg/kg) had an increase in their serum levels of about 50% (from 73 to 112 micrograms/mL), within 3 weeks of starting to take sodium valproate (adjusted to the maximum tolerated dose). Sedation occurred and ethosuximide dose reductions were necessary. In a single-dose study in 6 healthy subjects, treatment with sodium valproate for 9 days was reported to have increased the ethosuximide half-life and reduced the clearance by 15%. However, other studies have described no changes or even lower serum ethosuximide levels (level to dose ratio reduced by 36%).

One study in 13 children found that ethosuximide can lower valproate serum levels. In the presence of ethosuximide the valproate levels were lower than with valproate alone (87 versus 120 micrograms/mL). After stopping ethosuximide the valproate levels rose by about 40%.

Mechanism

The most probable explanation for the fall in ethosuximide levels is that the carbamazepine and the other enzyme-inducing antiepileptics increase the metabolism and clearance of ethosuximide, which is known to be metabolised by the cytochrome P450 isoenzyme CYP3A.

Importance and management

The concurrent use of antiepileptics is common and often advantageous. Information on these interactions is sparse and even contradictory and their clinical importance is uncertain. Nevertheless, good monitoring would clearly be appropriate if these drugs are used with ethosuximide to monitor for potential toxicity and to ensure adequate seizure control.

Felbamate + Antacids

An aluminium/magnesium hydroxide-containing antacid had no effect on the absorption of felbamate.
Clinical evidence, mechanism, importance and management

Felbamate 2.4 g daily was given to 9 epileptic women for 2 weeks. For a third week the felbamate was taken with an antacid containing aluminium/magnesium hydroxide (Maalox Plus). No significant changes in the plasma levels or AUC were seen.1 No special precautions would seem to be needed if felbamate is taken with this or any other similar antacid.

Fosphenytoin + Miscellaneous

Fosphenytoin is a prodrug of phenytoin, which is rapidly and completely hydrolysed to phenytoin in the body. It is predicted to interact with other drugs in the same way as phenytoin.1,2 No drugs are known to interfere with the conversion of fosphenytoin to phenytoin.2

Gabapentin + Antacids

Aluminium/magnesium hydroxide slightly reduces the absorption of gabapentin.

Clinical evidence, mechanism, importance and management

An aluminium/magnesium hydroxide antacid (Maalox TC) reduced the bioavailability of gabapentin 400 mg by about 20% when given either at the same time or 2 hours after gabapentin. When the antacid was given 2 hours before the gabapentin, the bioavailability was reduced by about 10%.1 These small changes are unlikely to be of clinical importance. However, the manufacturer does recommend that gabapentin is taken about 2 hours after aluminium/magnesium-containing antacids.2

Gabapentin + Cimetidine

A brief report notes that cimetidine decreased the renal clearance of gabapentin by 12%, which was not expected to be clinically important. No study details were given.1

Gabapentin + Food

Food, including protein and enteral feeds, does not have a clinically important effect on the absorption of gabapentin.

Clinical evidence, mechanism, importance and management

A high-protein meal (80 g of total protein) increased the maximum serum levels of a single 800-mg dose of gabapentin by 36% in healthy subjects. The AUC was increased by 11%, which was not statistically significant. These findings were the opposite of those expected, since L-amino acids compete for gabapentin intestinal transport in vitro.1

In another single-dose study, the absorption of gabapentin capsules did not differ when opened and mixed with either apple sauce or orange juice, but tended to be higher (AUC increased by 26%) when mixed with a protein-containing vehicle (chocolate pudding).2 Similarly, no change in absorption was found when gabapentin syrup was mixed with tap water, grape juice, or an enteral feed (Sustacal), but a modest 31% increase in AUC was seen when it was mixed with chocolate milk.3 These small changes are unlikely to be of clinical importance, so it does not matter when gabapentin is taken in relation to food.

Gabapentin + Other antiepileptics

Gabapentin does not normally affect the pharmacokinetics of carbamazepine, phenytoin, phenobarbital or sodium valproate, and no dosage adjustments are needed on concurrent use. However, isolated reports describe increased phenytoin levels and toxicity in two patients given gabapentin.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of both phenytoin and gabapentin remained unchanged in 8 epileptics who were given gabapentin 400 mg three times daily for 8 days, in addition to phenytoin, which they had been taking for at least 2 months.1 Other studies confirm that the steady-state pharmacokinetics of phenytoin are unaffected by gabapentin, and that the pharmacokinetics of gabapentin are similarly unaffected by phenytoin.2,3 These reports contrast with an isolated report of a patient taking phenytoin, carbamazepine and clobazam whose serum phenytoin levels increased three to fourfold, with symptoms of toxicity, on two occasions when gabapentin 300 to 600 mg daily was given. Carbamazepine serum levels remained unchanged. The author suggests that this differing reaction may be because the patient was taking more than one antiepileptic, unlike previous studies where only single drugs had been used.4 However, another case of phenytoin toxicity possibly attributable to gabapentin has been described in a patient who was not taking any other antiepileptics.5

Gabapentin does not affect **phenobarbital** levels, nor is it affected by **phenobarbital**. Other studies confirm that the steady-state pharmacokinetics of **carbamazepine** and **sodium valproate** are unaffected by gabapentin, and that the pharmacokinetics of gabapentin are similarly unaffected by these antiepileptics. It would seem therefore that no dosage adjustments are normally needed if gabapentin is added to treatment with most of these antiepileptics. However, if gabapentin is added to **phenytoin** it may be wise to bear the possibility of raised **phenytoin** levels in mind. For mention that gabapentin may prolong the half-life of **felbamate**, see ‘**Felbamate + Gabapentin**’, p.540. For mention of the lack of interaction between **levetiracetam** and gabapentin, see ‘**Levetiracetam + Other antiepileptics**’, p.543.

**Gabapentin + Probenecid**

*A brief report notes that probenecid had no effect on the renal clearance of gabapentin. No study details were given.*

**Lamotrigine + Antimycobacterials**

Rifampicin markedly increased the clearance of lamotrigine in a pharmacokinetic study. A case report has described a similar finding, and also included some limited evidence suggesting that isoniazid may inhibit lamotrigine metabolism.

**Clinical evidence**

**Rifampicin** 600 mg daily for 5 days increased the clearance of a single 25-mg dose of lamotrigine by 97% and decreased the AUC by 44% in 10 healthy subjects. The amount of lamotrigine glucuronide recovered in the urine was increased by 36%. Similarly, a case report describes a 56-year-old woman taking lamotrigine 150 mg daily who had unexpectedly low serum lamotrigine levels of 1.3 mg/L after starting rifampicin, isoniazid and pyrazinamide. The lamotrigine dosage was therefore increased to 250 mg daily. After treatment was changed to isoniazid and ethambutol, the lamotrigine serum levels rose to 12.4 mg/L. Levels less than 10 mg/L are associated with less toxicity; however, in this patient no toxicity was seen.

**Mechanism**

Rifampicin increases the loss of lamotrigine from the body, probably by inducing glucuronidation via UDP-glucuronyl transferases. It was suggested that isoniazid may have inhibited lamotrigine metabolism.

**Importance and management**

Information appears to be limited to these reports, but the interaction between lamotrigine and rifampicin would appear to be established. Be aware that rifampicin could reduce the efficacy of lamotrigine, and that increased lamotrigine doses are likely to be required.

The case report also raises the possibility of an interaction between lamotrigine and isoniazid. If isoniazid is added to or withdrawn from lamotrigine treatment, be alert for the need to adjust the lamotrigine dosage.

**Lamotrigine + Cimetidine**

*Cimetidine 400 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 25-mg dose of lamotrigine in 10 healthy subjects. No change in lamotrigine dose appears to be needed during concurrent use.*

**Lamotrigine + Felbamate**

Felbamate appears not to affect the pharmacokinetics of lamotrigine.

**Clinical evidence, mechanism, importance and management**

In 21 healthy subjects felbamate 1.2 g twice daily had minimal effects on the pharmacokinetics of lamotrigine 100 mg twice daily when they were given together for 10 days. A 14% increase in the lamotrigine AUC was seen, which was not considered clinically relevant. Similarly, there was no difference between lamotrigine pharmacokinetics in 6 patients receiving lamotrigine and felbamate and 5 patients taking lamotrigine alone. Therefore the dose of lamotrigine does not need to be adjusted if felbamate is given.

**Lamotrigine + Valproate**

Phenobarbital has been associated with reduced lamotrigine serum levels. Phenobarbital and primidone levels were unchanged.

**Clinical evidence, mechanism, importance and management**

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was lower in patients also taking phenobarbital than in those receiving lamotrigine monotherapy (0.52 versus 0.99), suggesting that phenobarbital lowers lamotrigine levels. Similar findings have been reported in another study. No changes in the serum levels of phenobarbital or primidone were seen in a study in 12 patients given lamotrigine 75 to 400 mg daily.

Lamotrigine + Phenytoin

Phenytoin has been associated with reduced lamotrigine serum levels. Lamotrigine has no effect on phenytoin levels.

Clinical evidence, mechanism, importance and management

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was much lower in patients receiving concomitant phenytoin than in those taking lamotrigine monotherapy (0.32 versus 0.98), suggesting that phenytoin lowers lamotrigine levels. Other studies in patients taking lamotrigine with phenytoin have reported similar findings. In another study, the mean lamotrigine levels were approximately doubled when phenytoin was withdrawn.5 In contrast one study suggests that the serum level of lamotrigine was unchanged in patients given lamotrigine 75 to 400 mg daily.

Phenytoin is a known hepatic enzyme inducer, which increases lamotrigine metabolism. The recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking phenytoin is twice that of patients receiving lamotrigine monotherapy.6,7

However, note that if they are also taking valproate in addition to phenytoin, the lamotrigine dose should be reduced, see ‘Lamotrigine + Valproate’, below. The lamotrigine dosage may need to be reduced if phenytoin is withdrawn.

Lamotrigine + Sertraline

A report describes two cases, which suggest that sertraline may increase lamotrigine levels and cause toxicity.

Clinical evidence, mechanism, importance and management

A patient’s lamotrigine levels were found to have doubled and symptoms of toxicity were noted (confusion, cognitive impairment) 6 weeks after sertraline 25 mg daily was started.7 The lamotrigine dose was halved, and the sertraline dose titrated to 50 mg daily. Symptoms of toxicity resolved, but the lamotrigine levels were still 24% higher than before sertraline was started. In another patient taking sertraline and lamotrigine with signs of lamotrigine toxicity, a 33% reduction in sertraline dose resulted in a halving of the lamotrigine level even though the lamotrigine dose was increased by 33%.

The authors suggest that sertraline may competitively inhibit the glucuronidation of lamotrigine. Evidence so far appears limited to this case report. In view of the increased risk of rash with increased lamotrigine levels, a 33% reduction in sertraline dose resulted in a halving of the lamotrigine level even though the lamotrigine dose was increased by 33%.

The authors suggest that sertraline may competitively inhibit the glucuronidation of lamotrigine. Evidence so far appears limited to this case report. In view of the increased risk of rash with increased lamotrigine levels, a 33% reduction in sertraline dose resulted in a halving of the lamotrigine level even though the lamotrigine dose was increased by 33%.

Lamotrigine + Topiramate

Topiramate does not appear to alter the pharmacokinetics of lamotrigine, although one study suggested that it reduced lamotrigine levels. Lamotrigine has no effect on topiramate levels.

Clinical evidence, mechanism, importance and management

In the preliminary report of one study, it was found that serum lamotrigine levels decreased by 40 to 50% in 4 of 7 patients stable taking lamotrigine 350 to 800 mg daily when they were given topiramate, titrated to 800 mg daily.1 In contrast, other authors reported that the addition of topiramate 75 to 800 mg daily had little effect on the steady state serum levels of lamotrigine 100 to 950 mg daily in 24 patients. The mean lamotrigine level before topiramate was 10.4 mg/L and during topiramate was 9.7 mg/L. Only 2 of the patients had reductions of greater than 30% (40% and 43%).9 A further study by the same research group confirmed the lack of effect of topiramate on lamotrigine pharmacokinetics.10 The authors of the second study9 note that there is some evidence that peak-to-trough variations of as much as 30 to 40% can occur during lamotrigine therapy, and therefore timing of blood sampling might be a factor in the findings of the first study.

Lamotrigine had no effect on topiramate pharmacokinetics in one study in 13 patients. The oral clearance of topiramate 400 mg daily was 2.6 L/hour when given alone, and 2.7 L/hour when given with lamotrigine, and the AUC and plasma levels of topiramate were also similar.11

The balance of the evidence suggests that there is no important pharmacokinetic interaction between topiramate and lamotrigine. No special precautions appear to be necessary during concurrent use.

Lamotrigine + Valproate

The serum levels of lamotrigine can be markedly increased by valproate. Concurrent use has been associated with skin rashes, tremor and other toxic reactions. Lamotrigine has been found to cause small increases, decreases or no changes in valproate levels.

Clinical evidence

(a) Effects on lamotrigine levels

In 6 healthy subjects sodium valproate 200 mg every 8 hours reduced the clearance of lamotrigine by 20%, and increased its AUC by 30%.1 In another study, in 18 healthy subjects receiving valproate 500 mg twice daily, the clearance of lamotrigine 50, 100 or 150 mg daily was also markedly reduced, and the half-life increased.2 In a retrospective study, the lamotrigine serum concentration-to-dose ratio was markedly higher in patients also taking valproate than in those receiving lamotrigine monotherapy (3.57 versus 0.98), suggesting that valproate increases lamotrigine levels. In patients also taking phenytoin, the effects of valproate on lamotrigine were offset (0.99 versus 0.98). However, the effects of valproate on lamotrigine were not completely offset by either carbamazepine or phenobarbital (1.67 or 1.8, respectively versus 0.98).3 Other studies have reported broadly similar findings.4-6 Three studies have found that the effect of valproate on lamotrigine was independent of the valproate dose or serum level (that is, it is maximal within the usual therapeutic dose range of valproate) 6,8 Another study has shown that the inhibition of lamotrigine clearance by valproate begins at very low valproate dosages (less than 125 mg daily), and is maximal at doses of about 500 mg daily.9

(b) Effects on valproate levels

In one study, 18 healthy subjects taking valproate 500 mg twice daily were also given lamotrigine 50, 100 or 150 mg daily. The lamotrigine caused a 25% decrease in valproate serum levels and a 25% increase in valproate oral clearance.4 A study in 11 children taking valproate and other antiepileptic drugs noted that no clinically important changes in valproate serum levels occurred when lamotrigine was added.10 A retrospective analysis found that lamotrigine was associated with only a 7% reduction in valproate levels, which would not be expected to be clinically significant.11

(c) Toxic reactions

1. Tremor. In 3 patients severe and disabling tremor (sometimes preventing them from feeding themselves) occurred when they were given lamotrigine and sodium valproate. The problem resolved when the dosages were reduced.12 In a study of 13 adult patients, all developed upper limb tremor when given lamotrigine with valproate, which could be minimised by reducing the dosage of either or both drugs.13 Other studies have found similar effects.4,14,15
2. Rash. In a survey of adult epileptics who had lamotrigine added to their existing treatment, 33 were taking valproate. Of these, 10 patients (30%) developed a rash, whereas only 6 of the 70 (8%) not taking valproate did so.14 In another analysis of skin rash in patients taking lamotrigine, 11 of 12 patients with serious rash were also taking sodium valproate, and all but one had a lamotrigine starting dose that is higher than currently recommended.17 However, in another study in which patients taking valproate were given lower initial doses of lamotrigine, there was no difference in incidence of rash in those taking lamotrigine and valproate, when compared with those taking lamotrigine and other antiepileptics (13% versus 14.2%).18

3. Other. Severe multiorgan dysfunction and disseminated intravascular coagulation was seen in 2 children when they took lamotrigine with valproate.19 Patients taking lamotrigine developed neurotoxicity (confusion, lethargy after starting to take valproate (an intravenous bolus dose of valproic acid then oral therapy). Lamotrigine levels had risen by 2.9 to 6.9 times those before valproic acid.14 Confusion, disorientation, visual disturbances and behavioural changes were reported in another patient 4 days after valproate was added to her treatment with lamotrigine. Lamotrigine levels were found to be 22.9 micrograms/mL (normal range 1 to 13 micrograms/mL). She recovered within 2 days of the discontinuation of both drugs.20

One study reported that the formation of hepatotoxic metabolites of valproate was unaffected by lamotrigine.2

**Mechanism**

Not fully understood. It is thought that valproate reduces lamotrigine glucuronidation by competitive inhibition, which results in a decreased lamotrigine clearance.1,2,21 Raised lamotrigine levels have been implicated in the development of rash.18,22 Increased valproate clearance may be due to enzyme induction. Torem may be the result of a pharmacodynamic interaction.7,13

**Importance and management**

A well documented interaction. Concurrent use can be therapeutically valuable, but the lamotrigine dosage should be reduced by about half when valproate is added to avoid possible toxicity (sedation, tremor, ataxia, fatigue, rash).2,7,9,12,18,23 In patients already taking valproate, the manufacturer of lamotrigine recommends a lamotrigine starting dose that is half of that of lamotrigine monotherapy, irrespective of whether they are also receiving enzyme-inducing anticonvulsants, and a very gradual dose-escalation rate.23 The outcome should be very well monitored. The CSM in the UK has suggested that the concurrent use of sodium valproate is one of the main risk factors for the development of serious skin reactions to lamotrigine, because it prolongs the half-life of lamotrigine.22 Rashes are potentially serious and should be evaluated promptly.18,24,25 The reports cited above12,19 also suggest that sometimes other serious reactions (disabling tremor, multiorgan dysfunction) can occur.

**Levetiracetam + Food**

The oral absorption of levetiracetam is not significantly affected by food.

**Clinical evidence, mechanism, importance and management**

In a study, 10 healthy subjects were given a 500-mg levetiracetam tablet with 120 mL of water or crushed and mixed with either 4 oz apple sauce or 120 mL of an enteral nutrition formulation (Sustacal). The overall rate and extent of absorption of oral levetiracetam were not significantly affected by crushing and mixing the tablet with either apple sauce or an enteral nutrition preparation, although the peak serum level of levetiracetam may be slightly reduced if it is mixed with enteral nutrition.1

**Levetiracetam + Other antiepileptics**

There is some evidence that the enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin and primidone) may modestly reduce levetiracetam levels, but this is not thought to be clinically relevant. Levetiracetam does not usually alter the levels of these antiepileptics. However, some studies have found modestly raised phenytoin levels, and cases of possible carbamazepine toxicity have also been reported. There appears to be no pharmacokinetic interaction between levetiracetam and gabapentin, lamotrigine, or valproate.

**Clinical evidence, mechanism, importance and management**

(a) Carbamazepine

Evidence from clinical studies suggests that levetiracetam does not affect the serum levels of carbamazepine.1,3 There is also some evidence that patients taking levetiracetam and also receiving enzyme-inducing antiepileptics such as carbamazepine had modestly (24%) lower levetiracetam levels than those also receiving antiepileptics not considered to be enzyme-inducers, but this was not considered clinically relevant, see (d) below.4 Similarly, another retrospective analysis of patient data found that the serum levetiracetam level to dose ratio was modestly lower in patients also receiving monotherapy (0.32 versus 0.52) suggesting that carbamazepine moderately lowers levetiracetam levels. One report describes 4 patients who experienced disabling symptoms compatible with carbamazepine toxicity when levetiracetam was added. The symptoms resolved after a decrease in the carbamazepine dosage or withdrawal of the levetiracetam. A pharmacodynamic interaction was suggested, because levels of carbamazepine and its metabolite, carbamazepine-10,11-epoxide, were not affected.6
In general, there is no need to modify the dose of either carbamazepine or levetiracetam when used together. However, the report of possible toxicity suggests that some caution is warranted.

(b) Phenytoin

There is some evidence that patients taking levetiracetam with enzyme-inducing antiepileptics such as phenytoin had modestly (24%) lower levetiracetam levels than those taking other antiepileptics not considered to be enzyme inducers, but this was not considered clinically relevant, see (d) below. Similarly, another retrospective analysis of patient data found that the serum levetiracetam level-to-dose ratio was modestly lower in patients also receiving phenytoin than those receiving monotherapy (0.32 versus 0.52), suggesting that phenytoin modestly lowers levetiracetam levels.

However, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of phenytoin. Similarly, in another study, levetiracetam 1.5 g twice daily for 12 weeks had no effect on the steady-state pharmacokinetics of phenytoin in 6 subjects with epilepsy who were taking stable doses of phenytoin. In one clinical study the addition of levetiracetam increased phenytoin levels by 27% to 52% in 4 patients. A further patient had a 75% increase in phenytoin levels [estimated from figure] and experienced signs of toxicity (sedation, ataxia) and required a reduction in his phenytoin dose. Another patient with raised phenytoin levels [estimated increase of 47%] had the dose of levetiracetam reduced.

In general, therefore, there is no need to modify the dose of either phenytoin or levetiracetam when they are used together. However, the report of raised phenytoin levels suggests that some caution is warranted.

(c) Valproate

There was no difference in the pharmacokinetics of a single 1.5-g dose of levetiracetam given to healthy subjects before or after sodium valproate 500 mg twice daily for 8 days. In addition, levetiracetam did not affect the pharmacokinetics of valproate. In an analysis of clinical study data, the AUC of levetiracetam in 57 patients also taking valproic acid was slightly (11%) higher than in 28 patients also taking antiepileptics not thought to affect microsomal enzymes (gabapentin, lamotrigine, vigabatrin), but this was not thought to be clinically relevant. In another retrospective analysis of patient data, the serum levetiracetam level-to-dose ratio was the same in patients also receiving valproic acid than those receiving monotherapy (0.53 versus 0.52), suggesting that valproate does not alter levetiracetam levels. Furthermore, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of valproate.

There appears to be no need to adjust the doses of either sodium valproate or levetiracetam if these drugs are used together.

(d) Other antiepileptics

The AUC of levetiracetam tended to be lower in 436 patients also taking enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin, primidone) than in 28 patients also taking antiepileptics not thought to affect microsomal enzymes (gabapentin, lamotrigine, vigabatrin), but the difference was modest (24%). Another retrospective analysis of patient data of patients taking levetiracetam level-to-dose ratio did not differ significantly between patients also taking lamotrigine and those taking valproate (0.45 versus 0.52), but was modestly lower in those taking oxcarbazepine (0.34 versus 0.52).

Furthermore, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of gabapentin, lamotrigine, phenobarbital, or primidone. In general, therefore, no dosage adjustments would seem to be needed if levetiracetam is used as add-on therapy with any of these drugs.

Levetiracetam + Probencid

Probencid increased the plasma levels of an inactive metabolite of levetiracetam.

Clinical evidence, mechanism, importance and management

Probencid 500 mg four times daily did not affect the renal excretion of levetiracetam. However, the renal excretion of its primary and pharmacologically inactive metabolite (ucb L057) was reduced by 61%, and plasma concentrations increased 2.5-fold, although the manufacturer notes that these levels were still low. The clinical relevance of elevated levels of ucb L057 is not known, therefore some have suggested caution is warranted.

The effect of levetiracetam on probencid has not been studied.

Mesuximide + Other antiepileptics

Phenobarbital, phenytoin, and possibly felbamate increase the levels of the active metabolite of mesuximide, N-desmethylmesuximide. Mesuximide increases the serum levels of phenobarbital and phenytoin, and decreases the levels of lamotrigine, and to a lesser extent, valproate.

Clinical evidence

(a) Felbamate

Three adolescent epileptic patients taking mesuximide developed mild adverse effects within 3 days of starting to take felbamate, which became more serious after one month (decreased appetite, nausea, weight loss, insomnia, dizziness, hiccups, slurred speech). During this time the levels of the active metabolite of mesuximide, N-desmethylmesuximide, rose by 26% and 46% in two patients, respectively. The adverse effects disappeared and N-desmethylmesuximide levels fell when the mesuximide dosage was reduced. Other antiepileptics being taken were carbamazepine, ethothein and valproate.

(b) Lamotrigine

In 6 patients taking mesuximide, lamotrigine levels were 53% lower (range 36 to 72%), when compared with lamotrigine levels before starting or after stopping mesuximide. In some patients deterioration in seizure control was seen while taking mesuximide, and an improvement in seizure control occurred after mesuximide was stopped. In another study, lamotrigine levels were about 70% lower in 13 patients also taking mesuximide than in 64 patients taking lamotrigine alone, when corrected for dose. Note that in patients also taking valproate, the reduction in lamotrigine levels caused by mesuximide was compensated for by the increase caused by valproate, see also ‘Lamotrigine + Valproate’, p.542.

(c) Phenobarbital or primidone

A study in hospitalised patients with petit mal epilepsy found that when mesuximide was given to 8 patients taking phenobarbital and 13 patients taking primidone, the mean decrease in mesuximide levels was 62% and 50%, respectively. Dose reductions were needed in 50% and 62% of patients, respectively. It was also found that the concurrent use of phenobarbital increased the serum levels of the active metabolite of mesuximide, N-desmethylmesuximide.

(d) Phenytoin

Mesuximide was given to 17 patients taking phenytoin, which resulted in a 78% rise in the phenytoin serum levels. These dose reductions in about 30% of the patients. It was also found that the concurrent use of phenytoin increased the serum levels of the active metabolite of mesuximide, N-desmethylmesuximide.

(e) Valproate

A retrospective analysis of serum valproate levels was carried out in 17 patients who started and/or stopped taking mesuximide and whose concurrent medication remained unaltered. In the 14 patients starting mesuximide, a mean decrease in valproate levels of 32% was seen. In the 8
patients who stopped mesuximide a 30% increase in valproate levels occurred.\(^5\) Note that the related drug, ethosuximide, has also been reported to lower valproate levels, see ‘Ethosuximide + Other antiepileptics’, p.539.

**Mechanism**

It has been suggested that phenobarbital, phenytoin and felbamate compete with mesuximide for the same metabolic mechanisms (hydroxylation) in the liver. As a result each one is metabolised more slowly and therefore their levels increase. Mesuximide appears to increase the clearance of valproate, and lamotrigine (which is principally via glucuronidation).

**Importance and management**

Information about these interactions is limited. Nevertheless, concurrent use should be monitored. Anticipate the need to reduce the dose of phenytoin, phenobarbital or primidone if mesuximide is given. The dose of lamotrigine may need to be increased if mesuximide is given. There is also some evidence that the dose of valproate may need to be increased.

The activity of mesuximide is thought to be due to its active metabolite, N-desmethylmesuximide. Therefore, it has been suggested that levels of this metabolite should also be monitored. Anticipate the need to reduce the dose of mesuximide if felbamate is added. Other antiepileptics such as phenobarbital and phenytoin may also increase levels of N-desmethylmesuximide.\(^5\)

---

**Oxcarbazepine + Erythromycin**

Erythromycin does not appear to affect the pharmacokinetics of oxcarbazepine.

**Clinical evidence, mechanism, importance and management**

In a study in 8 healthy subjects the pharmacokinetics of a single 600-mg dose of oxcarbazepine was unaffected by erythromycin 500 mg twice daily for 7 days.\(^1\) Erythromycin appears not to interact with oxcarbazepine, and no special precautions therefore seem to be required during concurrent use.

---

**Oxcarbazepine + Felbamate**

Felbamate has no clinically relevant effect on the pharmacokinetics of oxcarbazepine, but concurrent use appears to increase the incidence of adverse effects.

**Clinical evidence, mechanism, importance and management**

A double-blind, randomised study in 8 healthy subjects found that oxcarbazepine 300 to 600 mg every 12 hours, given with felbamate 600 to 1200 mg every 12 hours for 10 days had no effect on the plasma levels of the major active metabolite of oxcarbazepine (monohydroxyoxcarbazepine). However, the levels of dihydroxyoxcarbazepine (a minor, inactive metabolite) were reduced, and the maximum serum levels of oxcarbazepine were reduced, by about 20%. Although these changes were considered to be clinically irrelevant, the incidence of some adverse effects (dizziness, somnolence, nausea, diplopia) rose during concurrent use.\(^1\)

---

**Oxcarbazepine + Other antiepileptics**

Oxcarbazepine appears not to affect the pharmacokinetics of carbamazepine, phenobarbital or valproate to a clinically relevant extent, but may modestly reduce lamotrigine levels. High doses of oxcarbazepine increase phenytoin levels, and a reduction in the phenytoin dose may be required. Phenytoin and phenobarbital can increase the loss of the active metabolite of oxcarbazepine, monohydroxyoxcarbazepine, although this is probably not clinically relevant. Lamotrigine may increase levels of monohydroxyoxcarbazepine, although one study found no pharmacokinetic interaction.

**Clinical evidence**

*Effects of oxcarbazepine on other antiepileptics*\(^a\)

A double-blind, crossover comparison of oxcarbazepine and carbamazepine in 42 epileptic patients found that when carbamazepine was replaced by oxcarbazepine, the serum levels of valproate rose by 32%, and the serum levels of phenytoin rose by 23%. In patients taking both valproate and phenytoin together, oxcarbazepine caused a rise in the serum levels of 21% and 25% respectively. The study extended over 12 weeks to establish steady-state levels.\(^1\) Another study in 4 young epileptic patients (aged 13 to 17) found that the level to dose ratio of free valproate rose when switched from concurrent carbamazepine to oxcarbazepine, with an increase in valproate adverse effects, which resolved when the valproate dose was decreased.\(^2\)

A later study in 35 epileptic patients found that when oxcarbazepine 300 mg three times daily was added to treatment with carbamazepine, sodium valproate or phenytoin for 3 weeks there were no clinically relevant changes in the pharmacokinetics of any of these anticonvulsants.\(^3\) However, analysis of data from clinical studies found that oxcarbazepine decreased carbamazepine levels by about 15 to 22%, increased phenobarbital levels by about 14%, and at high doses increased phenytoin levels by up to 40%.\(^4,5\) In another analysis, lamotrigine levels were about 34% lower in 14 patients also taking oxcarbazepine than in 64 patients taking lamotrigine alone, when corrected for dose. In this study, the effect of oxcarbazepine was less than that of carbamazepine (34% versus 47%).\(^6\) Similarly, in another analysis, the addition of oxcarbazepine to lamotrigine reduced lamotrigine levels by 15 to 75%.\(^7\) However in contrast to these findings, one study in healthy subjects found that oxcarbazepine had no effect on the pharmacokinetics of lamotrigine, although adverse effects were reported to be more frequent and severe during concurrent treatment.\(^8\)

*Effects of other antiepileptics on oxcarbazepine*\(^a\)

The AUCs of oxcarbazepine and its active metabolite (monohydroxyoxcarbazepine) were reduced by phenobarbital, by 43% and 25%, respectively. There were no other significant effects on the pharmacokinetics of oxcarbazepine.\(^9\) Another study found that phenytoin caused a 29% reduction in the AUC of monohydroxyoxcarbazepine.\(^3\) Another study found that the serum levels of monohydroxyoxcarbazepine were not affected by phenobarbital or phenytoin but its further conversion to dihydroxyoxcarbazepine was increased.\(^10\) Since the conversion to dihydroxyoxcarbazepine is a minor step in the metabolism of monohydroxyoxcarbazepine, the overall antiepileptic action of oxcarbazepine is unlikely to be altered. Correspondingly, a study found that phenytoin 100 to 375 mg daily increased the clearance of the active metabolite, monohydroxyoxcarbazepine by almost 40%.\(^11\) The AUC of monohydroxyoxcarbazepine was also 40% lower in the presence of carbamazepine.\(^3\) Similarly, carbamazepine, phenobarbital, and phenytoin were found to increase the apparent clearance of monohydroxyoxcarbazepine by 31 to 35% in a study in children.\(^12\)

A retrospective analysis found that monohydroxyoxcarbazepine levels to oxcarbazepine dose ratios were higher in 7 patients also taking lamotrigine than in those taking oxcarbazepine alone,\(^13\) suggesting that lamotrigine decreased oxcarbazepine metabolism. However in contrast to these findings, one study in healthy subjects found that lamotrigine had no effect on the pharmacokinetics of oxcarbazepine or monohydroxyoxcarbazepine although adverse effects were reported to be more frequent and more severe during concurrent treatment.\(^8\)
Mechanism

Unlike carbamazepine, oxcarbazepine appears not to have marked enzyme-inducing properties so that it would not be expected to have as great an effect on the metabolism of other antiepileptics. However, oxcarbazepine does appear to act as an inhibitor of the cytochrome P450 isoenzyme CYP2C9 at high concentrations and therefore may raise phenytoin levels (see ‘Phenytoin + Carbamazepine’, p.544, for more on this mechanism). Other antiepileptics can increase the metabolism of the active metabolite of oxcarbazepine, monohydroxycarbazepine. The situation with lamotrigine is not clear. In one study lamotrigine appeared to decrease the metabolism of oxcarbazepine but another study found no pharmacokinetic interaction.

Importance and management

Information about the concurrent use of oxcarbazepine and other antiepileptics is limited, but growing. The overall picture seems to be that, oxcarbazepine induces the CYP2C19 enzyme less than carbamazepine, and therefore it does not markedly affect the serum levels of other antiepileptics. If oxcarbazepine is substituted for carbamazepine, be aware that drug levels of some other antiepileptics may rise. High oxcarbazepine doses may increase phenytoin levels, and the manufacturer notes that a decrease in the phenytoin dose may be required. The clinical relevance of the modest reductions in lamotrigine levels is uncertain. For mention of modestly reduced levetiracetam levels, see ‘Levetiracetam + Other antiepileptics’, p.543.

Any changes in the pharmacokinetics of oxcarbazepine brought about by other antiepileptics seem to be of minimal clinical relevance. However, the clinical relevance of the increase in the active metabolite monohydroxycarbazepine with lamotrigine requires further study. In addition, there is the theoretical risk that monohydroxycarbazepine levels might rise to toxic levels if carbamazepine or phenytoin were withdrawn. For mention that there may be an increase in adverse effects if oxcarbazepine is used with felbamate, see ‘Oxcarbazepine + Felbamate’, p.545.

Phenobarbital + Primidone + Allopurinol

Allopurinol appears not to alter phenobarbital levels, including those derived from primidone.

Clinical evidence, mechanism, importance and management

In a study of add-on therapy, allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months, had no effect on phenobarbital levels in 46 patients taking antiepileptics including phenobarbital. In another similar study, allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks had no effect on serum phenobarbital levels in 11 patients taking primidone or phenobarbital with or without other antiepileptics. Therefore phenobarbital or primidone dosage alterations are unlikely to be required if allopurinol is used.

Phenobarbital + Azoles

Limited evidence suggests phenobarbital causes a marked decrease in itraconazole levels, and might decrease ketoconazole levels. Phenobarbital is also predicted to decrease posaconazole levels and markedly decrease voriconazole levels.

Clinical evidence, mechanism, importance and management

(a) i) Itraconazole

The serum levels of itraconazole 200 mg daily were very low (0.01 to 0.03 mg/L, therapeutic range 0.25 to 2 mg/L) in a patient taking phenobarbital. Two months after stopping the phenobarbital they were higher (0.15 mg/L), but still below the therapeutic range, apparently because carbamazepine had been recently started. For mention of two other patients who had very low itraconazole levels while taking both phenytoin and phenobarbital, see ‘Phenytoin + Azoles’, p.552. Some makers of itraconazole say that concurrent use of potent enzyme inducers such as phenobarbital is not recommended.

(b) Ketoconazole

Low ketoconazole levels in a patient with leukaemia receiving various antineoplastics was attributed to the concurrent use of phenytoin and phenobarbital therapy. It may be prudent to monitor the effects of ketoconazole if phenobarbital is also given.

(c) Posaconazole

Based on the evidence with ‘phenytoin’, (p.552), the manufacturer of posaconazole predicts that phenobarbital will reduce posaconazole levels, and therefore suggests avoiding the combination unless the benefits outweigh the risks. If concurrent use is necessary monitor for posaconazole efficacy.

(d) Voriconazole

Based on the evidence with ‘phenytoin’, (p.552), the manufacturer of voriconazole predicts that phenobarbital will reduce voriconazole levels, and found increases in paraldehyde levels and hypnotic effect, with only small increases in acetaldehyde and no increase in toxicity. In addition, there appear to be no reports of a disulfiram reaction involving paraldehyde in humans. Three cases of mental confusion have been reported in patients receiving disulfiram and paraldehyde. Note that, patients with liver disease are at greater risk of adverse effects of paraldehyde, and the addition of disulfiram results in a further risk. Therefore it may be prudent to avoid concurrent use.

Phenobarbital + Dextropropoxyphene (Propoxyphene)

An average 20% rise was seen in the serum phenobarbital levels of 4 epileptic patients after they took dextropropoxyphene 65 mg three times a day for a week. This rise is unlikely to be clinically significant in most patients.

Phenobarbital or Primidone + Felbamate

Felbamate causes a moderate increase in plasma phenobarbital levels (including those derived from primidone), which has resulted in phenobarbital toxicity.

Clinical evidence

When 24 healthy subjects taking phenobarbital 100 mg daily were also given felbamate 1.2 g twice daily for 10 days, the AUC and the maximum plasma levels of phenobarbital were raised by 22% and 24%, respectively. Concurrent use was said to be safe and well tolerated. A 30% increase in phenobarbital plasma concentrations was seen in another 19 patients taking phenobarbital or primidone (which is metabolised to phenobarbital) when given felbamate (average dose 2458 mg daily). A phenobarbital dosage reduction of about 30% was needed in another 6 patients when they started to take felbamate. A man taking sodium valproate and phenobarbital had almost 50% increase in phenobarbital serum levels over a 5-week period after felbamate 50 mg/kg was added, despite an initial phenobarbital dosage reduction from 230 mg to 200 mg daily. He was hospitalised because of increased lethargy, anorexia and ataxia and was eventually discharged on a phenobarbital dosage of 150 mg daily.

It was noted that felbamate levels were lower in patients taking phenobarbital than in historical control patients who were not taking phenobarbital. However, in a modelling study, phenobarbital apparently had little or no effect on the pharmacokinetics of felbamate.

Mechanism

Not established. It seems possible that the felbamate may inhibit more than one pathway in the metabolism of the phenobarbital, resulting in a reduction in its loss from the body. The cytochrome P450 isoenzyme CYP2C19 may be involved.

Importance and management

An established interaction. If felbamate is added to established treatment with phenobarbital or primidone, particularly in patients already taking substantial doses, monitor well for any evidence of increased adverse effects (drowsiness, lethargy, anorexia, ataxia) and reduce the dosages of the phenobarbital or primidone if necessary.

Phenobarbital + Valproate

Serum phenobarbital levels can be increased by valproate, which may result in excessive sedation and lethargy. Small reductions in valproate levels have also been reported. Combined use of phenobarbital and valproate may cause an increase in serum liver enzymes.

Clinical evidence

A 6-month study in 11 epileptic patients taking phenobarbital 90 to 400 mg daily found that when they were also given valproic acid 11.2 to 42.7 mg/kg daily sedation developed. On average the dosage of phenobarbital was reduced to 54% of the original dose with continued good seizure control. Another 2 patients who did not have their phenobarbital dose reduced had an increase in their phenobarbital levels of 12% and 48%, respectively, when valproic acid was added.

A reduction in sodium valproate levels of about 25% has also been reported, but the effect on seizure control was not mentioned. A reduction

Influenza vaccine can cause a moderate rise in serum phenobarbital levels.

Clinical evidence, mechanism, importance and management

Serum phenobarbital levels rose by about 30% in 11 out of 27 children when given 0.5 mL of a whole virus influenza vaccine USP, types A and B (Squibb). Levels remained elevated 28 days after vaccination.

It was suggested that the vaccine inhibits the liver enzymes concerned with the metabolism of phenobarbital, thereby reducing its loss from the body. Information is very limited. Note that, a similar 30% increase in phenobarbital levels with felbamate has eventually required a dosage adjustment; however with this interaction the increase will eventually be self-limiting. Therefore it seems unlikely that this moderate increase in phenobarbital levels will be of clinical significance.

Phenobarbital + Troleandomycin

Troleandomycin caused a modest fall in the plasma phenobarbital levels of one patient.

Clinical evidence, mechanism, importance and management

A patient phenobarbital and carbamazepine had a modest fall in plasma phenobarbital levels from about 40 to 31 micrograms/mL, and a rise in carbamazepine levels, when given troleandomycin. The general importance of this single report is uncertain, but this modest is probably of limited clinical importance. For a discussion of the rise in carbamazepine levels with troleandomycin, see ‘Carbamazepine + Macrolides’, p.531.

in valproate levels caused by phenobarbital has also been reported else-where.\textsuperscript{20}

The incidence of increased liver enzyme activity was found to be higher in 41 patients receiving phenobarbital with valproate than in 40 patients taking valproate alone (ALT 7.3\% versus 0\%). When phenytoin was also given an even greater incidence of increases (ALT 26.1\% and AST 28.3\% versus about 20\%) occurred. However, the increases were mild and were not considered clinically important.\textsuperscript{21}

**Mechanism**

The evidence indicates that valproate inhibits three steps in the metabo-

| lism of phenobarbital by the liver, leading to its accumulation in the body. The inhibited steps are the formation of \( p \)-hydroxyphenobarbital by the cytochrome P450 isoenzyme CYP2C\textsubscript{9},\textsuperscript{22} the \( N \)-glucosidation of phenobarbital\textsuperscript{23} and the \( O \)-glucuronidation of \( p \)-hydroxyphenobarbital.\textsuperscript{23}

**Importance and management**

An extremely well documented and well established interaction of clinical import-

ance. The incidence seems to be high. The effects of concurrent use made as necessary to avoid toxicity. The dosage may need to be reduced or stopped to avoid toxicity. The dosage may need to be reduced or stopped to avoid toxicity. The dosage may need to be reduced or stopped to avoid toxicity. The dosage may need to be reduced or stopped to avoid toxicity. The dosage may need to be reduced or stopped to avoid toxicity.

**Phenytoin + Allopurinol**

A case report describes phenytoin toxicity in a boy given allopurinol. Another study found raised phenytoin levels in 2 of 18 pa-

ents given allopurinol.

**Clinical evidence, mechanism, importance and management**

A 13-year-old boy with Lesch-Nyhan syndrome who was taking pheno-

barbital, clonazepam, valproic acid and phenytoin 200 mg daily became somnolent within 7 days of starting to take allopurinol 150 mg daily. His serum phenytoin levels were found to have increased from 7.5 to 20.8 micrograms/mL.\textsuperscript{1} In another study, 2 patients had a marked increase in phenytoin levels when given allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months, which in one case led to withdrawal from the study, and in the other to a phenytoin dosage reduction. However, 16 other patients had no change in phenytoin levels while taking this dose of allopurinol.\textsuperscript{2}

The reason for this reaction is not known. An animal study confirmed that 50 mg/kg, but not 20 mg/kg, of allopurinol reduced phenytoin elimi-

nation, but was unable to work out the mechanism.\textsuperscript{3}

Although information is limited, it appears that allopurinol may raise phenytoin levels in some patients. It would therefore be prudent to monitor for phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsi-

ness) when allopurinol is added.

**Phenytoin + Amiodarone**

Serum phenytoin levels can be raised by amiodarone, markedly so in some individuals, and phenytoin toxicity may occur. Amio-

darone serum levels are reduced by phenytoin.

**Clinical evidence**

(a) Phenytoin serum levels increased

Three patients had a marked rise in serum phenytoin levels 10 days to 4 weeks after being given amiodarone 400 mg to 1.2 g daily. One of them developed phenytoin toxicity (ataxia, lethargy, vertigo) within 4 weeks of starting to take amiodarone and had a serum phenytoin level of 40 micrograms/mL, representing a three to fourfold rise. Levels restabil-

ised when the phenytoin dosage was withheld and then reduced from 300 to 200 mg daily. The serum phenytoin levels of the other 2 patients were approximately doubled by the amiodarone.\textsuperscript{4}

A study in healthy subjects found that amiodarone 200 mg daily for 3 weeks increased the AUC of a single 5-mg/kg intravenous dose of phenytoin by 40\%.\textsuperscript{5} Another pharmacokinetic study found that amiodarone 200 mg daily for 6 weeks raised the AUC and steady-state peak serum levels of phenytoin by 40\% and 33\%, respectively. Phenytoin 2 to 4 mg/kg daily was given orally for 14 days before and during the last 2 weeks of amiodarone therapy.\textsuperscript{6} Other case reports describe 3 patients who had two to threefold rises in serum phenytoin levels, and toxicity, 2 to 6 weeks af-

ter starting amiodarone.\textsuperscript{6}

(b) Amiodarone serum levels reduced

A study in 5 healthy subjects given amiodarone 200 mg daily found that over a 5-week period the serum amiodarone levels gradually increased. When phenytoin 3 to 4 mg/kg daily was added for a period of 2 weeks, the serum amiodarone levels fell to concentrations that were between about 50 and 65\% of those predicted.\textsuperscript{7}
Mechanism
Uncertain. It seems possible that amiodarone inhibits the liver enzymes concerned with the metabolism of phenytoin, resulting in a rise in its serum levels. It seems unlikely that drug displacement from protein binding sites had a part to play as free and bound levels of phenytoin remained constant.

Phenytoin is an enzyme-inducing drug that possibly increases the metabolism of the amiodarone by the liver.

Importance and management
Information seems to be limited to the reports cited, but both interactions appear to be clinically important. Concurrent use should not be undertaken unless the effects can be well monitored.

The phenytoin dosage should be reduced as necessary. A 25 to 30% reduction has been recommended for those taking phenytoin 2 to 4 mg/kg daily, but it should be remembered that small alterations in phenytoin dose may result in a large change in phenytoin levels, as phenytoin kinetics are non-linear. Note that the phenytoin levels in some individuals were doubled after only 10 days of concurrent use. Amiodarone has a long half-life so that this interaction will persist for weeks after its withdrawal. Continued monitoring is important. Be aware that ataxia due to phenytoin toxicity (e.g., blurred vision, nystagmus, ataxia or drowsiness) may be confused with amiodarone-induced ataxia. It is not clear whether or not the amiodarone dosage should be increased to accommodate this interaction because the metabolite of amiodarone (N-desethylamiodarone) also has important antiarrhythmic effects.

Phenytoin + Antacids

Some studies have shown that antacids can reduce phenytoin serum levels and this may have been responsible for some loss of seizure control in a few patients. However other studies have shown no interaction, and it seems that usually no clinically important interaction occurs.

Clinical evidence

(a) Evidence of an interaction
A review briefly mentions that 3 patients taking phenytoin were found to have low serum phenytoin levels of 2 to 4 micrograms/mL when they were given phenytoin at the same time as antacids (unnamed), but when the antacid administration was delayed by 2 hours the serum phenytoin levels rose to two to threefold.

Elsewhere, 2 epileptic patients are reported to have had inadequate seizure control, which coincided with the ingestion of aluminium/magnesium hydroxide antacids for dyspepsia. The AUC of a single dose of phenytoin was reduced by about 25% in 8 healthy subjects given either aluminium/magnesium hydroxide or calcium carbonate.

(b) Evidence of no interaction
A study in 6 healthy subjects given aluminium or magnesium hydroxide failed to show any change in the rate or extent of absorption of a single dose of phenytoin, and a similar study found calcium carbonate also had no effect on the absorption of phenytoin. A controlled study in 6 epileptic patients found that a magnesium trisilicate and aluminium hydroxide antacid (Gelusil) caused a slight 12% reduction in steady-state serum phenytoin levels, which would not be expected to be clinically significant. Seizure frequency was not affected.

Phenytoin + Antidiabetics

Large and toxic doses of phenytoin have been observed to cause hyperglycaemia, but normal therapeutic doses do not usually affect the control of diabetes. Two isolated cases of phenytoin toxicity have been attributed to the use of tolazamide or tolbutamide. Miglitol does not affect the bioavailability of phenytoin.

Clinical evidence

(a) Response to antidiabetics
Phenytoin has been shown in a number of reports to raise the blood glucose levels of both diabetics and non-diabetics. However, in all but one of these cases the phenytoin dosage was large (at least 8 mg/kg) or even in the toxic range (70 to 80 mg/kg). There is little evidence that a hyperglycaemic response to usual doses of phenytoin is normally large enough to interfere with the control of diabetes, either with diet alone or with conventional antidiabetic drugs. In the one case where the interaction occurred with a therapeutic dose of phenytoin (1.2 g in the 24 hours following status epilepticus), the situation was complicated by the use of many other drugs and by renal impairment.

(b) Response to phenytoin
Tolbutamide 500 mg two or three times daily was given to 17 patients taking phenytoin 100 to 400 mg daily. The patients had a transient 45% rise in the amount of non-protein-bound phenytoin by day 2, which had disappeared by day 4. The introduction to this report briefly mentions a man given phenytoin and tolazamide who developed phenytoin toxicity, which disappeared when the tolazamide was replaced by insulin. A woman previously uneventfully treated with phenytoin and tolbutamide developed toxicity on a later occasion when she took tolbutamide with twice the previous dose of phenytoin. One study in healthy subjects found that miglitol 100 mg three times daily for 5 days did not affect the bioavailability of a single 400-mg dose of phenytoin.

Mechanism

Studies in animals and man suggest that phenytoin-induced hyperglycaemia occurs because the release of insulin from the pancreas is impaired. This implies that no interaction is possible without functional absorption of phenytoin was not altered by a mixture of aluminium/magnesium hydroxide and magnesium trisilicate, or calcium carbonate.

In another study, no statistically significant decrease in absorption was seen in 6 healthy subjects given a dimeticone, aluminium hydroxide and magnesium oxide antacid (Aslione).
pancreatic tissue. Just why the phenytoin appeared to interact with tolazamide and tolbutamide is uncertain, but it is possible that these antibiotics competitively inhibit phenytoin hydroxylation by the cytochrome P450 isoenzyme CYP2C9.14

Importance and management

The weight of evidence shows that no interaction of clinical importance normally occurs between phenytoin and the antidiabetic drugs (most of the studies involved sulphonylureas). No special precautions seem normally to be necessary.

Phenytoin + Antimycobacterials

Serum phenytoin levels are markedly reduced by rifampicin, but can be raised by isoniazid. Those who are slow acetylators (slow metabolisers) of isoniazid may develop phenytoin toxicity if the dosage of phenytoin is not reduced appropriately. If rifampicin and isoniazid are given together, serum phenytoin levels may fall in patients who are fast acetylators of isoniazid, but may occasionally rise in those who are slow acetylators. Clofazimine may reduce serum phenytoin levels.

Clinical evidence

(a) Isoniazid

A study in 32 patients given phenytoin 300 mg daily found that within a week of starting to take isoniazid 300 mg daily and aminosalicylic acid 15 g daily, 6 of them had phenytoin levels almost 5 micrograms/mL higher than the rest of the group. On the following days when the phenytoin levels of these 6 patients rose above 20 micrograms/mL, the typical signs of phenytoin toxicity were seen. All 6 had unusually high serum isoniazid levels and were identified as slow acetylators of isoniazid.

Rises in serum phenytoin levels and toxicity induced by the concurrent use of isoniazid has been described in numerous other reports,2–15 involving large numbers of patients, one of which describes a fatality.5

(b) Rifampicin

A study in 6 patients found that the clearance of intravenous phenytoin 100 mg doubled, from 46.7 to 97.8 mL/minute, when rifampicin 450 mg daily was taken for 2 weeks.16

A man taking phenytoin 400 mg daily experienced a seizure 3 days after starting rifampicin 600 mg daily. His phenytoin level was low (5.1 micrograms/mL) so the rifampicin was stopped and the phenytoin dose increased to 500 mg daily. His level increased slowly over the next 2 weeks, eventually ranging between 16 and 25 micrograms/mL.17 Another man taking phenytoin needed a dosage reduction from 375 to 325 mg daily to keep his serum phenytoin levels within the therapeutic range when he stopped taking rifampicin.18 See also, Rifampicin and Clofazimine, below.

(c) Rifampicin and Clofazimine

A man with AIDS taking a large number of drugs (rifampicin, clofazimine, ciprofloxacin, ethambutol, clarithromycin, diphenoxylate, bismuth, octreotide, co-trimoxazole, amphotericin, fluyclosine, amikacin, zalcitabine) was also given phenytoin to control a right-sided seizure disorder. Despite taking phenytoin 1.6 g daily, and a trial of intravenous treatment, his trough phenytoin plasma levels remained almost undetectable until the rifampicin was withdrawn, when they rose to 5 micrograms/mL with the oral dose. When the clofazimine was withdrawn the levels rose even further to 10 micrograms/mL.19

(d) Rifampicin and Isoniazid

A patient taking phenytoin 300 mg daily developed progressive drowsiness (a sign of phenytoin toxicity) during the first week of taking isoniazid, rifampicin and ethambutol. His serum phenytoin levels rose to 46.1 micrograms/mL. He slowly recovered when the phenytoin was stopped, and he was later stabilised taking only 200 mg of phenytoin daily.

He proved to be a slow acetylator of isoniazid.20 Another patient taking phenytoin 300 mg daily was also given isoniazid, rifampicin and ethambutol but, in anticipation of the response seen in the previous patient, his phenytoin dosage was reduced to 200 mg daily. Within 3 days he developed seizures because his serum phenytoin levels had fallen to only 8 micrograms/mL. He needed a daily dosage of 400 mg of phenytoin to keep the serum levels within the therapeutic range. He was a fast acetylator of isoniazid.20

The clearance of phenytoin was doubled in 14 patients given rifampicin 450 mg, isoniazid 300 mg and ethambutol 900 mg to 1.2 g daily for 2 weeks. No further changes occurred in the pharmacokinetics of phenytoin after 3 months of antitubercular treatment. In this study, the interaction was of a similar magnitude in both the slow and the fast acetylators.16

Mechanism

Rifampicin (a known potent liver enzyme inducer) increases the metabolism and clearance of the phenytoin from the body so that a larger dose is needed to maintain adequate serum levels. Isoniazid inhibits the liver microsomal enzymes that metabolise phenytoin, and as a result the phenytoin accumulates and its serum levels rise.21 Only those who are slow acetylators (slow metabolisers) of isoniazid normally attain blood levels of isoniazid that are sufficiently high to cause extensive inhibition of the phenytoin metabolism. Fast acetylators (fast metabolisers) remove the isoniazid too quickly for this to occur. Acetylator status is genetically determined. Thus some individuals will show a rapid rise in phenytoin levels, which eventually reaches toxic concentrations, whereas others will show only a relatively slow and unimportant rise to a plateau within, or only slightly above the therapeutic range.

If isoniazid and rifampicin are given together, the enzyme inhibitory effects of isoniazid may oppose the effects of rifampicin in those who are slow acetylators of isoniazid, but in those who are fast acetylators, the isoniazid will be cleared too quickly for it effectively to oppose the rifampicin effects. However, in one study isoniazid did not counter the effects of rifampicin in slow acetylators.16

The interaction involving clofazimine is not understood.

Importance and management

Direct information seems to be limited to these reports, but the interactions appear to be of clinical importance. Monitor the serum phenytoin levels and increase the dosage appropriately if rifampicin alone is started. Reduce the dosage if the rifampicin is stopped. If both rifampicin and isoniazid are given, the outcome may depend on the isoniazid acetylator status of the patient. Those who are fast acetylators will probably also need an increased phenytoin dosage. Those who are slow acetylators may need a smaller phenytoin dosage if toxicity is to be avoided. All patients should be monitored very closely as, unless acetylator status is known, the outcome is unpredictable.

The interaction with phenytoin and isoniazid alone is well documented, well established, clinically important and potentially serious. About 50% of the population are slow or relatively slow metabolisers of isoniazid,1 but not all of them develop serum phenytoin levels in the toxic range. The reports indicate that somewhere between 10 and 33% of patients are at risk.1,4,16 This adverse interaction may take only a few days to develop fully in some patients, but several weeks in others. Therefore concurrent use should be very closely monitored, making suitable dosage reductions as
necessary. One patient was reported to have had better seizure control with fewer adverse effects while taking both drugs than with phenytoin alone.22

Information about clofazimine seems to be limited to one report. Monitor concurrent use, anticipating the need to increase the phenytoin dosage.

Johnson J, Freeman HL. Death due to isoniazid (INH) and phenytoin. Br J Psychiatry (1975) 129, 511.

Phenytoin + Aspirin or NSAIDs

Serum phenytoin levels can be markedly increased by azapropazone and toxicity can develop rapidly. It is advisable for patients to take these drugs together. Phenytoin serum levels can also be increased by phenylbutazone and phenytoin toxicity may occur. It seems likely that oxyphenbutazone will interact similarly.

High-dose aspirin can cause protein-binding displacement of phenytoin, but this does not usually seem to be clinically important. No clinically significant interaction occurs between phenytoin and bromfenac, etodolac or tolfenamic acid.

Clinical evidence, mechanism, importance and management

(a) Aspirin

It has been suggested that if a patient has been taking large quantities of aspirin, phenytoin is ‘potentiated’. This comment remains unconfirmed, although a study in 10 healthy subjects did find that aspirin 975 mg every 4 hours caused protein binding displacement of phenytoin, resulting in a 16% rise in free salivary phenytoin levels and a 24% decrease in serum levels. However, these changes were considered unlikely to be clinically significant, and aspirin doses of 325 and 650 mg every 4 hours had no appreciable effect on phenytoin.2 Similar effects on protein binding displacement have been seen in other studies.3,4 However, although the ratios of free and bound phenytoin may change, there does not appear to be a clinical effect, possibly because the extra free phenytoin is metabolised by the liver.4 A study in 10 epileptics taking phenytoin found that when they were also given aspirin 500 mg three times daily for 3 days, no significant changes in serum phenytoin levels or antiepileptic effects occurred.5 The extremely confined use of aspirin, and the almost total silence in the literature about an adverse interaction between phenytoin and aspirin implies that no special precautions are likely to be needed.

(b) Azapropazone

A patient taking phenytoin developed phenytoin toxicity within 2 weeks of starting azapropazone 600 mg twice daily. Further study in 5 healthy subjects given phenytoin 125 to 250 mg daily found that azapropazone 600 mg twice daily, briefly decreased their mean serum phenytoin levels from 5 to 3.7 micrograms/mL before they rose steadily over the next 7 days to 10.5 micrograms/mL.9,10 An extension of this study is described elsewhere.11

Another report describes phenytoin toxicity in a woman taking phenytoin and ibuprofen where fenclofenac was replaced by azapropazone 1.2 g daily.12

The most likely explanation is that azapropazone inhibits the liver enzymes concerned with the metabolism of phenytoin, resulting in its accumulation. It also seems possible that azapropazone displaces phenytoin from its plasma protein binding sites so that levels of unbound (and active) phenytoin rise. Information seems to be limited to the reports cited, but it appears to be a clinically important interaction. The incidence is uncertain, but an interaction occurred in all 5 of the subjects in the study cited.11 The manufacturers contraindicate azapropazone in patients taking phenytoin.13

(c) Bromfenac

Twelve healthy subjects were given bromfenac 50 mg three times daily for 4 days and then phenytoin 300 to 330 mg for up to 14 days (to achieve stable levels), and then both drugs for 8 days. It was found that the peak phenytoin serum levels and AUC were increased by 9% and 11%, respectively, while the bromfenac peak levels and AUC were reduced by 42%. The suggested reason for the reduction in bromfenac levels is that the phenytoin increases its metabolism by the liver.14 In practical terms these results indicate that there is no need to adjust the dosage of phenytoin if bromfenac is added, nor any need to increase the bromfenac dosage unless there is any evidence that its efficacy is diminished.

(d) Celecoxib

An elderly woman taking phenytoin 300 mg daily who had also been taking celecoxib for the previous 6 months, developed signs of phenytoin toxicity. She was found to have a phenytoin level of 42 micrograms/mL, and a very slow rate of elimination.15 It was thought that celecoxib may have competed with phenytoin for elimination via the cytochrome P450 isoenzyme CYP2C9. Further study is needed. Until then, it may be prudent to warn patients to monitor for signs of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness). If celecoxib is started, or considered monitoring phenytoin levels.

(e) Etofiban

A three-way crossover study in 16 healthy subjects found that etofiban 200 mg every 12 hours for 3 days had no effect on the pharmacokinetics or the pharmacological effects of phenytoin (100 mg twice daily for 2 days, 100 mg on day three).16 There would seem to be no reason to avoid the concurrent use of these drugs.

(f) Ibuprofen

Studies in healthy subjects found that the pharmacokinetics of single 300- or 900-mg doses of phenytoin were not significantly altered by ibuprofen 300 or 400 mg every 6 hours.17,18 However, a single report describes a woman stabilised on phenytoin 300 mg daily who developed phenytoin toxicity within a week of starting to take ibuprofen 400 mg four times daily.19 Her serum phenytoin levels had risen to about 25 micrograms/mL. The phenytoin was stopped for 3 days and the ibuprofen withdrawn, and within 10 days the phenytoin level had dropped to about 17 micrograms/mL. The reasons for this interaction are not understood.

Both phenytoin and ibuprofen have been available for many years and this case seems to be the first and only report of an adverse interaction. No special precautions would normally seem to be necessary.

(g) Oxyphenbutazone or Phenylbutazone

Six epileptic patients taking phenytoin 200 to 350 mg daily who were then also given phenylbutazone 100 mg three times daily had a mean fall in their phenytoin serum levels from 15 to 13 micrograms/mL over the first 3 days, after which the levels rose steadily to 19 micrograms/mL over the next 11 days. One patient developed symptoms of toxicity. His levels of free phenytoin more than doubled.20 Another study found that phenylbutazone increased the steady state half-life of phenytoin from 13.7 to 22 hours.21,22

The predominant effect of phenylbutazone seems to be the inhibition of
the enzymes concerned with the metabolism of phenytoin, leading to its accumulation in the body and a rise in its serum levels. The initial transient fall may possibly be related in some way to the displacement by the phenylbutazone of the phenytoin from its plasma protein binding sites. An established interaction, although the documentation is very limited. Monitor the outcome of adding phenylbutazone and reduce the phenytoin dosage as necessary.

There is no direct evidence that oxyphenbutazone interacts like phenylbutazone, but since it is the main metabolic product of phenylbutazone in the body and has been shown to prolong the half-life of phenytoin in animals it would be expected to interact similarly.

(h) Tolifenamic acid

Tolifenamic acid 300 mg daily for 3 days had no significant effect on the levels of phenytoin in 11 patients. No special precautions seem necessary if these drugs are taken concurrently.

Clinical evidence

(a) Fluconazole

In a randomised, placebo-controlled study, 10 subjects given phenytoin 200 mg daily for the last 3 days of a 14-day course of fluconazole 200 mg daily had increases in phenytoin levels that could be clinically relevant.16

(b) Voriconazole

Studies in healthy subjects found that phenytoin 300 mg daily decreased the maximum serum levels and AUC of voriconazole by 49% and 69%, respectively. Also, voriconazole 400 mg twice daily increased the maximum serum levels and AUC of phenytoin 300 mg daily by 67% and 81%, respectively.17

Mechanism

Fluconazole inhibits the cytochrome P450 isoenzymes responsible for phenytoin metabolism (probably CYP2C9). Voriconazole and micona-
Phenytoin levels. Phenytoin is an enzyme inducer, and appears to induce the metabolism of these azoles to varying degrees.

**Importance and management**

The increase in serum phenytoin levels with **fluconazole** is established and clinically important. Toxicity can develop within 2 to 7 days unless the phenytoin dosage is reduced. Monitor serum phenytoin levels closely and reduce the dosage appropriately. Also be alert for any evidence of reduced fluconazole effects.

The decrease in **itraconazole** levels with phenytoin is established, clinically important and its incidence appears to be high. Because such a marked fall in itraconazole levels occurs, it is difficult to predict by how much its dosage should be increased, for which reason the authors of one report advise using another antifungal instead. Similarly, the UK manufacturer of itraconazole says that use with potent enzyme inducers such as phenytoin is not recommended. The small rise in serum phenytoin levels caused by itraconazole is unlikely to be clinically important.

Information on the interaction between **ketocanazole** and phenytoin appears to be limited to these reports, but be alert for any signs of a reduced antifungal response. It may be necessary to increase the dosage of the ketoconazole. Ketoconazole probably does not have an important effect on phenytoin levels.

Evidence for increased phenytoin levels with **miconazole** is limited, even so it would be prudent to monitor serum phenytoin levels, including when the oral gel is used at a dose of 5 to 10 mL four times daily (15 mg/kg per day).

Phenytoin halves **posaconazole** levels, and posaconazole might increase phenytoin levels. The manufacturer of posaconazole suggests that concurrent use should be avoided unless the benefits outweigh the risks. If used together it would seem sensible to consider increasing the posaconazole dose, and increase monitoring of phenytoin adverse effects, taking levels as necessary, and adjusting the phenytoin dose as appropriate.

The interaction between phenytoin and **voriconazole** is established. The UK manufacturers say that concurrent use of voriconazole and phenytoin should be avoided unless the benefits outweigh the risks. If used together, the manufacturers recommend careful monitoring of phenytoin levels and adverse effects, and doubling the dose of oral voriconazole (from 200 to 400 mg twice daily and from 100 mg to 200 mg twice daily in patients less than 40 kg) or increasing the dose of intravenous voriconazole (from 4 to 5 mg/kg twice daily).

**Phenytoin + Bile-acid binding resins**

Neither colestyramine nor colestipol affect the absorption of phenytoin from the gut.

**Clinical evidence, mechanism, importance and management**

Neither colestyramine 5 g nor colestipol 10 g had a significant effect on the absorption of a single 500-mg dose of phenytoin in 6 healthy subjects. The resins were given 2 minutes before and 6 and 12 hours after the phenytoin. Another study in 6 healthy subjects found that colestyramine 4 g four times daily for 5 days had no significant effect on the extent of the absorption of a single 400-mg dose of phenytoin (given on day 3, two min- utes after the colestyramine). No special precautions would seem to be necessary if either of these drugs and phenytoin is taken concurrently.

**Phenytoin + Calcium-channel blockers**

Diltiazem can increase serum phenytoin levels. A single case report describes phenytoin toxicity with nifedipine and another case report describes neurological toxicity when a patient taking phenytoin and carbamazepine was given irsadipline. The plasma levels of felodipine and nisoldipine are very markedly reduced by phenytoin (either alone or with carbamazepine). Case reports suggest that nimodipine and verapamil levels may be reduced by phenytoin, and that phenytoin levels may be raised by nifedipine.

**Clinical evidence**

(a) Diltiazem

Elevated serum phenytoin levels and signs of toxicity developed in 2 out of 14 patients taking phenytoin when they were also given diltiazem. A patient taking phenytoin 250 mg twice daily developed signs of toxicity within 2 weeks of starting to take diltiazem 240 mg every 8 hours.

(b) Felodipine

After taking felodipine 10 mg daily for 4 days, 10 epileptic patients (including 2 taking phenytoin alone and 3 taking phenytoin with carbamazepine) had markedly reduced plasma felodipine levels (peak levels of 1.6 nanomol/L compared with 8.9 nanomol/L in 12 control subjects). The felodipine bioavailability was reduced to 6.6%.

(c) Isradipine

A man taking carbamazepine and phenytoin developed neurological toxicity while also taking isradipine, which the authors attributed to a phar- macodynamic rather than pharmacokinetic interaction between the phenytoin and isradipine. However, a commentator considered that an interaction between the carbamazepine and isradipine was more plausible.

(d) Nifedipine

An isolated report describes phenytoin toxicity in a man taking phenytoin, 3 weeks after he started to take nifedipine 30 mg daily. His serum phenytoin level was 30.4 micrograms/mL. The nifedipine was stopped, and over the next 2 weeks his serum phenytoin levels fell to 10.5 micrograms/mL. A further 2 weeks later all the symptoms had resolved. However, a retrospective study of 8 patients suggested that nifedipine does not usually interact. One of the manufacturers of nifedipine notes that the bioavailability of nifedipine may be reduced by concurrent phenytoin.

(e) Nimodipine

A study in 8 epileptic patients one of whom was taking phenytoin with carbamazepine found that the AUC of a single 60-mg oral dose of nimodipine was only about 15% of that obtained from a group of healthy subjects.
Phenytoin + Carbamazepine

Some reports describe rises in serum phenytoin levels, with toxicity, whereas others describe falls in phenytoin levels. Genetic differences in the metabolism of these drugs may be an explanation for the differences. Falls in carbamazepine serum levels, sometimes with rises in carbamazepine-10,11-epoxide levels, have been described.

Clinical evidence

(a) Reduced serum phenytoin levels

Carbamazepine 600 mg daily for 4 to 14 days reduced the serum phenytoin levels of 3 out of 7 patients, from 15 to 7 micrograms/mL, from 18 to 12 micrograms/mL, and from 16 to 10 micrograms/mL, respectively. Phenytoin serum levels rose again 10 days after carbamazepine was withdrawn.1

(b) Raised serum phenytoin levels

A study in 6 epileptic patients taking phenytoin 350 to 600 mg daily found that over a 12-week period the addition of carbamazepine 600 to 800 mg daily increased the phenytoin serum levels by 35%, increased its half-life by 41% and reduced its clearance by 36.5%. Neurotoxicity increased by 204%, with additional symptoms of toxicity (sedation, ataxia, nystagmus, etc.) developing in 5 of the 6 patients. The phenytoin dosage remained unchanged throughout the period of the study.9

Other reports have also described increases in serum phenytoin levels,1,2,12 which were as large as 81%, and even up to 100% in some cases.8,10

(c) Reduced serum carbamazepine levels

A series of multiple regression analyses on data from a large number of patients [the precise number is not clear from the report], showed that phenytoin reduced plasma carbamazepine, by, on average, 0.9 micrograms/mL for each 2 mg/kg per day of phenytoin.7

Reduced serum carbamazepine levels have been described in other studies and reports.3,11,13,16

Two studies found that phenytoin markedly increased the levels of the active metabolite of carbamazepine, carbamazepine-10,11-epoxide.17,18

Mechanism

Not understood. Both carbamazepine and phenytoin are enzyme inducers, and might therefore be expected to decrease the metabolism of each other. However, more recently it has been shown that carbamazepine can inhibit the cytochrome P450 isoenzyme CYP2C19, which is one of the enzymes involved in phenytoin metabolism.19 Carbamazepine might therefore cause increases in phenytoin levels by this mechanism. Moreover, CYP2C19 shows genetic polymorphism (see ‘Genetic factors in drug metabolism’, (p.4), for a general discussion), so an interaction via this mechanism would not occur in all patients.

Importance and management

Phenytoin may decrease carbamazepine levels, but carbamazepine has variable effects on phenytoin levels, with both increases and decreases described. Monitor antiepileptic levels during concurrent use (where possible including the active metabolite of carbamazepine, carbamazepine-10,11-epoxide) so that steps can be taken to avoid the development of toxicity or lack of efficacy. Not all patients appear to have an adverse interaction, and, at present, it does not seem possible to identify those potentially at risk. The risk of carbamazepine-induced water intoxication is reported to be reduced in patients also taking phenytoin.14

Nisoldipine

Twelve epileptic patients receiving long-term phenytoin treatment and 12 healthy subjects were given single 40- or 20-mg doses of nisoldipine. The mean nisoldipine AUCs (normalised for a 20-mg dose) were 1.6 micrograms/L per hour for the epileptics, and 15.2 micrograms/L per hour for the healthy subjects.12

Verapamil

A woman taking phenytoin who was then also given verapamil had persistently subnormal plasma verapamil levels (less than 50 nanograms/mL) unchanged throughout the period of the study.9

References

Phenytoin + Chloramphenicol

Serum phenytoin levels can be raised by intravenous chloramphenicol and phenytoin toxicity may occur. Other evidence indicates that phenytoin may increase or decrease serum chloramphenicol levels in children.

Clinical evidence

(a) Effect on chloramphenicol

A child given a 6-week course of intravenous chloramphenicol 100 mg/kg daily in four divided doses had a reduction in chloramphenicol peak and trough serum levels of 46% and 74%, respectively, within 2 days of starting phenytoin 4 mg/kg daily. Levels were further reduced by 63% and 87%, respectively, by the addition of phenobarbital 4 mg/kg daily. Consider also ‘Chloramphenicol + Phenobarbital’, (p.300). In contrast, 6 children (aged 1 month to 12 years) developed raised, toxic chloramphenicol levels while receiving phenytoin.

(b) Effect on phenytoin

A man taking phenytoin 100 mg four times daily developed signs of toxicity within a week of also receiving intravenous chloramphenicol (1 g every 6 hours for 4 doses then 2 g every 6 hours). His serum phenytoin levels had risen by about threefold, from about 7 to 24 micrograms/mL. Consider also ‘Chloramphenicol + Phenobarbital’, (p.300). In contrast, 6 children (aged 1 month to 12 years) developed raised, toxic chloramphenicol levels while receiving phenytoin.

Mechanism

It seems probable that chloramphenicol, a known enzyme inhibitor, affects the liver enzymes (possibly cytochrome P450 isoenzyme CYP2C19) concerned with the metabolism of phenytoin thereby reducing its rate of clearance from the body. The changes in the pharmacokinetics of chloramphenicol in children are not understood.

Importance and management

The rise in serum phenytoin levels with intravenous chloramphenicol in adults is well documented and clinically important. A two to fourfold rise can occur within a few days. Concurrent use should be avoided unless the effects can be closely monitored and appropriate phenytoin dosage reductions made as necessary. The use of a single prophylactic dose of phenytoin or fosphenytoin may be an exception to this. It seems very doubtful if enough chloramphenicol is absorbed from eye drops or ointments for an interaction to occur.

The general clinical importance of the changes in serum chloramphenicol levels in children is uncertain, but the effects of concurrent use should certainly be monitored. More study is needed.

Phenytoin + Chlorphenamine

In two patients phenytoin toxicity was attributed to the concurrent use of chlorphenamine.

Clinical evidence, mechanism, importance and management

A week or so after starting to take chlorpharamine 4 mg three times daily, a woman taking phenytoin and phenobarbital developed phenytoin toxicity with serum phenytoin levels of about 65 micrograms/mL. The toxic symptoms disappeared and phenytoin levels fell when the chlorphenamine was withdrawn. Another woman taking antiepileptics, including phenytoin, developed slight grimacing of the face and involuntary jaw movements (but no speech slurring, ataxia or nystagmus) within 12 days of starting to take chlorphenamine 12 to 16 mg daily. Her serum phenytoin level had risen to 30 micrograms/mL but it fell when the chlorphenamine was withdrawn.

The reason for these reactions is not clear but it has been suggested that chlorphenamine may have inhibited the metabolism of phenytoin by the liver. These are isolated cases, and their general relevance is uncertain, but it seems likely to be small.

Phenytoin + Coumarins and related drugs

The serum levels of phenytoin can be increased by dicoumarol (toxicity seen) and phenprocoumon, but they are usually unchanged by warfarin and phenindione. However, a single case of phenytoin toxicity has been seen with warfarin. Phenytoin would be expected to reduce the anticoagulant effects of coumarin anti-coagulants, and this has been demonstrated for dicoumarol and warfarin. However, cases of increased effects of warfarin have been reported, and one study showed the effects of phenprocoumon were generally unaltered. A single case of severe bleeding has been described in a patient taking acenocoumarol, phenoxetine and phenytoin.

Clinical evidence

The reports of interactions between phenytoin and various anticoagulants are summarised in ‘Table 14.2’, (p.556), and discussed in further detail below.

(a) Acenocoumarol

A 68-year-old woman with a double mitral valve lesion, atrial fibrillation and hypertension, taking digoxin and diuretics, was stabilised on acenocoumarol 17 mg per week in divided doses and paroxetine. Phenytoin 400 mg daily for 3 days then 300 mg daily was started because of a seizure at 11 days later she developed ataxia, lethargy and nystagmus (free phenytoin levels of 12.5 micromol/L). At the same time her INR was found to have risen from a range of 2 to 4, up to 14.5 and a huge retroperitoneal haematoma was discovered. After appropriate treatment she was discharged taking acenocoumarol 13 mg per week in divided doses and half the phenytoin dosage.

(b) Dicoumarol

Phenytoin 300 mg daily was given to 6 subjects taking dicoumarol 40 to 160 mg daily for a week. No significant changes in the prothrombin-pro-

An increased anticoagulant response to warfarin for the first 6 days after phenytoin was added. The anticoagulant effect then declined to less than the level seen before the addition of phenytoin. Conversely, a population pharmacokinetic analysis reported that the clearance of warfarin was increased by 30% in 6 patients taking phenytoin or phenobarbital. However, the findings were not reported separately for the two drugs, and are therefore difficult to interpret (phenobarbital is a known inducer of warfarin clearance, see ‘Coumarins + Barbiturates’, p.390).

A study in 2 patients taking phenytoin 300 mg daily found that their serum phenytoin levels were unaffected by warfarin given for 7 days, and the half-life of phenytoin in 4 other patients was unaffected. However, a patient taking phenytoin 300 mg daily developed symptoms of toxicity shortly after starting to take warfarin. Another patient developed phenytoin toxicity 6 months after starting to take phenytoin with warfarin.

**Mechanism**

Multiple, complex and poorly understood. Dicoumarol and phenprocoumon (but not normally warfarin) appear to inhibit the metabolism of phenytoin by the liver, so that its loss from the body is reduced. Phenytoin is an inducer of the cytochrome P450 isoenzyme CYP2C9, which is involved in metabolism of the coumarin anticoagulants. Phenytoin would therefore be expected to decrease the levels and effect of some coumarins, and this has been shown for dicoumarol. However, increased effects of warfarin have been noted, suggesting reduced metabolism of warfarin. Why this occurs is uncertain, but poor CYP2C9 metaboliser phenotype (see ‘Genetic factors’, (p.4)) may provide an explanation. Phenytoin possibly also has a diverse depressant effect on the liver, which lowers blood clotting factor production.

**Importance and management**

None of these interactions has been extensively studied nor are they well established, but what is known suggests that the use of dicoumarol with phenytoin should be avoided or monitored very closely. Serum phenytoin levels and anticoagulant control should be well monitored if acenocoumarol, phenprocoumon or warfarin is given with phenytoin. Dosage adjustments may be needed to accommodate any interactions. Information about other anticoagulants (apart from phenindione, which had no effect on anticoagulant effect, and only fell to previous levels 5.5 weeks after stopping the phenytoin.

A study in 6 subjects taking phenytoin 300 mg daily found that when they were also given dicoumarol (doses adjusted to give prothrombin values of about 30%) their serum phenytoin levels rose on average by almost 10 micrograms/mL (126%) over 7 days. In another study the half-life of phenytoin in 4 other patients was unaffected. However, a patient taking dicoumarol 60 mg daily were also given phenytoin 300 mg daily for the first week of treatment, and then 100 mg daily for 5 more weeks. The prothrombin-proconvertin concentration had risen from 20 to 70% after 2 weeks of concurrent treatment, representing an antagonism of the anticoagulant effect, and only fell to previous levels 5.5 weeks after stopping the phenytoin.

A study in 4 patients taking phenytoin 300 mg daily found that when they were also given dicoumarol, the prothrombin time of a patient taking warfarin increased from 21 to 32 seconds over a month when phenytoin 300 mg daily was also given, despite a 22% reduction in the warfarin dosage. He was restabilised on the original warfarin dosage when the phenytoin was withdrawn. Six other reports describe this interaction. One of them describes a patient who had an increased anticoagulant response to warfarin for the first 6 days after phenytoin was added. The anticoagulant effect then declined to less than the level seen before the addition of phenytoin. Conversely, a population pharmacokinetic analysis reported that the clearance of warfarin was increased by 30% in 6 patients taking phenytoin or phenobarbital. However, the findings were not reported separately for the two drugs, and are therefore difficult to interpret (phenobarbital is a known inducer of warfarin clearance, see ‘Coumarins + Barbiturates’, p.390).

A study in 2 patients taking phenytoin 300 mg daily found that their serum phenytoin levels were unaffected by warfarin given for 7 days, and the half-life of phenytoin in 4 other patients was unaffected. A patient taking phenytoin 300 mg daily developed symptoms of toxicity shortly after starting to take warfarin. Another patient developed phenytoin toxicity 6 months after starting to take phenytoin with warfarin.

**Mechanism**

Multiple, complex and poorly understood. Dicoumarol and phenprocoumon (but not normally warfarin) appear to inhibit the metabolism of phenytoin by the liver, so that its loss from the body is reduced. Phenytoin is an inducer of the cytochrome P450 isoenzyme CYP2C9, which is involved in metabolism of the coumarin anticoagulants. Phenytoin would therefore be expected to decrease the levels and effect of some coumarins, and this has been shown for dicoumarol. However, increased effects of warfarin have been noted, suggesting reduced metabolism of warfarin. Why this occurs is uncertain, but poor CYP2C9 metaboliser phenotype (see ‘Genetic factors’, (p.4)) may provide an explanation. Phenytoin possibly also has a diverse depressant effect on the liver, which lowers blood clotting factor production.

**Importance and management**

None of these interactions has been extensively studied nor are they well established, but what is known suggests that the use of dicoumarol with phenytoin should be avoided or monitored very closely. Serum phenytoin levels and anticoagulant control should be well monitored if acenocoumarol, phenprocoumon or warfarin is given with phenytoin. Dosage adjustments may be needed to accommodate any interactions. Information about other anticoagulants (apart from phenindione, which had no effect
on phenytoin levels) appears to be lacking, but it would clearly be prudent to monitor the effects of concurrent use.

Phenytoin + Dextromethorphan

Dextromethorphan appears not to affect the serum levels of phenytoin.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 4 epileptic patients with severe complex partial seizures found that dextromethorphan 120 mg daily in liquid form (Delsym) over 3 months had no effect on their serum phenytoin levels. There was a non-significant alteration in the complex partial seizure frequency.1

Phenytoin + Dextropropoxyphene

Although no interaction generally appears to occur between phenytoin and dextropropoxyphene, a case report describes phenytoin toxicity in a patient given both drugs.

Clinical evidence, mechanism, importance and management

Only a very small rise in serum phenytoin levels occurred in 6 patients who took dextropropoxyphene 65 mg three times daily for 6 to 13 days.1 In contrast, a review briefly mentions one patient who developed toxic serum phenytoin levels while taking dextropropoxyphene in doses of up to 600 mg daily on an as-required basis.2

Concurrent use need not be avoided, but since rises in the serum levels of phenytoin can occur it would be prudent to monitor the outcome. It is probably sufficient just to monitor for increased adverse effects (blurred vision, nystagmus, ataxia or drowsiness).

Phenytoin + Diazoxide

Three children and one adult had very marked reductions in serum phenytoin levels when diazoxide was given, and in one case seizure control was lost. There is some evidence that the effects of diazoxide may also be reduced.

Clinical evidence

A child receiving phenytoin 29 mg/kg daily and an adult receiving phenytoin 1 g daily were unable to achieve therapeutic phenytoin serum levels while taking diazoxide. When the diazoxide was withdrawn, satisfactory serum phenytoin levels were achieved with dosages of only 6.6 mg/kg and 400 mg daily, in the child and the adult, respectively. When diazoxide was restarted experimentally in the adult, the serum phenytoin levels became undetectable after 4 days, and seizures occurred.1 Two other reports describe this interaction.2,3 In addition it appears that the effects of the diazoxide can also be reduced.2,4

Mechanism

What is known suggests that diazoxide increases the metabolism and the clearance of phenytoin from the body.1,2 The half-life of phenytoin is possibly reduced by phenytoin.4

Importance and management

Information is limited to these reports, but the interaction would appear to be established. Monitor the effects of concurrent use, being alert for the need to increase the phenytoin dosage. The clinical importance of the reduced diazoxide effects is uncertain.

Phenytoin + Dichloralphenazone

There is some evidence that serum phenytoin levels may be reduced by dichloralphenazone.

Clinical evidence, mechanism, importance and management

After taking dichloralphenazone 1.3 g each night for 13 nights the total body clearance of a single intravenous dose of phenytoin was doubled in 5 healthy subjects.1 The phenazone component of dichloralphenazone is a known enzyme inducer and the increased clearance of phenytoin is probably due to an enhancement of its metabolism by the liver. There seems to be no additional reports of adverse effects in patients given both drugs, so that the clinical importance of this interaction is uncertain. However, it would seem prudent to watch for a reduction in serum phenytoin levels if dichloralphenazone is added to established treatment with phenytoin.

Phenytoin + Felbamate

Felbamate causes a moderate increase in plasma phenytoin levels. Felbamate plasma levels are reduced, but the importance of this is uncertain.

Clinical evidence

A pilot study in 4 patients noted that felbamate increased plasma phenytoin levels.1 Therefore, in a further study the phenytoin dose was automatically reduced by 20% when felbamate was given. Of 5 patients, one needed a slight increase in phenytoin dosage, whereas 2 others needed a further reduction in their phenytoin dosage.2 In a later full report of this study, it was noted that phenytoin dosage decreases of 10 to 30% were required to maintain stable levels.2 Another study in epileptic patients found that felbamate 1.2 or 1.8 g daily increased the maximum plasma phenytoin levels by 31% and 69%, respectively. Higher felbamate doses necessitated phenytoin dose reductions of 20 to 40%.

Sorption of phenytoin.\textsuperscript{3} Another report suggested that this effect was dose-independent.\textsuperscript{3}

**Mechanism**

Uncertain but felbamate probably acts as a competitive inhibitor of phenytoin metabolism, thereby reducing its loss from the body and increasing its serum levels,\textsuperscript{2,3} whereas phenytoin induces felbamate metabolism, thereby increasing its clearance.\textsuperscript{4}

**Importance and management**

Established interactions. The phenytoin dosage may need to be reduced (a 20 to 40% reduction seems to be about right\textsuperscript{2,4}) if felbamate is added, and to increase it if felbamate is withdrawn. However, note that as phenytoin pharmacokinetics are non-linear any dosage adjustments will need to be assessed in individual patients. The importance of the reduced felbamate levels is uncertain, but is probably less important because felbamate has a wide therapeutic range.\textsuperscript{4}

**Phenytoin + Food**

The absorption of phenytoin can be affected by some foods. A very marked reduction in phenytoin absorption has been described when it was given with enteral feeds (e.g. Isocal, Osmolite), by nasogastric or jejunostomy tubes.

**Clinical evidence**

(a) Food by mouth

A study found that serum drug levels were lower than expected when phenytoin was disguised in vanilla pudding and given to children. However, when the phenytoin was mixed with apple sauce, 3 out of 10 patients developed serum phenytoin levels within the toxic range, and the mean levels were twice those seen when the tablets were mixed with the vanilla pudding.\textsuperscript{1} The absorption of phenytoin as the acid in a micronised form (Fenantoin, ACO, Sweden) was faster and the peak serum levels were on average 40% higher when it was given after a standardised breakfast.\textsuperscript{2}

In a further study to investigate the effects of component parts of the standardised breakfast, the same authors found that fat had no measurable effect, but carbohydrate may enhance and protein reduce the absorption of phenytoin.

Another study in 5 subjects found that the bioavailability of a single dose of phenytoin was enhanced when it was given immediately after a ‘balanced’ meal. Administration after a high-lipid meal resulted in large inter-patient variability in phenytoin bioavailability.\textsuperscript{3} One single dose study found that, when taken with a high-protein meal, the total absorption of phenytoin was not affected, although it was slightly delayed.\textsuperscript{3}

An epileptic had a marked fall in his serum phenytoin levels accompanied by an increased seizure frequency when phenytoin was given at bedtime with 8 oz of a food supplement (Ensure).\textsuperscript{6} Another patient had reduced phenytoin serum levels when phenytoin was given as an oral suspension with oral Fresubin liquid food concentrate.\textsuperscript{7}

However, in contrast, a study in 10 healthy subjects found that when Ensure or Vivonex TEN was given every 4 hours for 24 hours, the absorption of a single 400-mg dose of phenytoin was unaffected.\textsuperscript{8} Similarly, a single-dose study in healthy subjects found that the bioavailability of phenytoin sodium 400 mg in a capsule formulation (Dilantin Kapseals) was not affected by concurrent enteral feeds (Ensure).\textsuperscript{9}

A study in healthy subjects found phenytoin levels were reduced by enteral feeds, but that it was easier to attain therapeutic levels of phenytoin in those also receiving a meat-based formulation (Compleat Modified) rather than a protein hydrolysate formulation (Osmolite).\textsuperscript{10}

(b) Food by nasogastric tube

A patient taking phenytoin 300 mg daily who was being fed with Fortison through a nasogastric tube, following a brain injury sustained in a road traffic accident, had a phenytoin serum level of only 1 mg/L. When phenytoin 420 mg was given diluted in water and separated from the food by 2 hours, a serum level of 6 mg/L was achieved.\textsuperscript{11} This report describes a similar reaction in another patient with a cerebral tumour.\textsuperscript{11}

A study in 20 patients and 5 healthy subjects found that phenytoin absorption was reduced by about 70% when it was given by nasogastric tube with an enteral feed product (Isocal) at a rate of 100 to 125 mL/hour.\textsuperscript{12} Other reports describe the same interaction in patients given Ensure,\textsuperscript{13} Isocal,\textsuperscript{14,15} or Osmolite.\textsuperscript{16}

However, another study in healthy subjects found the absolute bioavailability of phenytoin suspension or phenytoin sodium solution given by nasogastric tube was not affected by an enteral feed product (Isocal).\textsuperscript{17}

(c) Food by jejunostomy tube

A woman with a history of seizures had acceptable serum phenytoin levels when phenytoin was given intravenously, but they fell from 19.1 micrograms/mL to less than 2.5 micrograms/mL when a comparable dose of phenytoin suspension was given in the presence of an enteral feed product (Jevity), given by jejunostomy tube.\textsuperscript{18}

**Mechanism**

Not fully resolved. Phenytoin can bind to some food substances, which reduces its absorption.\textsuperscript{21,22} One study in healthy subjects failed to find any difference in phenytoin bioavailability after fasting or with Ensure (given hourly or every 4 hours), suggesting that factors other than direct contact of phenytoin and feed contribute to decreased phenytoin bioavailability.\textsuperscript{23} Phenytoin can also become bound to the nasogastric tubing\textsuperscript{24} and may also be poorly absorbed if the tubing empties into the duodenum rather than the stomach.\textsuperscript{24} Delivery into the jejunum appears to have an even greater detrimental effect on phenytoin absorption, because there is even less time for adequate absorption.\textsuperscript{20} Other factors that could contribute to the interaction are gastrointestinal transit time, the nitrogen source in the feed, the calcium content and pH of the feed, the dose form of phenytoin or its dilution before administration.\textsuperscript{25}

**Importance and management**

Phenytoin is often taken orally with food to reduce gastric irritation. This normally appears not to have a marked effect on absorption, but the studies cited above show that some formulations and some foods can interact. If there are problems with the control of seizures or evidence of toxicity, review how and when the patient is taking the phenytoin.

Some studies in healthy subjects failed to find an interaction between phenytoin and enteral feeding.\textsuperscript{5,9,19} However, many studies in patients have found a clinically important interaction between phenytoin and enteral feeds given orally or by nasogastric tube. The markedly reduced bioavailability associated with the nasogastric route has been successfully managed by giving the phenytoin diluted in water 2 hours after stopping the feed, flushing with 60 mL of water, and waiting another 2 hours before restarting the feed.\textsuperscript{11,12} However, one limited study failed to confirm that this method is successful,\textsuperscript{13} and some sources suggest waiting 1 hour\textsuperscript{20} or 6 hours\textsuperscript{14} after the phenytoin dose before restarting the feed. Some increase in the phenytoin dosage may also be needed. Monitor concurrent use closely. The same problem can clearly also occur when enteral feeds are given by jejunostomy tube. Approaches on how to minimise any potential interaction have been reported,\textsuperscript{25,27} including the development and use of an algorithm.\textsuperscript{25}
Phenytoin + H₂-receptor antagonists

Phenytoin serum levels are raised by the use of cimetidine and toxicity has occurred. Limited evidence suggests that low (non-prescription) doses of cimetidine may not interact. Very rarely bone marrow depression develops on concurrent use. Famotidine, nizatidine and ranitidine do not normally interact with phenytoin, although, rarely, cases of elevated phenytoin levels have been reported.

Clinical evidence

(a) Cimetidine

The serum phenytoin levels of 9 patients rose by 60% (from 5.7 to 9.1 micrograms/mL) when they were given cimetidine 200 mg three times daily and 400 mg at night for 3 weeks. The serum phenytoin level returned to its former levels within 2 weeks of stopping the cimetidine.1

This interaction has been described in many reports and studies involving patients2 and healthy subjects.3-11 Phenytoin toxicity has developed in some individuals. The extent of the rise in serum levels is very variable depending on cimetidine dose. One study found that the effect of cimetidine 2.4 g daily was greater than that of 1.2 g daily or 400 mg daily, which is dependent on cimetidine dose. One study found that the effect of cimetidine was greater than that of 1.2 g daily or 400 mg daily, which is dependent on cimetidine dose.

(b) Famotidine

A study in 10 subjects found that famotidine 40 mg daily for 7 days did not alter the pharmacokinetics of a single dose of phenytoin. However, a single case report describes phenytoin toxicity and an almost doubled serum level (increase from 18 to 33 micrograms/mL) in a patient given famotidine. This was managed by a reduction in the phenytoin dose.

(c) Nizatidine

Nizatidine 150 mg twice daily for 9 doses had no effects on the pharmacokinetics of a single dose of phenytoin in 18 healthy subjects.

(d) Ranitidine

A study in 4 patients found that ranitidine 150 mg twice daily for 2 weeks did not alter phenytoin levels.1,2 Similarly, a double-blind, crossover study in healthy subjects found that ranitidine 150 mg twice daily for 6 days had no significant effect on steady state phenytoin levels. However, one patient had a 40% increase in serum phenytoin levels over a month when ranitidine 150 mg twice daily was given, and two others also developed elevated serum phenytoin levels and signs of toxicity, which were attributed to the use of ranitidine.2,3 Another patient developed a severe skin reaction when treated with phenytoin, ranitidine and dexamethasone after resection of a brain tumour, which resolved on discontinuing phenytoin.

Mechanism

Cimetidine inhibits the activity of the liver enzymes concerned with the metabolism of phenytoin, thus allowing it to accumulate in the body and, in some instances, to reach toxic concentrations. Famotidine, nizatidine and ranitidine normally do not affect these enzymes. Agranulocytosis and thrombocytopenia are relatively rare manifestations of bone marrow depression caused by both phenytoin and the H₂-receptor antagonists.

Importance and management

The interaction between phenytoin and cimetidine is well documented and clinically important. It is not possible to identify individuals who will show the greatest response, but those with serum levels at the top of the therapeutic range are most at risk. Do not give cimetidine to patients already taking phenytoin unless the serum levels can be monitored and suitable dosage reductions made as necessary. The results from one small study suggest that low doses of cimetidine (such as those available without a prescription in the UK) may not interact.13 Since there are only rare cases cited for famotidine, nizatidine, and ranitidine extra monitoring beyond that usually carried out in patients receiving phenytoin does not appear to be warranted but be alert for signs of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) when these H₂-receptor antagonists are first added to established treatment with phenytoin.

Phenytoin + Immunglobulins

An isolated report describes an epileptic patient taking phenytoin who died, probably from hypersensitivity myocarditis, two days after receiving immunoglobulins for Guillain-Barré syndrome.

Clinical evidence, mechanism, importance and management

A man who had been taking phenytoin for 8 years was diagnosed as having Guillain-Barré syndrome for which intravenous immunoglobulin was started at 400 mg/kg daily. On day 2 the patient complained of abdominal pain, achings and backache. He subsequently developed hypotension and died, despite resuscitation attempts. A post-mortem suggested that he had died from hypersensitivity myocarditis, which the authors of the report suggest might have resulted from the long-term use of the phenytoin. This hypersensitivity with phenytoin has been reported before. Because this complication is so serious, the authors of this report suggest that leukocyte counts, in particular eosinophils, should be monitored if immunoglobulins and phenytoin are given concurrently. One general importance of this alleged interaction is not known. However, note that subsequent to this report, intravenous immunoglobulin has successfully been used to treat a few cases of hypersensitivity syndrome to phenytoin, one including eosinophilia. Intravenous immunoglobulin alone has also been associated with causing myocarditis.

Mechanism

Where an interaction occurs it is suggested that it may be due to the inhibitory effect of the vaccine on the liver enzymes concerned with the metabolism of the phenytoin, resulting in a reduced clearance from the body.

Importance and management

The outcome of immunisation with influenza vaccine on phenytoin levels is uncertain. Concurrent use need not be avoided but it would be prudent to monitor the effects closely. Be aware that any alteration in levels may take a couple of weeks to develop and usually resolves spontaneously.

Phenytoin + Isotretinoin

A study in 7 healthy subjects taking phenytoin 300 mg daily found that the addition of isotretinoin 40 mg twice daily for 11 days had no effect on the steady-state pharmacokinetics of phenytoin. No special precautions would seem to be needed if these drugs are given concurrently.

Phenytoin + Loxapine

A single case report describes decreased serum phenytoin levels in a patient given loxapine.

Clinical evidence, mechanism, importance and management

The serum phenytoin levels of an epileptic patient were reduced by loxapine, and showed a marked rise when it was withdrawn. The general importance of this case is uncertain, but bear this interaction in mind, particularly as loxapine can lower the convulsive threshold.

Phenytoin + Macrolides

Erythromycin appears not to interact with phenytoin. Limited evidence suggests that clarithromycin may possibly raise serum phenytoin levels.
Clinical evidence

(a) Clarithromycin
A retrospective study of serum phenytoin levels in a group of 21 patients with AIDS and a large control group of 357 subjects suggested that the concurrent use of clarithromycin (a total of 22 samples from at least 10 patients) was associated with higher serum phenytoin levels. The concentration/dose ratio of the phenytoin was 1.6 without clarithromycin and 3.9 with clarithromycin.1

(b) Erythromycin
A single-dose study found that the mean clearance of phenytoin was unchanged by erythromycin 333 mg every 8 hours for 7 days in 8 healthy subjects. However, there were occasional large changes in phenytoin clearance.2 Similarly, in another study erythromycin 250 mg every 6 hours for 7 days had no effect on the pharmacokinetics of a single dose of phenytoin in 8 healthy subjects.3

Mechanism
Not known, but it could be that clarithromycin inhibits the metabolism of the phenytoin by the liver. An animal study found that erythromycin, clarithromycin, and roxithromycin reduced the metabolism and increased levels of phenytoin.4

Importance and management
This seems to be the first and only evidence that clarithromycin possibly interacts like this. Given that the interaction was identified retrospectively any interaction seems unlikely to cause an acute problem. Erythromycin appears not to interact with phenytoin, but nevertheless caution has been recommended.2

Phenytoin + Methylphenidate

Although two small studies found that methylphenidate did not alter phenytoin levels, raised serum phenytoin levels and phenytoin toxicity have been seen in three patients given methylphenidate.5

Clinical evidence
A 5-year-old hyperkinetic epileptic boy taking phenytoin 8.9 mg/kg and primidone 17.7 mg/kg daily, developed ataxia without nystagmus when he was also given methylphenidate 40 mg daily. Serum levels of both the antiepileptics were found to be at toxic levels and only began to fall when the methylphenidate dosage was reduced.1 A further case of phenytoin toxicity occurred in another child given methylphenidate.2 Only one other case has been reported, but this patient was later rechallenged with the two drugs and phenytoin toxicity was not seen.3

Furthermore, this interaction has not been seen in clinical studies and observations of 3 healthy subjects4 and more than 11 patients4 taking phenytoin and methylphenidate.

Mechanism
Not fully understood. The suggestion is that methylphenidate acts as an enzyme inhibitor, slowing the metabolism of the phenytoin by the liver and leading to its accumulation in those individuals whose drug metabolising system is virtually saturated by phenytoin.

Importance and management
These appear to be the only reports, and any interaction is not established. Concurrent use of phenytoin need not be avoided but be alert for any evidence of toxicity, particularly if the phenytoin dosage is high. It would seem prudent to monitor for symptoms of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) and take levels if necessary.

Phenytoin + Metronidazole

One study found that the half-life of phenytoin was modestly prolonged by metronidazole, whereas another found no change in phenytoin pharmacokinetics. An anecdotal report describes a few patients who developed toxic phenytoin levels when given metronidazole.

Clinical evidence, mechanism, importance and management
A pharmacokinetic study1 in 7 healthy subjects found that metronidazole 250 mg three times daily increased the half-life of a single 300-mg intravenous dose of phenytoin by about 40% (from 16 to 23 hours) and reduced the clearance by 15%. In contrast, another study in 5 healthy subjects found that the pharmacokinetics of a single 300-mg oral dose of phenytoin were unaffected by metronidazole 400 mg twice daily for 6 days.2 An anecdotal report describes several patients (exact number not stated) who developed toxic phenytoin serum levels when given metronidazole.3 These appear to be the only reports of this potential interaction, and the reason for their discordant findings is not clear. It seems likely that few patients are likely to experience a clinically significant interaction.

Phenytoin + Nefazodone

Nefazodone did not affect the pharmacokinetics of phenytoin in healthy subjects.

Clinical evidence, mechanism, importance and management
Nefazodone 200 mg twice daily for 7 days had no effect on the pharmacokinetics of a single 300-mg dose of phenytoin in healthy subjects, and no changes in vital signs, ECGs or other physical measurements were seen. There was no evidence that a clinically significant interaction was likely.1

Phenytoin + Nitrofurantoin

An isolated report describes a reduction in serum phenytoin levels and poor seizure control in a patient given nitrofurantoin.

Clinical evidence, mechanism, importance and management
A patient with seizures due to a brain tumour was taking phenytoin 300 mg daily. He had a seizure within a day of being given nitrofurantoin 200 mg for a urinary-tract infection and, despite a recent increase in the phenytoin dose to 350 mg, his serum phenytoin levels were found to be modestly reduced (from about 9 to 7.6 micrograms/mL). They continued to fall to 6.3 micrograms/mL despite a further increase in the phenytoin dosage to 400 mg daily. When the nitrofurantoin was stopped he was re-stabilised on his original dosage of phenytoin. The reasons are not understood but, on the basis of a noted rise in serum gamma glutamyltransferase levels during the use of the nitrofurantoin, the authors speculate that it...
increased the metabolism of the phenytoin by the liver. The general importance of this interaction is uncertain, but probably small.

Phenytoin + Orlistat

Orlistat does not alter the pharmacokinetics of phenytoin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, randomised, crossover study, 12 healthy subjects were given a single 300-mg dose of phenytoin on day 4 of a 7-day course of orlistat 120 mg three times daily. The pharmacokinetics of phenytoin were unchanged by orlistat, and no special precautions are therefore thought to be needed if these two drugs are given concurrently.

Phenytoin + Oxacillin

An isolated case describes a marked reduction in serum phenytoin levels, resulting in seizures, which was attributed to the use of oxacillin.

Clinical evidence, mechanism, importance and management

An epileptic woman taking phenytoin 400 mg daily, hospitalised for second degree burns sustained during a generalised seizure, experienced brief clonic seizures and was found to have an marked reduction in her serum phenytoin levels, from 16.3 to 3.5 micrograms/mL, which was attributed to the concurrent use of oral oxacillin 500 mg every 6 hours. The phenytoin dose was increased, but seizures continued and progressed to status epilepticus, and intravenous phenytoin was given. Doses of oral phenytoin of about 600 mg daily were required to maintain minimum therapeutic levels, sometimes with supplementation of small intravenous doses. Just before the oxacillin was withdrawn the serum phenytoin level was 22.3 micrograms/mL, but 6 months later it had risen to 39.9 micrograms/mL, and the phenytoin dose was reduced. Other studies have shown that penicillins such as oxacillin, cloxacillin and dicloxacillin can displace phenytoin from plasma protein binding, decreasing total serum levels but increasing the free fraction of phenytoin. If anything, this would be predicted to increase phenytoin toxicity. This seems to be only report of an adverse interaction between phenytoin and a penicillin. Its general importance is probably small.

Phenytoin + Phenobarbital

Phenytoin serum levels can be increased by about 50% by phenobarbital.

Clinical evidence, mechanism, importance and management

In 9 patients the steady-state half-life of phenytoin was prolonged from 32 to 47 hours by phenobarbital. Mean serum levels were raised by about 50% but fell rapidly over the 2 weeks after phenobarbital was withdrawn. This study confirms a previous report of this interaction. The reason for this interaction is uncertain, but since the two drugs have a similar structure it is possible that they compete for the same metabolising enzymes in the liv-
er, thereby resulting, at least initially, in a reduction in the metabolism of the phenytoin. If concurrent use is undertaken the outcome should be well monitored. Reduce the phenytoin dosage as necessary.

Phenytoin + Penicillins

Increased phenobarbital levels and possibly toxicity may result if phenytoin is given to patients taking phenobarbital.

Clinical evidence

A study in 10 epileptic patients taking phenobarbital 2.8 to 6.8 mg/kg daily found that while taking phenobarbital 1.1 to 2.5 mg/kg daily their serum phenytoin levels were reduced. Five patients had a mean reduction of about 65%, from 15.7 to 5.7 micrograms/mL. In most cases phenytoin levels rose again when the phenobarbital was withdrawn. In one patient this was so rapid and steep that he developed ataxia and a cerebellar syndrome with phenytoin levels of up to 60 micrograms/mL, despite a reduction in the phenytoin dosage.

This reduction in phenytoin levels by phenobarbital has been described in other reports. However, some of these levels were very transient and small rise or no alteration in serum phenytoin levels in individual patients. Three other studies have found that phenobarbital does not alter phenytoin levels.

Elevated serum phenobarbital levels occurred in epileptic children when they were also given phenytoin. In 5 patients the phenobarbital levels were approximately doubled. In some cases mild ataxia was seen but the relatively high barbiturate levels were well tolerated. A long-term study in 6 adult epileptics found that when phenytoin was added to phenobarbital, the level/dose ratio of the phenobarbital gradually rose by about 60% over one year, and then gradually fell again over the next 2 years. This suggests that initially, phenytoin reduces phenobarbital metabolism. In another patient taking phenobarbital 100 mg and phenytoin 160 mg daily, serum levels of phenobarbital increased by about 53% within about 2 days when the dose of phenytoin was increased to 490 mg daily.

Mechanism

Phenobarbital can have a dual effect on phenytoin metabolism: it may cause enzyme induction, which results in a more rapid clearance of the phenytoin from the body, or with large doses it may inhibit metabolism by competing for enzyme systems. The total effect will depend on the balance between the two drugs. The reason for the elevation of serum phenobarbi-
tal levels is not fully understood, but the extent may be dependent on the serum level of phenytoin.

Importance and management

Concurrent use can be therapeutically valuable. Changes in dosage or the addition or withdrawal of either drug need to be monitored to ensure that toxicity does not occur, or that seizure control is not worsened. The contradictory reports cited here do not provide a clear picture of what is likely to happen. Consider also ‘Primidone + Phenytoin’, p.570.

9. Booker HE, Torney A, Toussaint J. Concurrent administration of phenobarbital and diphe-

The serum levels of phenytoin can be raised or lowered by the use of chlorpromazine, prochlorperazine or thioridazine. Phenytoin may reduce levels of the active metabolite of thioridazine.

Clinical evidence

(a) Chlorpromazine

The serum phenytoin levels of a patient taking phenytoin, primidone and sulthiamine doubled after chlorpromazine 50 mg daily was taken for a month. However, another 4 patients taking chlorpromazine 50 to 100 mg daily showed no interaction. In another report, one out of 3 patients taking phenytoin and phenobarbital had a fall in their serum phenytoin levels when they were also given chlorpromazine. A further very brief report states that in rare instances chlorpromazine has been noted to impair phenytoin metabolism.

In a large study in patients taking phenytoin with various phenothiazines (chlorpromazine, thioridazine or mesoridazine), phenytoin levels were decreased by 44% when the phenothiazines were started, and by 33% when the phenothiazine dose was increased. A number of patients experienced an increased frequency of seizures. In patients who had these phenothiazines discontinued or the dosage decreased, the phenytoin levels increased by 55% and 71%, respectively, and toxic levels occurred in some patients.

(b) Prochlorperazine

A single very brief report states that in rare instances prochlorperazine has been noted to impair phenytoin metabolism.

(c) Thioridazine

One out of 6 patients taking phenytoin and phenobarbital had a marked rise in serum phenytoin levels when thioridazine was added, whereas 4 others had a fall in phenytoin levels. Phenytoin toxicity has also been described in 2 patients after about 2 weeks of concurrent treatment with thioridazine. A retrospective study in 27 patients taking phenytoin found that when they were given thioridazine their serum phenytoin levels were increased by at least 4 micrograms/mL (4 patients), decreased by at least 4 micrograms/mL (2), or were unchanged (21). Another retrospective study comparing 28 patients taking both phenytoin and thioridazine with patients taking either drug alone found no evidence that thioridazine increased the risk of phenytoin toxicity. A further study found no changes in serum phenytoin or thioridazine levels in patients given both drugs, but serum levels of mesoridazine (the active metabolite of thioridazine) were reduced, suggesting higher doses of thioridazine may be necessary to achieve the same effect. See also the study in section (a), which found a decrease in phenytoin levels and an increase in seizure frequency when patients took phenothiazines including thioridazine.

Mechanism

Uncertain. Phenothiazines such as thioridazine are inhibitors of the cytochrome P450 isoenzyme CYP2D6, and as such would not be expected to affect phenytoin metabolism, at least by this mechanism.

Importance and management

A confusing situation as the results are inconsistent. The concurrent use of phenytoin and the phenothiazines cited need not be avoided, but it would be prudent to watch for any signs of changes in serum phenytoin levels that would affect antiepileptic control. It is also worth remembering that phenothiazines may decrease the seizure threshold. In one study a trend towards increased seizure frequency was noted after phenothiazines were added, or doses increased. Also note that phenytoin may reduce levels of some phenothiazines. Whether all phenothiazines interact similarly is uncertain.

Phenytoin + Pheno pump inhibitors

A study in epileptic patients found that omeprazole 20 mg daily did not affect the serum levels of phenytoin, whereas earlier studies in healthy subjects suggested that phenytoin levels might be modestly raised by omeprazole 40 mg daily. A study with esomeprazole also suggests it may cause a minor rise in phenytoin levels. Lansoprazole does not normally affect phenytoin levels, but an isolated case report of toxicity is tentatively attributed to an interaction. Pantoprazole and rabeprazole appear not to interact.

Clinical evidence

(a) Esomeprazole

Esomeprazole inhibits the cytochrome P450 isoenzyme CYP2C19 so that the plasma levels of drugs metabolised by this enzyme might be expected to be increased by concurrent use. This is true for phenytoin, which the manufacturers say showed a 13% increase in trough plasma levels in patients given esomeprazole 40 mg.

(b) Lansoprazole

In a group of 12 healthy subjects lansoprazole 60 mg daily for 7 days caused only a very small and clinically irrelevant rise (less than 3%) in the AUC of a single intravenous dose of phenytoin. In contrast the manufacturer has received an isolated report of the development of blurred vision, diarrhoea, muscle pain, dizziness, abdominal pain, salivary hypersecretion, increased sweating and incoordination in a man taking phenytoin, which occurred within a day of stopping sustained-release propranolol 80 mg and starting lansoprazole. The phenytoin serum levels were not measured but the symptoms might possibly have been due to phenytoin toxicity, although it should be said that if an interaction with lansoprazole was responsible, it developed unusually quickly.

(c) Omeprazole

Omeprazole 20 mg daily for 3 weeks caused no changes in the mean steady-state serum phenytoin levels in 8 epileptic patients. Four patients had unchanged levels, 2 had falls and 2 had rises, but none of them was adversely affected by the omeprazole treatment.

After taking omeprazole 40 mg daily for 7 days the AUC of a single 500-mg dose of phenytoin was increased by 25% in 10 healthy subjects.

In another study the clearance of a 250-mg intravenous dose of phenytoin was reduced by 15% by omeprazole 40 mg given for 7 days. A further study found that 3 doses of omeprazole 40 mg had no effect on the pharmacokinetics of a single dose of phenytoin.

(d) Pantoprazole

In a randomised, crossover study in 23 healthy subjects it was found that pantoprazole 40 mg daily for 7 days did not alter the pharmacokinetics (AUC, maximum serum levels, half-life) of a single 300-mg dose of phenytoin. This study has also been published elsewhere.

(e) Rabeprazole

A preliminary report, which gives no details, states that when rabeprazole was used with phenytoin, no significant changes in the pharmacokinetics of phenytoin were seen.

Mechanism

Not understood. A possible explanation is that if the dosage of omeprazole is high enough, it may possibly reduce the metabolism of phenytoin by CYP2C19. However, CYP2C19 has only a minor role in phenytoin metabolism. Esomeprazole may interact similarly. With lansoprazole, the overall picture is that it does not act as an enzyme inducer or inhibitor.
Phenytoin + Shankhpushpi (SRC)

A case report, and an animal study, indicate that an antiepileptic Ayurvedic herbal preparation, Shankhpushpi (SRC), can markedly reduce plasma phenytoin levels, leading to an increased seizure frequency.

Clinical evidence

An epileptic man taking phenobarbital 120 mg daily and phenytoin 500 mg daily developed an increase in seizure frequency when Shankhpushpi (SRC) three times a day was given. His plasma phenytoin levels were found to have fallen from 18.2 to 9.3 micrograms/mL, whereas his phenobarbital levels were found to have fallen from 18 to 9.3 micrograms/mL. Notwithstanding, there is evidence from animal studies that SRC may affect the pharmacokinetics of the phenytoin and possibly its pharmacodynamics as well, thereby reducing its antiepileptic activity. It is also suggested that one of the ingredients of SRC may have some antiepileptic activity.

Mechanism

Not understood. There is evidence from animal studies that SRC may affect the pharmacokinetics of the phenytoin and possibly its pharmacodynamics as well, thereby reducing its antiepileptic activity. It is also suggested that one of the ingredients of SRC may have some antiepileptic activity.
However the fluvoxamine was started only 2 days after the phenytoin, in a dose of 200 mg twice daily, had been started, and the serum phenytoin levels were not checked until the toxicity had actually developed. Both drugs were then stopped and the phenytoin later successfully reinstated without the fluvoxamine. A worldwide analysis of data up to 1995 by the manufacturers of fluvoxamine identified only 2 reported cases of interactions (clinical symptoms only) between phenytoin and fluvoxamine.13

(c) Paroxetine
In a group of epileptic patients, paroxetine 30 mg daily for 16 days caused no changes in the plasma levels or therapeutic effects of phenytoin. Steady-state paroxetine plasma levels were lower in those also taking phenytoin (16 nanograms/mL) than in those taking carbamazepine (27 nanograms/mL) or valproate (73 nanograms/mL).10

(d) Sertraline
A double-blind, randomised, placebo-controlled study in 30 healthy subjects taking phenytoin 100 mg three times daily, found that sertraline 50 to 200 mg daily did not affect the steady-state trough serum levels of phenytoin, nor was there any evidence that concurrent use impaired cognitive function.11 However, another report describes 2 elderly patients whose serum phenytoin levels rose when they were given sertraline, but there was no evidence of toxicity. One of them had an almost fourfold rise in serum phenytoin levels whereas the other had a rise of only about one-third.12

In an analysis of plasma sertraline levels the concentration to daily dose ratio of sertraline was significantly lower in patients who had taken sertraline with phenytoin compared to those who had taken sertraline without phenytoin,13 which suggested that phenytoin increases sertraline metabolism.

Mechanism
An in vitro investigation found that fluoxetine and fluvoxamine inhibited the metabolism of phenytoin by the cytochrome P450 isoenzyme CYP2C9 in human liver tissue.15 This would presumably lead to a rise in serum phenytoin levels. In this study, sertraline was a weaker inhibitor of CYP2C9, and was considered less likely to interact with phenytoin.14 A similar study also suggested that the risk of interaction was greatest for fluoxetine, and less likely with sertraline and paroxetine.15 Sertraline plasma levels may be reduced because of enzyme induction by phenytoin which would increase its metabolism and clearance from the body.13

Importance and management
The interaction between phenytoin and fluoxetine appears to be established but its incidence is not known. Because of the unpredictable nature of this interaction, if fluoxetine is added to treatment with phenytoin in any patient be alert for the need to reduce the phenytoin dosage. Ideally the phenytoin serum levels should be monitored. Similarly, to be on the safe side phenytoin levels should be monitored when fluvoxamine is first added to the treatment.16

Phenytoin + Sulfisoxazole
In dogs.

Phenytoin + Sulfisoxazole
Some limited evidence indicates that phenytoin serum levels may be markedly increased by sulfisoxazole.

Mechanism
Uncertain. Reduced bioavailability has been demonstrated in a single-dose study in dogs when the drugs were used simultaneously, and this did not occur if the phenytoin were given 2 hours after the sulfisoxazole.4

Importance and management
Information is limited. The reduction in absorption shown in single-dose studies was quite small, and was not seen in a multiple-dose study, suggesting it is unlikely to be clinically relevant.

Clinical evidence
Sulfisoxazole 1 g was found to reduce the absorption (measured over a 24-hour period) of a single 300-mg dose of phenytoin in 8 healthy subjects by 20%.1 Peak serum phenytoin levels were also reduced, but this was not statistically significant. Another single-dose study found a reduction in phenytoin absorption of 7.7 to 9.5%.2 However, sulfisoxazole 1 g four times daily for 7 days had no effect on the steady-state levels of phenytoin 5 to 7 mg/kg daily in 6 healthy subjects. The fourth daily dose of sulfisoxazole was taken simultaneously with the daily phenytoin dose at bedtime. After 7 days, all phenytoin levels were within 15% of the baseline values (range, 6% decrease to 15% increase).3

Mechanism
In dogs.

Phenytoin + Sulfinpyrazone
Some limited evidence indicates that phenytoin serum levels may be markedly increased by sulfinpyrazone.

Clinical evidence
A review of the drug interactions of sulfinpyrazone identified two studies that found interactions with phenytoin.1 In the first, the serum phenytoin levels of 2 out of 5 patients taking phenytoin 250 to 350 mg daily were doubled from about 10 to 20 micrograms/mL within 11 days of starting to take sulfinpyrazone 800 mg daily. One of the remaining patients had a small increase in phenytoin levels, but the other two had no changes at all. When the sulfinpyrazone was withdrawn, the serum phenytoin concentrations fell to their former levels. The second study was a clinical study in epileptic patients that found that sulfinpyrazone 800 mg daily for a week increased the phenytoin half-life from 10 to 16.5 hours and reduced the metabolic clearance from 59 to 32 mL/minute.

Mechanism
Uncertain. It seems probable that sulfinpyrazone inhibits the metabolism of the phenytoin by the liver, thereby allowing it to accumulate in the body and leading to a rise in its serum levels. Displacement of phenytoin from its plasma protein binding sites may also have a small part to play.
Importance and management

Information seems to be limited to these studies, which await confirmation. A similar interaction with phenytoin has been reported with the use of sulfasalazine, which has a very close chemical relationship with sulfapyridazone (see ‘Phenytoin + Aspirin or NSAIDs’, p.551). Thus what is known suggests that concurrent use should be monitored and suitable phenytoin dosage reductions made where necessary.

Clinical Evidence

(a) Co-trimoxazole or Trimethoprim

A patient taking phenytoin 400 mg daily developed signs of toxicity (ataxia, nystagmus, loss of balance) within 2 weeks of starting to take co-trimoxazole 960 mg twice daily. His serum levels were found to have risen to about 38 micrograms/mL (normal range about 10 to 20 micrograms/mL).1

A child who was stable taking phenytoin and sulthiame developed phenytoin toxicity within 48 hours of starting co-trimoxazole. Toxicity resolved when the antibacterial was changed to amoxicillin.2 A clinical study found that co-trimoxazole and trimethoprim can increase the phenytoin half-life by 39% and 51%, respectively, and decrease the mean metabolic clearance by 27% and 30%, respectively.3 Sulfamethoxazole alone had only a small effect on the half-life and did not affect the clearance of phenytoin.4 A case report describes fatal acute hepatic failure in a 60-year-old woman 10 days after starting co-trimoxazole and 14 days after starting phenytoin.5 This patient was also given cimetidine, which may raise phenytoin levels (see ‘Phenytoin + H2-receptor antagonists’, p.559).

(b) Sulfadiazine

After taking sulfadiazine 4 g daily for a week, the half-life of a single intravenous dose of phenytoin was found to have increased by 80% in 8 patients. The mean metabolic clearance decreased by 45%.6

(c) Sulfamethizole

The development of phenytoin toxicity in a patient taking sulfamethizole prompted a study of this interaction in 8 patients given phenytoin. After the concurrent use of sulfamethizole 1 g four times daily for 7 days the phenytoin half-life had lengthened from 11.8 to 19.6 hours. Of the 4 patients receiving long-term treatment with phenytoin, 3 had rises in serum phenytoin levels from 22 to 33 micrograms/mL, from 19 to 23 micrograms/mL and from 4 to 7 micrograms/mL respectively. The phenytoin levels of the fourth patient were not affected.5,6 Another single-dose study found that the half-life of phenytoin was increased and the mean metabolic clearance reduced by 36%.5

(d) Other sulfonamides

Pretreatment for one week with sulfamethoxypyridazine or sulfadimethoxine did not significantly alter the pharmacokinetics of a single dose of phenytoin.3

Mechanism

The sulfonamides that interact appear to do so by inhibiting the metabolism of the phenytoin by the liver (possibly by the cytochrome P450 isoenzyme CYP2C9), resulting in its accumulation in the body. This would also seem to be true for trimethoprim. Depletion of glucuronic acid by phenytoin may have increased the hepatotoxicity of co-trimoxazole.4

Importance and management

The documentation seems to be limited to the reports cited, but the interaction is established. Co-trimoxazole, sulfamethizole, sulfadiazine and trimethoprim can increase serum phenytoin levels. The interaction probably occurs in most patients, but the small number of adverse reaction reports suggests that the risk of toxicity is small. It is clearly most likely in those with serum phenytoin levels at the top end of the range. If concurrent use is thought appropriate, the serum phenytoin levels should be closely monitored and the phenytoin dosage reduced if necessary. Alternatively, if appropriate, use a non-interacting antibacterial (in some circumstances ‘penicillins’, (p.562), or ‘macrolides’, (p.560), may be appropriate). There seems to be no information about other sulfonamides but it would be prudent to be alert for this interaction with any of them.

Phenytoin + Sulthiame

Serum Phenytoin levels can be approximately doubled by sulthiame and Phenyltoin toxicity may occur.

Clinical Evidence

The serum phenytoin levels in 6 out of 7 epileptic patients approximately doubled within about 5 to 25 days of starting to take sulthiame 400 mg daily. All experienced an increase in adverse effects and definite phenytoin toxicity occurred in 2 of them. In most of the patients, phenytoin serum levels fell back to baseline over the 2 months following the withdrawal of sulthiame.1 All of the patients were also taking phenobarbital and although greater variations in serum phenobarbital were seen, they were not considered to be clinically significant.4

A number of other reports confirm this interaction,2–8 some of which describe the development of phenytoin toxicity.

Mechanism

The evidence suggests that sulthiame interferes with the metabolism of the phenytoin by the liver, leading to its accumulation in the body.

Importance and management

A reasonably well-documented, established and clinically important interaction. The incidence seems to be high. If sulthiame is added to established treatment with phenytoin, increases in serum phenytoin levels of up to 75% or more may be expected.5,6 Phenytoin serum levels should be closely monitored and appropriate dosage reductions made to prevent the development of toxicity. The changes in phenobarbital levels appear to be unimportant.

**Phenytoin + Tamoxifen**

Some preliminary evidence suggests that high-dose tamoxifen can cause the serum levels of phenytoin to rise, causing toxicity. Phenytoin may lower tamoxifen levels.

**Clinical evidence, mechanism, importance and management**

A man who had undergone an operation 10 years previously for a brain tumour and had since remained seizure-free was taking phenytoin 200 mg twice daily to have breakthrough seizures. It was established that his brain tumour had recurred and so tamoxifen was started as experimental treatment. The dose of tamoxifen was slowly titrated to 200 mg daily over a 6-week period. He continued to receive phenytoin and was also given carbamazepine as his seizures were not controlled, but when the maximum dosage of tamoxifen (200 mg daily) was reached he began to develop symptoms of phenytoin toxicity with a serum level of 28 micrograms/mL. The toxicity disappeared and the phenytoin levels decreased when the phenytoin dosage was reduced. The carbamazepine serum levels remained unchanged throughout.1

The authors of this report say that other patients of theirs similarly treated with tamoxifen also developed phenytoin toxicity, which disappeared when the phenytoin dosage was reduced by 15 to 20%. Another study of the pharmacokinetics of high dose tamoxifen in patients with brain tumours found that the mean tamoxifen levels in 15 patients taking phenytoin were about 60% lower than in patients not taking phenytoin, although this did not reach statistical significance due to high inter-patient variability.2 The reasons for these possible interactions are not known, but it could be that tamoxifen and phenytoin both compete for the same metabolising enzymes.

The evidence for this interaction is very slim indeed and it may possibly only occur with high dose tamoxifen. Consider monitoring phenytoin levels if high-dose tamoxifen is added and monitor the efficacy of the tamoxifen. More study is needed.

**Phenytoin + Tizanidine**

Tizanidine reduces the metabolism of phenytoin. A number of case reports describe patients who developed phenytoin toxicity when tizanidine was added.

**Clinical evidence**

A 65-year-old man taking phenytoin 200 mg daily and clobazam developed signs of phenytoin toxicity (vertigo, ataxia, somnolence) within a week of starting tizanidine 250 mg daily. His serum phenytoin levels had risen from 18 mg/L to 34 mg/L. When the phenytoin dosage was reduced to 200 mg daily the toxic symptoms disappeared within a few days and his serum phenytoin levels fell to 18 mg/L. To test whether an interaction had occurred, the tizanidine was stopped, whereupon the serum phenytoin levels fell, within about 3 weeks, to 8 mg/L, during which time the patient experienced his first seizure in 2 years. When the ticlopidine was restarted, his serum phenytoin levels rose again, within a month, to 19 mg/L.1 A number of other case reports describe phenytoin toxicity, which occurred within 2 to 6 weeks of starting ticlopidine 250 mg once or twice daily.2,3 These were usually managed by reducing the phenytoin dose. One patient then experienced breakthrough seizures after the ticlopidine was stopped without re-adjusting the phenytoin dose.4 One case in a patient also taking phenobarbital reported that no change in phenobarbital levels occurred.4

A study in 6 patients taking phenytoin alone found that ticlopidine 250 mg twice daily approximately halved the steady-state phenytoin clearance.8

**Mechanism**

The metabolism of phenytoin to 5-(4-hydroxyphenyl)-5-phenylhydantoin (HPPH) by the cytochrome P450 isoenzyme CYP2C19, and to a lesser extent by CYP2C9, in the liver is inhibited by ticlopidine.1,3,4,9 Further metabolism of HPPH to dihydroxylated products is mediated mainly by CYP2C19 and this may also be inhibited by ticlopidine.9

**Importance and management**

The interaction is established and clinically important, but its incidence is unknown. It would now be prudent to monitor serum phenytoin levels very closely in any patient if ticlopidine is added to established treatment, being alert for the need to reduce the phenytoin dosage. If ticlopidine is discontinued, the phenytoin dose may need to be increased.

**Phenytoin + Trazodone**

An isolated case report describes phenytoin toxicity in a patient given trazodone.

**Clinical evidence, mechanism, importance and management**

A patient taking phenytoin 300 mg daily developed progressive signs of phenytoin toxicity after taking trazodone 500 mg daily for 4 months. His serum phenytoin levels had risen from 17.8 to 46 micrograms/mL.1 Therapeutic phenytoin serum levels were restored by reducing the phenytoin dosage to 200 mg daily and the trazodone dosage to 400 mg daily. The
reasons for this apparent interaction are not understood, and this appears to be the only reported case of an interaction. No general conclusions can be drawn.

Phenytoin + Tricyclic antidepressants

Evidence from two patients suggests that imipramine can raise serum phenytoin levels but nortriptyline and amitriptyline appear not to do so. Phenytoin possibly reduces serum desipramine levels. Note that the triyclics also lower the convulsive threshold.

Clinical evidence

(a) Phenytoin levels

The serum phenytoin levels of 2 patients rose over a 3-month period when they were given imipramine 75 mg daily. One of them had an increase in phenytoin levels from about 7.6 to 15 micrograms/mL and developed mild toxicity (drowsiness and uncoordination). These signs disappeared and the phenytoin serum levels of both patients fell when the imipramine was withdrawn. One of them was also taking nitrazepam and clonazepam, and the other sodium valproate and carbamazepine, but were stable on these combinations before the addition of imipramine.1

Other studies have shown that nortriptyline 75 mg daily had an insignificant effect on the serum phenytoin levels of 5 patients,2 and that amitriptyline had no effect on the elimination of phenytoin in 3 subjects.3

(b) Tricyclic antidepressant levels

A report describes 2 patients who had low serum desipramine levels, despite taking standard dosages, while they were also taking phenytoin.4

Mechanism

One suggestion is that imipramine inhibits the metabolism of the phenytoin by the liver, which results in its accumulation in the body. In vitro study5 has shown that the tricycles can inhibit the cytochrome P450 isoenzyme CYP2C19, but this isoenzyme usually has only a minor role in phenytoin metabolism (see ‘Antiepileptics’, (p.517)). The reduced desipramine levels may be a result of enzyme induction by the phenytoin.

Importance and management

The documentation is very limited indeed and none of these interactions is adequately established. The results of the in vitro study suggest that the interaction may only assume importance in those who are deficient in CYP2C9, the enzyme usually responsible for phenytoin metabolism.5 The tricyclic antidepressants as a group lower the seizure threshold,6 which suggests extra care should be taken if deciding to use them in epileptic patients. If concurrent use is undertaken the effects should be very well monitored.

Phenytoin + Valproate

The concurrent use of phenytoin and valproate is common and usually uneventful. Initially total serum phenytoin levels may fall but this is offset by a rise in the levels of free (and active) phenytoin, which may very occasionally cause some toxicity. After continued use the total serum phenytoin levels rise once again, and there might be sustained increases in free phenytoin levels. There is also some very limited evidence to suggest that concurrent use possibly increases the incidence of valproate hepatotoxicity.

Clinical evidence

(a) Phenytoin levels

A number of reports clearly show that total serum levels of phenytoin fall during the early concurrent use of valproate, while the concentrations of free phenytoin rise.1–5 In one report it was noted that within 4 to 7 days the total serum phenytoin levels had fallen from 19.4 to 14.6 micrograms/mL.1 A study extending over a year in 8 patients taking phenytoin and valproate found that by the end of 8 weeks the total serum phenytoin levels of 6 of them had fallen by almost as much as 50%, but had returned to their original levels in all but one patient by the end of the year.5 Similar results were found in another study.6 However, in a further study, some patients had a sustained increase in the free fraction of phenytoin.4 Another regression analysis showed that valproate increased the free fraction of phenytoin.8 The occasional patient may have symptoms of phenytoin toxicity and the dosage may need to be reduced.9 Delirium and an increased seizure frequency were seen in one patient taking valproic acid with phenytoin.10

(b) Valproate levels

Valproate levels are reduced by the presence of phenytoin.11,12 Valproate levels increased by 30 to 200% when phenytoin was discontinued in 12 patients taking both drugs, which allowed dosage reductions in 6 patients. In these patients, there was no change in seizure control when phenytoin was stopped.13

(c) Hepatotoxicity

Epidemiological studies suggest that the risk of fatal hepatotoxicity is higher when valproate is given as polytherapy with enzyme inducers such as phenytoin than when it is given as monotherapy, especially in infants.14,15 For mention of raised liver enzymes with concurrent use of valproate, phenobarbital and phenytoin, see ‘Phenobarbital + Valproate’, p.547.

Mechanism

The initial fall in total serum phenytoin levels appears to result from the displacement of phenytoin from its protein binding sites by valproate.1–5,10 the extent being subject to the diurnal variation in valproate levels.16 This allows more of the unbound drug to be exposed to metabolism by the liver and the total phenytoin levels fall. After several weeks the metabolism of the phenytoin is inhibited by the valproate and phenytoin levels rise.2,4 This may result in sustained elevation of free (active) phenytoin levels.17 Phenytoin reduces valproate levels, probably because it increases its metabolism by the liver. Because phenytoin is an enzyme inducer it may also possibly increase the formation of a minor but hepatotoxic metabolite of valproate (2-propyl-4-pentoenoic acid or 4-one-VPA).18

Importance and management

An extremely well-documented interaction (only a selection of the references being listed here). Concurrent use is common and usually advantageous. The adverse effects of the interactions between the drugs usually being of only minor practical importance. However, the outcome should still be monitored. A few patients may experience mild toxicity if valproate is started, but most patients taking phenytoin do not need a dosage change. During the first few weeks total serum phenytoin levels may fall by 20 to 50%, but usually no increase in the dosage is needed, because it is balanced by an increase in the levels of free (active) phenytoin levels. In the following period, the total phenytoin levels may rise again. This may result in a sustained rise in free phenytoin levels. When monitoring concurrent use it is important to understand fully the implications of changes in ‘total’ and ‘free’ or ‘unbound’ serum phenytoin concentrations. Where monitoring of free phenytoin levels is not available, various nomograms have been designed for predicting unbound phenytoin concentrations during the use of valproate.17,19 Bear in mind the evidence that the incidence of valproate induced liver toxicity may be increased, especially in infants.

Phenytoin + Vigabatrin

Vigabatrin causes a small to moderate fall in serum phenytoin levels.

Clinical evidence

In one early clinical study, the mean plasma phenytoin levels in 19 patients were about 30% lower when they were given vigabatrin 2 to 3 g daily: in 2 patients they fell below the therapeutic range. However, the change in phenytoin levels was not correlated with the change in seizure frequency.1 Another clinical study found that vigabatrin reduced the mean serum phenytoin levels by 20% in 53 patients; 41 patients had a decrease in phenytoin levels and 12 had an increase. In this study, some of the patients (number not stated) with decreased phenytoin levels had an increase in seizure frequency and required a phenytoin dosage increase.2-3 In another analysis, the decrease in phenytoin levels did not occur until the fifth week of vigabatrin therapy.4 Three other studies have shown roughly similar decreases in phenytoin levels when vigabatrin was added.5-7

Mechanism

Not understood. The decrease in phenytoin levels does not appear to be due to reduced metabolism or altered plasma protein binding.4 Similarly, it is not due to altered bioavailability, since the interaction occurred with intravenous phenytoin.4

Importance and management

The interaction between phenytoin and vigabatrin would appear to be established. Vigabatrin causes a modest decrease in phenytoin levels in some patients, which takes a number of weeks to become apparent. A small increase in the dosage of phenytoin may possibly be needed in some patients.

Phenytoin + Viloxazine

Viloxazine can cause a marked rise in serum carbamazepine levels and toxicity has been seen. Viloxazine can also raise serum phenytoin to toxic levels, but appears not to alter oxcarbazepine levels.

Clinical evidence

The clinical phenytoin levels of 10 epileptic patients rose by 37%, from 18.8 to 25.7 micrograms/mL over the 3 weeks following the addition of viloxazine 150 to 300 mg daily. The rise ranged from 7 to 94%. Signs of toxicity (ataxia, nystagmus) developed in 4 of the patients 12 to 16 days after starting the viloxazine. Their serum phenytoin levels had risen to between 32.3 and 41 micrograms/mL.1 When viloxazine was withdrawn the symptoms disappeared and phenytoin levels fell.1 The pharmacokinetics of viloxazine were unaffected by phenytoin.2

Mechanism

Uncertain. What is known suggests that viloxazine inhibits the metabolism of phenytoin, thereby reducing its clearance and raising its serum levels.

Phenytoin + Zidovudine

Although one study found that zidovudine did not alter the pharmacokinetics of phenytoin, there is other evidence suggesting that some changes possibly occur, although these may actually be due to HIV infection.

Clinical evidence, mechanism, importance and management

Although there are said to have been 13 cases of a possible interaction between zidovudine and phenytoin, the details are not described in the report.1 No significant changes in the pharmacokinetics of phenytoin 300 mg daily were seen in 12 asymptomatic HIV-positive patients who were taking zidovudine 200 mg every 4 hours.1 Another study found that the mean phenytoin dose was higher in HIV-positive patients, when compared to epileptic subjects without the virus, while the mean phenytoin levels in the HIV-positive group were lower (i.e. a higher phenytoin dose resulted in lower serum levels in HIV-positive subjects). Zidovudine did not appear to affect the levels.2 The current evidence would suggest that it is HIV infection, rather than zidovudine that affects phenytoin levels, but more study is needed to confirm this.

Phenytoin + Zileuton

The pharmacokinetics of phenytoin are unchanged by zileuton.

Clinical evidence, mechanism, importance and management

A controlled study in 20 healthy subjects found that the pharmacokinetics of a single 300-mg dose of phenytoin were unaltered by zileuton 600 mg every 6 hours for 5 days. An in vitro study found that zileuton had little effect on the isoenzymes responsible for the metabolism of phenytoin. These studies suggest that zileuton is unlikely to affect phenytoin levels in clinical use.

Piracetam + Other antiepileptics

Piracetam does not appear to alter the levels of sodium valproate or primidone. No interaction has been found between piracetam and carbamazepine, clonobarbital, phenobarbital, or phenytoin.

Clinical evidence, mechanism, importance and management

The addition of piracetam (2 to 4 g three times daily, increased to a maximum of 18 to 24 g daily) did not affect plasma levels of sodium valproate or primidone in patients with myoclonus. The exact number of patients taking these drugs is unclear, since the report just states that 28 patients were taking clonazepam, sodium valproate, or primidone, alone or in combination. Another similar report, briefly noted the same finding. The manufacturer notes that, although based on a small number of patients, no interaction has been found between piracetam and clonazepam, carbamazepine, phenytoin, phenobarbital and sodium valproate. No special precautions appear to be required if piracetam is used with these antiepileptics.

Pregabalin + Miscellaneous

There appears to be no pharmacokinetic interaction between pregabalin and carbamazepine, gabapentin, lamotrigine, phenobarbital, phenytoin, topiramate, valproate, alcohol, lorazapam, or oxycodone. However, the impairment of cognitive and gross motor function caused by oxycodone was additive with pregabalin, and pregabalin may potentiate the effects of alcohol and lorazepam.

Clinical evidence, mechanism, importance and management

(a) Alcohol or Lorazepam

The manufacturer notes that there was not a clinically relevant pharmacokinetic interaction between pregabalin and lorazepam or alcohol, and that concurrent use caused no clinically important effect on respiration. However, they note that pregabalin may potentiate the effects of lorazepam and alcohol.

(b) Other antiepileptics

Pregabalin 200 mg three times daily for 7 days was added to monotherapy with various antiepileptics in patients with partial epilepsy. Pregabalin did not alter the steady-state levels of phenytoin, carbamazepine (and its active metabolite, carbamazepine-10,11-epoxide), valproate or lamotrigine. In addition, the steady-state pharmacokinetics of pregabalin were not different to those seen previously in healthy subjects taking pregabalin alone, suggesting that these antiepileptics do not alter pregabalin pharmacokinetics. Similarly, population pharmacokinetic analyses of clinical studies found no important changes in the pharmacokinetics of lamotrigine, phenobarbital, phenytoin, topiramate or valproate when they were given with pregabalin, and the pharmacokinetics of pregabalin were unaffected by these drugs. The manufacturer also notes that there is no pharmacokinetic interaction between pregabalin and gabapentin.

(c) Oxycodone

The manufacturer notes that there was no clinically relevant pharmacokinetic interaction between pregabalin and oxycodone, and that there was no clinically important effect on respiration. However, pregabalin appeared to cause an additive impairment in cognitive and gross motor function when given with oxycodone. This suggests caution is warranted during combined use.

Primidone + Isoniazid

A single case report describes elevated serum primidone levels and reduced phenobarbital levels when primidone was given with isoniazid.

Clinical evidence, mechanism, importance and management

A patient taking primidone had raised serum primidone levels and reduced serum phenobarbital levels. This was attributed to the concurrent use of isoniazid, which inhibited the metabolism of the primidone by the liver. The half-life of primidone rose from 8.7 to 14 hours while taking isoniazid and steady-state primidone levels rose by 83%. The importance of this interaction is uncertain but prescribers should bear this interaction in mind in case of an unexpected response to primidone.

Primidone + Miscellaneous

Primidone is substantially converted to phenobarbital within the body and it is therefore expected to interact with other drugs in the same way as phenobarbital. Some drugs may increase the conversion of primidone to phenobarbital.

Clinical evidence, mechanism, importance and management

Primidone is substantially converted to phenobarbital within the body. For example, a group of patients taking long-term primidone developed serum primidone levels of 9 micrograms/mL and serum phenobarbital levels of 31 micrograms/mL. Primidone would therefore be expected to interact with other drugs in the same way as phenobarbital. Some enzyme-inducing drugs might increase the conversion of primidone to phenobarbital, and this has been demonstrated for ‘phenytoin’, below, and ‘carbamazepine’, (p.534). Some patients have been treated with a combination of phenobarbital and primidone. In this situation higher phenobarbital levels might be expected.

Primidone + Phenytoin

Primidone-derived serum phenobarbital levels are increased by phenytoin. This is normally an advantageous interaction, but phenobarbital toxicity occasionally occurs.

Clinical evidence

A study in 44 epileptic patients taking primidone and phenytoin found that their serum phenobarbital to primidone ratio was high (4.35) when compared with that in 15 other patients who were only taking primidone.
Phenytoin increases the metabolic conversion of primidone to phenobarbital, while possibly depressing the subsequent metabolic destruction (hydroxylation) of the phenobarbital. The net effect is a rise in phenobarbital levels. Phenobarbital may increase or decrease phenytoin levels, see 'Phenytoin + Phenobarbital', p.562.

**Importance and management**

Well documented. This is normally an advantageous interaction since phenobarbital is itself an active antiepileptic. However, it should be borne in mind that phenobarbital serum levels could sometimes reach toxic concentrations, even if only a small dose of phenytoin is added. Changes in phenytoin levels may also occur (see 'Phenytoin + Phenobarbital', p.562).

**Primidone + Valproate**

Valproate has been reported to cause increases, decreases, and no change in serum primidone levels. Primidone-derived phenobarbital levels appear to be increased by valproate.

**Clinical evidence**

In a number of cases, patients taking primidone required a decrease in the primidone dosage after valproate was added.1-4 In 6 cases this was due to an increase in the primidone-derived phenobarbital level, and in the other cases phenobarbital levels were not measured, but the dosage reduction was needed to overcome the sedation that occurred when the valproate was added.1-4 Primidone levels were not measured in any of these cases.1-4 In two other studies, primidone levels either decreased,5 or did not change when valproate was added.5 However, phenobarbital levels, where measured, had increased.5

In 7 children the serum levels of primidone 10 to 18 mg/kg daily rose two to threefold when valproate (dosage not stated) was also given. After 1 to 3 months of continued therapy the serum primidone levels fell in 3 of the patients but persisted in one. Follow-up primidone levels were not taken in the other 3 patients, and no patient had phenobarbital levels measured.7

In contrast, in a further study, neither phenobarbital levels nor primidone levels were significantly altered when valproate was given.8

**Mechanism**

It has been suggested that valproate decreases the conversion of primidone to phenobarbital, and decreases the metabolism of phenobarbital (see also 'Phenobarbital + Valproate', p.547). This would result in increased primidone and phenobarbital levels. However, increased renal clearance of primidone may occur, resulting in no overall change to the primidone levels. Depending on the balance between these various effects a variety of levels may result.8 The results of one study suggest that this proposed inhibition of phenobarbital metabolism caused by valproate may diminish over the first few months of concurrent use.7

**Important and management**

There seems to be little consistency about the effect of valproate on primidone levels. However, in the majority of cases phenobarbital levels seem to be raised (see also 'Phenobarbital + Valproate', p.547). It would seem prudent not to measure phenobarbital levels without corresponding phenobarbital levels. Monitor the patient for increased signs of sedation, which may be resolved by a reduction in the primidone dose.

**Progabide + Other antiepileptics**

Progabide may raise phenytoin levels and alter the serum levels of carbamazepine, clonazepam, phenobarbital. The effect of these antiepileptics on progabide levels appears to be only moderate or small.

**Clinical evidence**

(a) Phenytoin

Marked increases in serum phenytoin levels have been seen in a few patients also given progabide,1-4 while smaller changes have been described in some studies.5,6 and negligible changes in others.7

In one study, 17 out of 26 epileptics needed a reduction in their phenytoin dosage to keep the levels within 25% of the serum levels achieved in the absence of progabide. Over half the patients needed a dose reduction within 4 weeks of starting concurrent treatment. Most of those needing a dosage reduction had a maximum increase in the serum level of 40% or more, which was sometimes accompanied by toxicity.8,9 In a later report of this study, of a total of 32 epileptic patients taking carbamazepine with phenytoin and then given progabide, 22 needed a reduction in phenytoin dosage to maintain serum levels within 25% of those achieved in the absence of progabide. In addition, it appeared this effect on phenytoin serum levels continued for a while after progabide was withdrawn.4

(b) Other antiepileptics

Information about antiepileptics other than phenytoin is limited, but progabide is reported to minimally reduce,3,5,7 minimally increase1 or not to change carbamazepine,3,5,7 serum levels. An increase of up to 24% in the levels of carbamazepine-10,11-epoxide (the active metabolite of carbamazepine) has also been reported.6,10 Valproate,3,5,7 and clonazepam11 serum levels were not significantly affected by progabide. Progabide appears to cause a small increase in serum phenobarbital levels, which is of little clinical importance.1,5,7

**Mechanism**

Uncertain.

**Importance and management**

Some small to moderate changes in the serum levels of carbamazepine, phenobarbital, valproate and clonazepam can apparently occur in the presence of progabide, but only the interaction with phenytoin appears to be

Remacemide + Other antiepileptics

Remacemide causes modest increases in carbamazepine and phenytoin serum levels. Carbamazepine, phenobarbital and phenytoin moderately reduce remacemide serum levels. Valproate and lamotrigine do not appear to interact with remacemide.

Clinical evidence

(a) Carbamazepine

When a group of 10 patients taking carbamazepine were also given up to 300 mg of remacemide twice daily for 2 weeks, no patients had symptoms of carbamazepine toxicity. Another study of 11 patients taking carbamazepine found that remacemide caused a similar 20 to 30% increase in the AUC of carbamazepine, again without signs of toxicity. No consistent changes in the AUC of carbamazepine-10,11-epoxide, the main metabolite of carbamazepine, were seen.2 Another study reported a slight inhibitory effect of remacemide on phenytoin metabolism, which is in line with these other findings.3

(b) Lamotrigine

There was no clinically relevant pharmacokinetic interaction between remacemide (200 mg daily increased to 200 mg three times daily) and lamotrigine (200 mg twice daily decreased to 100 mg daily) in healthy subjects.4

(c) Phenobarbital

Phenobarbital 30 mg daily increased to 90 mg daily increased the clearance of remacemide 200 mg twice daily by 67%, and slightly increased the plasma levels of phenobarbital by 9% in a study in healthy subjects.5

(d) Phenytoin

A group of 10 patients taking phenytoin were also given up to 300 mg remacemide twice daily for 2 weeks. On average remacemide did not affect phenytoin pharmacokinetics but 5 patients had an increase in minimum serum levels of 30% or more. No patients had symptoms of phenytoin toxicity.6 In another study 10 epileptics, who had been taking phenytoin for at least 3 months, were given remacemide 300 mg twice daily for 12 days. Phenytoin maximum plasma levels were increased by 13.7% and the AUC was raised by 11.5%. Average concentrations of remacemide and its main metabolite were around only 40% and 30%, respectively, of those achieved in healthy subjects taking remacemide alone, at the same dosage.7 Another study reported a slight inhibitory effect of remacemide on phenytoin metabolism, which is in line with these other findings.8

(e) Sodium valproate

A group of 10 patients taking valproate were also given remacemide up to 300 mg twice daily for 14 days. The pharmacokinetics of valproate remained unchanged.9 Another study in 17 patients confirmed these findings,10 and an earlier study by the same authors also noted no effect of remacemide on valproate metabolism.11

Mechanism

Not fully understood, but in vitro studies indicate that remacemide inhibits the cytochrome P450 isoenzyme CYP3A4, which in practice would be expected to result in a reduction in the metabolism of the carbamazepine resulting in an increase in its serum levels. Remacemide appears to inhibit CYP2C9 to a lesser extent, which is reflected in a smaller interaction with phenytoin. Valproate is metabolised by glucuronidation and is therefore unaffected.12

Carbamazepine and phenytoin, known enzyme inducers, also seem to increase the metabolism of the remacemide.13

Importance and management

Information is limited, but the interactions of remacemide with carbamazepine, phenobarbital and phenytoin appear to be established, but so far only the carbamazepine interaction seems to have been shown to be of clinical importance. Even so, until more experience has been gained, monitor the effects of concurrent use with phenytoin or phenobarbital. No interaction occurs between remacemide and valproate or lamotrigine.

Retigabine + Other antiepileptics

The clearance of retigabine is increased by carbamazepine and phenytoin, but not by phenobarbital, topiramate, or valproate. Retigabine does not alter the pharmacokinetics of any of these antiepileptics. There is a modest pharmacokinetic interaction between retigabine and lamotrigine.

Clinical evidence, mechanism, importance and management

(a) Enzyme-inducing antiepileptics

The preliminary report of a study notes that the clearance of retigabine was increased (amount not stated) by carbamazepine and phenytoin, whereas retigabine did not alter carbamazepine or phenytoin pharmacokinetics in patients with epilepsy.1 This is consistent with the known enzyme-inducing properties of carbamazepine and phenytoin, and the fact that retigabine has not been shown to induce hepatic enzymes. In contrast, a study in healthy subjects, phenobarbital 90 mg daily did not affect the pharmacokinetics of retigabine 200 mg every 8 hours, and the pharmacokinetics...
of phenobarbital were not altered by retigabine. The clinical relevance of the effect of carbamazepine and phenytoin on retigabine remains to be assessed. No dosage adjustments seem to be necessary with phenobarbital.

(b) Lamotrigine

In a study in 14 healthy subjects lamotrigine 25 mg daily for 5 days increased the AUC of a single 200-mg dose of retigabine by 15% and decreased the clearance by 13%. In another 15 subjects, retigabine 200 mg twice daily increased to 300 mg twice daily over 15 days decreased the AUC of a single 200-mg dose of lamotrigine by 18% and increased clearance by 22%. It was suggested that lamotrigine competes for renal elimination with retigabine, but the mechanism behind the decreased lamotrigine levels is unknown. These modest changes are unlikely to be clinically important for most patients, but the authors suggest that the effects need to be assessed at the upper recommended dose ranges, and therefore advise caution.

(c) Topiramate

The preliminary report of a study notes that the pharmacokinetics of retigabine and topiramate were not altered by concurrent use in patients with epilepsy. No special dosing precautions are necessary.

(d) Valproate

The preliminary report of a study notes that the pharmacokinetics of retigabine and valproic acid were not altered by concurrent use in patients with epilepsy. No special dosing precautions are necessary.

Stiripentol + Other antiepileptics

Stiripentol causes marked rises in the serum levels of carbamazepine, phenobarbital and phenytoin. Stiripentol causes only a small rise in the serum levels of valproate.

Clinical evidence

Epileptic patients taking two or three antiepileptics (phenytoin, phenobarbital, carbamazepine, clobazam, primidone, nitrazepam) were also given stiripentol, increasing from 600 mg to 2.4 g daily. The 5 patients taking phenytoin had an average 37% reduction in the phenytoin clearance when they took stiripentol 1.2 g daily, and a 78% reduction when they took stiripentol 2.4 g daily. These changes in clearance were reflected in marked rises in the steady-state serum levels of phenytoin: for example the serum phenytoin levels of one patient rose from 14.4 to 27.4 mg/L over 30 days while he was taking stiripentol, despite a 50% reduction in his phenytoin dosage. Phenytoin toxicity was seen in another two subjects. The clearance of carbamazepine in one subject fell by 39% when stiripentol 1.2 g daily was taken and by 71% when stiripentol 2.4 g daily was taken. Phenytoin clearance in two subjects fell by about 30 to 40% when they took stiripentol 2.4 g daily. Three other studies in adults and children confirmed that stiripentol reduces the clearance of carbamazepine by between about 50% and 65%, and significantly increases carbamazepine levels. Another study found that the formation of carbamazepine-10,11-epoxide, the active metabolite of carbamazepine, was markedly reduced in children taking carbamazepine with stiripentol.

Valproate 1 g daily was given to 8 subjects with or without stiripentol 1.2 g daily. The stiripentol caused a 14% increase in the peak serum levels of valproate. In another 11 patients no adverse effects on motor, perceptual or attention tests were seen when stiripentol was given with other antiepileptic drugs, but the doses of phenobarbital, phenytoin and carbamazepine were reduced before the combination was taken.

Mechanism

Stiripentol inhibits the activity of various cytochrome P450 liver isoenzymes including CYP1A2, CYP2C9, CYP2C19, CYP2D6 and CYP3A4, some of which are concerned with the metabolism of other antiepileptics. As a result the loss of the antiepileptic from the body is reduced and the serum levels rise accordingly. In the case of valproate, cytochrome P450-mediated metabolism is only involved in minor valproate metabolic pathways and therefore only a small rise in serum levels occurs. However, there is evidence that stiripentol may reduce the formation of a minor but hepatotoxic metabolite of valproate (2-propyl-4-pentenoic acid or 4-ene-VPA).

Importance and management

Established and clinically important interactions. The phenytoin, phenobarbital and carbamazepine dosages should be reduced to avoid the development of elevated serum levels and possible toxicity during the concurrent use of stiripentol. One study suggests that the carbamazepine dosage should be decreased incrementally over 7 to 10 days, beginning as soon as the stiripentol is started and, regardless of age, the maintenance dose of carbamazepine should aim to give serum levels of 5 to 10 micrograms/mL. Stiripentol causes only small changes in the serum levels of valproate and dosage adjustments are unlikely to be needed with this combination.

Tiagabine + Miscellaneous

The pharmacokinetics of tiagabine were not altered by cimetidine or erythromycin. No clinically relevant pharmacokinetic interactions occur between tiagabine and theophylline or warfarin.

Clinical evidence, mechanism, importance and management

Cimetidine 400 mg twice daily for 5 days increased the steady-state AUC of tiagabine 4 mg twice daily by just 5% in a study in 12 healthy subjects. This change would not be clinically relevant.

Erythromycin 500 mg twice daily had no clinically relevant effect on the steady-state pharmacokinetics of tiagabine 4 mg twice daily in a study in 14 healthy subjects. No dose adjustment would be required during concurrent use.

Multiple dose studies in healthy subjects have also excluded any clinically relevant pharmacokinetic interactions between tiagabine and theophylline or warfarin.

Tiagabine + Other antiepileptics

Tiagabine plasma levels are reduced by enzyme-inducing antiepileptics (carbamazepine, phenytoin, phenobarbital and primi-
done). Tiagabine doses may need to be lower in patients not taking these drugs. Tiagabine may cause a slight reduction in valproate levels (not clinically relevant), but has no effect on carbamazepine, phenytoin or vigabatrin levels.

Clinical evidence, mechanism, importance and management

In an early clinical study, tiagabine was reported to have no significant effect on the plasma levels of carbamazepine, phenytoin, valproate, and vigabatrin.1 Similarly, tiagabine (titrated from 8 mg up to a maximum of 48 mg daily over 18 days) did not alter the steady-state pharmacokinetics of phenytoin or carbamazepine in 12 patients with epilepsy.2 However, in another similar study, it reduced the AUC of valproate by 10%, but this reduction is not expected to be clinically significant.3

A study in patients taking 1 to 3 other enzyme-inducing antiepileptics (phenobarbital, phenytoin, carbamazepine, primidone) found that tiagabine half-lives were shorter (3.8 to 4.9 hours) when compared with vigabatrin.4

Mechanism
Carbamazepine appears to induce the metabolism of topiramate. Although topiramate can weakly induce CYP2A4 this does not usually appear to have a clinically relevant effect on carbamazepine metabolism, unless carbamazepine is already at the maximum tolerated dose.

Importance and management
Carbamazepine possibly results in a moderate reduction in topiramate plasma levels, but this is probably of limited clinical importance. There is some evidence that the toxicity seen when topiramate is added to maximum tolerated doses of carbamazepine may respond to a reduction in the carbamazepine dose.

Topiramate + Carbamazepine

Topiramate plasma levels may be reduced by carbamazepine. Carbamazepine levels are not affected by topiramate. However, one report suggests that the toxicity seen when topiramate is added to maximum tolerated doses of carbamazepine may respond to a reduction in the carbamazepine dose.

Clinical evidence

(a) Carbamazepine levels

In a study in 12 epileptic patients topiramate titrated up to a maximum of 400 mg twice daily had no effect on the steady-state plasma levels of carbamazepine 300 to 800 mg every 8 hours or on its main metabolite, carbamazepine-10,11-epoxide.1 An earlier study in epileptic patients also reported that topiramate does not affect the pharmacokinetics of carbamazepine.2 In contrast, another report describes 2 patients taking a maximum tolerated dose of carbamazepine who started treatment with topiramate and subsequently developed symptoms suggestive of carbamazepine toxicity. In both these cases, the symptoms resolved when the carbamazepine dose was reduced, and this enabled continued titration of the topiramate dose in one. A review of the clinical use of these two drugs found another 23 cases that fitted this pattern. Carbamazepine levels were not reported.3

(b) Topiramate levels

The topiramate plasma levels and AUC were found to be about 40% lower in the presence of carbamazepine in a study in 12 epileptic patients.1 A population pharmacokinetic study reported that patients taking carbamazepine had 32% lower morning topiramate level than patients not taking enzyme-inducing antiepileptics.4 In a study in healthy subjects carbamazepine 600 mg daily was found to cause a twofold increase in the AUC of topiramate (2,3-diol-TPM and 10-OH-TPM), although 41% of topiramate was excreted unchanged in the urine in the presence of carbamazepine.5 In contrast, an earlier study reported that carbamazepine did not have a major effect on the pharmacokinetics of topiramate.2

Topiramate + Phenobarbital or Primidone

Topiramate appears not to alter the pharmacokinetics of phenobarbital or primidone. Phenobarbital reduces topiramate levels.

Clinical evidence, mechanism, importance and management

A review of data from double blind, placebo-controlled studies found that over periods of 8 to 12 weeks the plasma levels of phenobarbital or primidone in patients (number not stated) with partial seizures remained unchanged when they were also given topiramate.1

A population pharmacokinetic study reported that patients taking phenobarbital had 31% lower morning topiramate levels than patients not taking enzyme-inducing antiepileptics.2 Another study that grouped carbamazepine, phenobarbital and phenytoin reported that patients taking one or more of these drugs had 1.5-fold greater topiramate clearance than patients taking lamotrigine or valproate.3 Phenobarbital probably induces the metabolism of topiramate thereby reducing its levels.

When topiramate is added to existing treatment with phenytoin or phenobarbital its dose should be titrated to effect. If phenobarbital or primidone are withdrawn or added, be aware that the dose of topiramate may need adjustment.

Topiramate + Phenytoin

In some patients the plasma levels of phenytoin are slightly raised by topiramate, and topiramate plasma levels may be reduced by phenytoin.

Clinical evidence
Topiramate, titrated to a maximum of 400 mg twice daily, was given to 12 epileptic patients taking phenytoin 260 to 600 mg daily. When the maximum tolerated dose of topiramate was reached, the phenytoin dose was then reduced, and in some cases the phenytoin was subsequently discontinued. Topiramate clearance was assessed in 2 patients and was found to be increased two to threefold by phenytoin. Similarly, a population pharmacokinetic study reported that patients taking phenytoin and topiramate had 50% lower morning topiramate levels than patients not taking enzyme-inducing antiepileptics.2
In the first study above, 3 of the 12 patients had a decrease in phenytoin clearance and an increase of 25 to 55% in the AUC of phenytoin when taking topiramate: the other 9 had no changes.\(^1\) This slight increase is said not to be clinically significant based on analyses from six add-on studies.\(^3\)

### Mechanism

An in vitro study using human liver microsomes found that topiramate does not inhibit most hepatic cytochrome P450 isoenzymes, except for CYP2C19 at high concentrations.\(^1\) This isoenzyme plays a minor role in phenytoin metabolism, but it has been suggested this may become important at high doses of topiramate in patients who are poor CYP2C9 metabolisers,\(^1\) (see ‘genetic factors in drug metabolism’, (p.4), for more information). Phenytoin appears to induce the metabolism of topiramate.

### Importance and management

The interaction between topiramate and phenytoin appears to be established, and topiramate dose adjustments may be required if phenytoin is added or discontinued. No reduction in the phenytoin dosage seems necessary in the majority of patients, but be aware that a few patients may have increased phenytoin levels, particularly at high topiramate doses. Monitor phenytoin levels.

### Topiramate + Valproate

Encephalopathy has been reported in patients given topiramate with or without valproate. One study found no clinically relevant pharmacokinetic interaction between topiramate and valproate.

#### Clinical evidence, mechanism, importance and management

Six patients with severe epilepsy developed stuporous encephalopathy with marked cognitive impairment when taking topiramate with valproate (5 patients) or when taking topiramate alone (1 patient). Four of the patients had hyperammonaemia which resolved when topiramate or valproate were withdrawn. The toxicity was possibly due to a synergistic effect of valproate and topiramate on liver ornithine metabolism resulting in hyperammonaemia. It was also possible that the encephalopathy was due to topiramate toxicity in at-risk patients such as those with pre-existing chronic encephalopathy.\(^1\)

In a study in 12 epileptic patients, the pharmacokinetics of both topiramate, titrated to 400 mg twice daily, and valproate 1 to 4.5 g daily were slightly changed by concurrent use. The topiramate AUC was raised by about 18%, and the valproate AUC was reduced by 11.3%, but these changes were not considered to be clinically relevant.\(^2\) However, the proportion of various metabolites of valproate was altered by topiramate: metabolism to 4-ene-valproate (a putative hepatotoxin) and metabolism by oxiurinol is used.

Therefore valproate dosage alterations are unlikely to be required if allopurinol is used.

### Valproate + Antacids

#### Valproate + Allopurinol

Allopurinol appears not to alter valproate levels.

#### Clinical evidence, mechanism, importance and management

A study investigating allopurinol in refractory epilepsy found that allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients for 4 months) had no effect on valproate levels in 28 patients taking antiepileptics including valproate.\(^1\) In another similar study, allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks had no effect on serum valproate levels in 6 patients taking antiepileptics including valproate.\(^2\) Therefore valproate dosage alterations are unlikely to be required if allopurinol is used.

#### Valproate + Antacids

The absorption of valproate was slightly, but not significantly, increased by an aluminium/magnesium hydroxide suspension but not by magnesium trisilicate or a calcium carbonate suspension.

#### Clinical evidence, mechanism, importance and management

In 7 healthy subjects the AUC of a single 500-mg dose of valproic acid, given 1 hour after breakfast, was increased by 12% (range 3 to 28%) by 62 mL of an aluminium/magnesium hydroxide suspension (Maalox) given with and 2 hours after valproate. Neither magnesium trisilicate suspension (Trisogel) nor calcium carbonate suspension (Tirituc) had a significant effect on absorption.\(^3\) No special precautions would seem necessary during concurrent use.

#### Valproate + Aspirin or NSAIDs

Valproate toxicity developed in three patients given large and repeated doses of aspirin. Increased levels of free valproate were found in 5 children within hours of them taking aspirin. Conversely, a slightly reduced valproate level was reported in one patient who took ibuprofen. Modestly altered protein binding has been shown when sodium valproate was given with diflunisal or naproxen, but this appears unlikely to be clinically important.

#### Clinical evidence, mechanism, importance and management

(a) Aspirin

A 17-year-old girl taking valproate 21 mg/kg daily was prescribed aspirin 18 mg/kg daily for lupus arthritis. Within a few days she developed a disabling tremor which disappeared when the aspirin was stopped. Total serum valproate levels were not significantly changed, but the free fraction fell from 24% to 14% when the aspirin was withdrawn. Similar toxic reactions (tremor, nystagmus, drowsiness, ataxia) were seen in 2 children,
aged 6 and 4 years, given 12 and 20 mg/kg aspirin every 4 hours while taking valproate. In 5 epileptic children taking valproate, free valproate levels increased by 31 to 66% (average 49%) 17 hours after starting aspirin 11.5 to 16.9 mg/kg four times daily. One case report of fatal hyperammonemia was speculated to have been induced by valproate, and the authors also considered that concurrent use of aspirin and clopidogrel (p.578) may have contributed. Aspirin displaces valproate from its protein binding sites and also alters its metabolism by the liver so that the levels of free (and pharmacologically active) valproate rise. This could temporarily increase both the therapeutic and toxic effects of the valproate. However, there is evidence that increased hepatic elimination of valproate counterbalances this effect.

Direct information seems to be limited to the studies cited. Clinically relevant interactions appear rare, probably because in most cases the effects of aspirin on free valproate levels cancel each other out. The combination need not necessarily be avoided, but it would seem prudent to be aware of this interaction if valproate and high-dose aspirin are used.

(b) Diflunisal

Diflunisal 250 mg twice daily for 7 days given with sodium valproate 200 mg twice daily caused a 20% increase in the unbound fraction of valproate in 7 healthy subjects. There was a 35% increase in the AUC of one of the oxidation metabolites of valproate, and a small decrease in the AUC of some of the diflunisal glucuronide metabolites. This was shown to be due to changes in renal clearance of these metabolites. Whether any of these modest changes have any clinical relevance remains to be seen, but it appears unlikely.

(c) Ibuprofen

A 15-year-old boy was found to have a subtherapeutic valproate level (43 micrograms/mL) 3 days after starting to take ibuprofen 600 mg every 6 hours for post-fracture analgesia. The ibuprofen was stopped, and after one week the valproate levels were within the therapeutic range (60 micrograms/mL). The general importance of this isolated case is unknown. More study is needed.

(d) Naproxen

A study in 6 healthy subjects found that naproxen 500 mg twice daily moderately decreased the AUC of a single 800-mg dose of sodium valproate by 11%. Similarly, in another study, when naproxen 500 mg twice daily was given with sodium valproate 500 mg twice daily the AUC of valproate was decreased by 20% and the AUC of naproxen was increased by 7%. It is suggested that naproxen and sodium valproate displace each other from their protein binding sites. The clinical relevance of these modest changes is uncertain, but is likely to be small.

Valproate + Carbapenems

Panipenem/betamipron dramatically reduced the valproate serum levels of 6 patients. Imipenem and meropenem have similar effects and seizures have occurred when they were given to patients taking valproate. Ertapenem is predicted to interact similarly.

Clinical evidence

(a) Imipenem

A report describes a reduction in valproate levels from 80 micrograms/mL to 24 then 33 micrograms/mL in an epileptic patient 4 and 11 days after imipenem treatment. It was given to treat a Pseudomonas aeruginosa infection.

(b) Meropenem

A report describes two patients whose valproate levels fell when meropenem and amikacin were given. The first patient had been maintained on intravenous valproate 1.2 to 1.6 g daily with valproate levels of between 50 and 100 mg/L. Two days after the addition of the antibacterials the levels had halved, and after 3 days of subtherapeutic levels, phenytoin was substituted for valproate. The other patient experienced a drop in valproate levels from 44 mg/L to 5 mg/L within 24 hours of being given meropenem, despite being given greater doses of valproic acid. Other reports describe reductions in valproate levels in several other patients when they were also given meropenem: three of them developed seizures.

(c) Panipenem

A report describes 3 cases of Japanese children taking antiepileptic drugs who had marked reductions in valproate serum levels while receiving panipenem/betamipron for serious chest infections. An increased seizure frequency occurred in 2 of the patients. In one case the serum valproate levels fell from 30.1 to 1.53 mg/L within 4 days of starting panipenem, and rose again when it was stopped. All 3 patients were also taking carbamazepine but its serum levels were unchanged by the panipenem/betamipron. In a further 3 cases, 60 to 100% reductions in valproate levels were reported, which occurred within 2 days of starting concurrent treatment. Increased seizure frequency occurred in 2 cases.
Mechanism
Unknown, but the speed of the interaction is said to be inconsistent with enzyme induction, and accelerated renal excretion has been suggested.12
Altered protein binding has been shown in animal and in vitro studies.11

Importance and management
Although there is only an isolated report of an interaction between valproate and imipenem, there are now several reports of the interaction between valproate and meropenem or panipenem. Seizures or increased seizure frequency have been reported. It would therefore seem prudent to monitor the valproate levels in any patient also given carbapenems, being alert for the need to increase the valproate dosage, or to use another anti-bacterial, or an alternative to valproate. Carbamazepine6 and phenytoin2 did not interact in the above reports. The manufacturers of ertapenem have no reports of an interaction on their files,12 but prudently warn about

clinical evidence, mechanism, importance and management
A woman taking lithium and valproate 3.5 g daily developed fatigue and walking difficulties a day after starting to take erythromycin 250 mg four times daily. Within a week she had also developed slurred speech, confusion, difficulty in concentrating and a worsening gait. Her serum valproate levels had risen from 88 mg/L (measured 2 months before) to 260 mg/L. She recovered within 24 hours of the valproate and erythromycin being withdrawn. Her serum lithium levels remained unchanged.1 A child taking sodium valproate had a threefold increase in serum valproate levels after taking erythromycin 150 mg every 8 hours and aspirin 250 mg every 6 hours for 3 days.2 These case reports contrast with another study in a 10-year-old boy taking valproic acid 375 mg twice daily who had only very small and clinically unimportant changes in the pharmacokinetics of valproate, consistent with inhibition of cytochrome P450 metabolism, when given erythromycin 250 mg four times daily.3

Another child taking valproic acid developed a deficiency of pro-thrombin complex after taking erythromycin 300 mg three times daily. This resolved when the patient was given oral vitamin K. It was suggested that the effect was because the numbers of vitamin-K producing intestinal bacteria were reduced.4 The general relevance of these isolated reports is unclear, but probably small. Further study is needed.

Valproate + Chlorpromazine
Valproate serum levels are slightly raised in patients given chlorpromazine, but this appears to be of minimal clinical importance. An isolated report describes severe hepatotoxicity on concurrent use.

Clinical evidence, mechanism, importance and management
The steady-state trough serum levels of valproate 400 mg daily rose by 22% when 6 patients taking valproate were given chlorpromazine 100 to 300 mg daily. The half-life increased by 14% and the clearance fell by 14% (possibly due to some reduction in its liver metabolism).1 This interaction would normally seem to be of minimal importance. Severe hepatotoxicity occurred in another patient given both drugs,2 but remember that both drugs independently can be hepatotoxic.3

Valproate + Erythromycin
Two isolated reports describe valproate toxicity in a woman and a child given erythromycin. Another report describes vitamin K deficiency in a child given valproate and erythromycin.
Valproate + Fluoxetine

Isolated reports describe marked increases or modest decreases in valproate levels in a small number of patients given fluoxetine. Valproate toxicity occurred in one patient.

Clinical evidence

A woman with an atypical bipolar disorder and ‘severe mental retardation’ taking semisodium valproate (divalproex sodium) 3 g daily had a rise in her serum valproic acid levels from 93.5 to 152 mg/L within 2 weeks of starting to take fluoxetine 20 mg daily. The valproate dosage was reduced to 2.25 g daily and 2 weeks later the serum valproic acid levels had fallen to 113 mg/L. No adverse effects were seen.1 Another woman taking valproic acid developed elevated serum valproate levels (a rise from 78 to 126 mg/L) without any accompanying clinical symptoms within 1 month of starting to take fluoxetine 20 mg daily. Valproate levels fell again when the fluoxetine was stopped.2 Similarly, a 17-year-old taking valproic acid and felbamate developed drowsiness and difficulty in being roused 2 weeks after starting fluoxetine 20 mg daily. His valproate level had increased to 141 micrograms/mL from a previous range of 100 to 110 micrograms/mL. His valproate dose was reduced by about 15%, and his consciousness improved.3

In contrast 2 cases of reduced valproate levels have also been reported in patients taking fluoxetine. In the first case, a 67-year-old woman taking valproic acid 2 g daily and fluoxetine 20 mg daily had a serum valproate level of 51.9 mg/L. This increased to 64.9 mg/L 9 days after fluoxetine was discontinued and fell to 32.6 mg/L 6 days after fluoxetine was restarted. In the second case, an 81-year-old woman was taking valproic acid 1 g with fluoxetine 20 mg daily and had serum valproate levels of 41.9 mg/L. The fluoxetine was stopped, and 6 days later valproate serum levels had risen to 56.2 mg/L. After re-introduction of fluoxetine her valproate levels fell to 45.6 mg/L.4

Mechanism

Not understood.

Importance and management

These reports are somewhat confusing and inconsistent, but the overall picture is that concurrent use need not be avoided, but that the outcome should probably be monitored (indicators of valproate toxicity include nausea, vomiting, and dizziness). More study is needed.

Valproate + Food

A study in 12 healthy subjects found that dietary fibre (citrus pectin 14 g) did not affect the rate or extent of absorption of a single 500-mg dose of valproate.5

Valproate + H₂-receptor antagonists

Aside from one tentative case report, cimetidine and ranitidine do not appear to have a clinically significant interaction with valproate.

Clinical evidence, mechanism, importance and management

The clearance of a single oral dose of sodium valproate was reduced in 6 patients by 2 to 17% after a 4-week course of cimetidine, but was not affected by ranitidine.1 It seems doubtful if the interaction between valproate and cimetidine is of clinical importance. However, a case of fatal hyperammonaemia in a patient with systemic lupus erythematosus was speculated to have been induced by valproate, and the authors also considered that the concurrent use of cimetidine and aspirin (see ‘Valproate + Aspirin or NSAIDs’, p.575) may have contributed.2 The general importance of this case is unknown.

Valproate + Isoniazid

An isolated report describes the development of raised serum valproate levels and toxicity in a child given isoniazid while taking valproate. Another report describes raised hepatic enzymes and drowsiness in a patient taking both drugs.

Clinical evidence, mechanism, importance and management

A 5-year-old girl with left partial seizures, successfully treated with valproate 600 mg daily and clonazepam for 7 months, developed signs of valproate toxicity (drowsiness, asthenia) shortly after starting to take isoniazid 200 mg daily (because of a positive tuberculin reaction). Her serum valproate levels were found to have risen to around 121 to 139 mg/L (normal therapeutic range 50 to 100 mg/L).1 Over the next few months various changes were made in her treatment, the most significant being a 62% reduction in the dosage of valproate, which was needed to maintain satisfactory therapeutic levels. Later when the isoniazid was stopped her valproate levels fell below therapeutic levels and seizures recurred. It was then found necessary to increase the valproate to its former dosage. The suggested explanation for this interaction is that the isoniazid inhibited the metabolism (oxidation) of valproate by the liver so that it accumulated. The child was found to be a very slow acetylator of isoniazid.2 Another child who had been treated with valproate for several years was prescribed isoniazid for the treatment of tuberculosis. At the same time, seizures recurred, and the valproate was stopped and primidone 750 mg daily started. Seven months later seizures persisted, and she was admitted to hospital. Liver enzyme values were normal. Valproate 300 mg daily increased to 600 mg daily was added, and within 2 days she was vomiting and drowsy. After 5 days she had increased liver enzymes and her prothrombin time had fallen, so the valproate was stopped. Valproate levels were 81 micrograms/mL. It was speculated that the CNS effects and hepatic impairment were due to an interaction between the valproate and isoniazid.2

The general importance of these cases is uncertain, but bear them in mind in the event of an unexpected response to treatment.

Valproate + Methylphenidate

Two children taking valproic acid rapidly developed severe dyskinesias and bruxism after the first and second dose of methylphenidate, respectively. Valproate appears to potentiate the effects of methylphenidate, possibly by a pharmacokinetic mechanism, or because of additive dopaminergic effects. The authors of the re-
port advise clinical observation while the dose of methylphenidate is being established.¹

**Valproate + Propranolol**

One patient had a reduction in valproate clearance when also given propranolol, but 12 other patients had no changes.

**Clinical evidence, mechanism, importance and management**

An isolated report describes a 28% reduction in valproate clearance in a patient taking valproate semisdium with propranolol 40 mg, and a 35% reduction with propranolol 80 mg. However, 12 other patients taking valproate had no changes in clearance, serum levels or half-life when given propranolol 60 or 120 mg daily for 3 weeks.¹ This interaction would therefore not appear to be of general importance. No special precautions would seem necessary.

**Valproate + Theophylline**

A study in 6 healthy subjects found that oral aminophylline 200 mg every 6 hours for 3 doses did not affect the pharmacokinetics of a single 400-mg dose of sodium valproate.¹

**Vigabatrin + Clomipramine**

An isolated case report describes mania in an epileptic patient taking vigabatrin and clomipramine.

**Clinical evidence, mechanism, importance and management**

An isolated report describes an epileptic man taking carbamazepine and clomipram who started taking clomipramine 35 mg daily for depression. About one month later, vigabatrin 2 g daily was added for better seizure control. After about a week, the patient then progressively showed signs of mania, requiring hospitalisation after about 10 weeks. The clomipramine was stopped, the vigabatrin continued (because of its efficacy), and haloperidol started. Within a week the patient’s mood had stabilised. The authors of the report attributed the mania to an interaction between the vigabatrin and the clomipramine.¹ Note that both clomipramine and vigabatrin can cause psychiatric disorders including mania, and vigabatrin should be used with caution in patients with depression. No general conclusions can be based on this single report.

**Vigabatrin + Valproate**

No pharmacokinetic interaction appears to occur between vigabatrin and valproate.

**Clinical evidence, mechanism, importance and management**

Vigabatrin 40 to 80 mg/kg daily did not change the serum levels of sodium valproate in 11 children.¹ The combined use of vigabatrin and sodium valproate in 13 children with refractory epilepsy was found not to affect the steady-state serum levels of either drug and the combination reduced the frequency of seizures.² However, a retrospective analysis of serum samples from 53 patients found that the vigabatrin concentration-to-dose ratio was increased as the valproate trough steady state levels increased,³ suggesting that valproate slightly raises vigabatrin levels. However, no dosage adjustments usually appear to be necessary on combined use.

**Vigabatrin + Felbamate**

No clinically relevant pharmacokinetic interactions appear to occur between vigabatrin and felbamate.

**Clinical evidence, mechanism, importance and management**

In a study of 16 subjects, felbamate 2.4 g daily increased the AUC of vigabatrin 2 g daily by 13%, which is unlikely to be clinically significant. In a second study in a further 18 subjects, vigabatrin did not affect felbamate pharmacokinetics.¹ There would therefore seem to be no reason for avoiding concurrent use.

**Zonisamide + Miscellaneous**

Cimetidine does not alter zonisamide pharmacokinetics. Food has no effect on the absorption of zonisamide. A case of reduced zonisamide levels possibly caused by risperidone has been described.
Potent inhibitors of CYP3A4 are predicted to modestly decrease zonisamide clearance.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

When a single 300-mg oral dose of zonisamide was given to healthy subjects, it was found that cimetidine 300 mg four times daily for 13 days did not affect zonisamide clearance, half-life, apparent volume of distribution or the amount of drug recovered from the urine. The drugs were well tolerated.\(^1,2\) No special precautions would seem to be needed if both drugs are used.

(b) Food

There was no difference in the pharmacokinetics of a single 300- or 400-mg dose of zonisamide when given in the fasted state or after breakfast in a study in healthy subjects. Zonisamide may be taken without regard to the timing of meals.\(^3\)

(c) Risperidone

A 57-year-old man taking zonisamide was prescribed risperidone 2 mg daily, which was gradually increased to 10 mg daily. About 2 months after starting the risperidone, the zonisamide level had fallen from 23.7 to 10.7 micrograms/mL. The risperidone was stopped, and the zonisamide level had slightly increased again to 12.4 micrograms/mL about one month later. It was suggested that a metabolic interaction occurred.\(^4\) More study is needed to establish any interaction.

(d) Cytchrome P450 isoenzyme CYP3A4 inhibitors

In vitro studies have shown that the cytochrome P450 isoenzyme CYP3A4 is based on the principal enzyme involved in the metabolism of zonisamide.\(^5\) Based on in vitro data, it is predicted that itraconazole, ciclosporin, miconazole and fluconazole may cause a modest to minor decrease in the clearance of zonisamide. Conversely, itraconazole and triazolam are not predicted to have an effect.\(^6\) In vitro predictions do not always mirror what happens in clinical use, therefore, further study is needed.

Zonisamide + Other antiepileptics

Phenobarbital, phenytoin and carbamazepine can cause a small to moderate reduction in the serum levels of zonisamide, while lamotrigine may increase zonisamide levels. Clonazepam and valproate have little or no effect. Zonisamide shows variable effects (a modest decrease, an increase, or no effect) on carbamazepine serum levels, but has no important effect on lamotrigine, phenobarbital, primidone or valproate levels. Most studies also suggest that zonisamide has no effect on phenytoin levels, but two showed a modest increase.

Clinical evidence

(a) Carbamazepine

In one study the ratio of plasma level to dose of zonisamide was 39% lower in 17 patients taking carbamazepine than in 28 patients taking zonisamide alone, suggesting that carbamazepine modestly reduces zonisamide levels.\(^1\) Similarly, in another study in 12 epileptic children taking zonisamide 8.6 to 13.6 mg/kg daily, carbamazepine 12.1 to 18.1 mg/kg daily reduced zonisamide plasma levels by about 35 to 37%.\(^2\) In an early study in 2 groups of patients, one taking carbamazepine and the other phenytoin, it was noted that the zonisamide AUC following a single 400-mg dose was 40% higher in the carbamazepine group than the phenytoin group.\(^3\) However, in the first study, the plasma concentration-to-dose ratio was the same in patients taking carbamazepine as in those taking phenytoin.\(^4\) Therefore the comparative effects of carbamazepine and phenytoin on zonisamide levels are unclear.

In one study, the ratio of carbamazepine-10,11-epoxide (the major active metabolite of carbamazepine) to carbamazepine in the plasma was 50% lower in patients also taking zonisamide, suggesting that zonisamide reduces carbamazepine metabolism. However, the plasma concentration-to-dose ratio of carbamazepine was only 20% higher, which was not significant.\(^5\) An early pilot study had noted a consistent rise in carbamazepine plasma levels following initiation of zonisamide therapy in 7 patients (range 26 to 270%).\(^6\) The opposite effect was seen in a study of 16 paediatric patients in whom zonisamide reduced the ratio of carbamazepine serum levels to dose by up to 22% and increased the relative amount of its major metabolite in the serum by up to 100%, suggesting that zonisamide increases the metabolism of carbamazepine. However, the free fraction of carbamazepine remained unaltered.\(^7\)

Contrasting with these three studies are four others that found no changes in the serum levels of carbamazepine or carbamazepine-10,11-epoxide when zonisamide was used.\(^2,6,8\) Although in one of the studies, the renal clearance of carbamazepine-10,11-epoxide was significantly reduced by zonisamide.\(^8\) A further study similarly found no change in the plasma level of carbamazepine in 41 patients also given zonisamide (7.5 versus 7.4 micrograms/mL).\(^9\)

(b) Clonazepam

In one study the ratio of plasma level to dose of zonisamide did not differ between 8 patients also taking clonazepam and 28 patients taking zonisamide alone, suggesting clonazepam has no effect on zonisamide levels.\(^1\)

(c) Lamotrigine

Zonisamide 100 mg daily increased to 200 mg twice daily did not alter the steady-state pharmacokinetics of lamotrigine in 18 patients.\(^10\) Further, the pharmacokinetics of zonisamide were unaffected by lamotrigine.\(^11\) However, in 2 patients who were stable taking zonisamide 600 mg daily or 800 mg daily, the addition of lamotrigine (incremental doses up to 400 mg daily) caused about twofold increases in their zonisamide levels, with symptoms of toxicity that were maximal 40 to 60 minutes after taking a zonisamide dose.\(^12\)

(d) Phenobarbital or Primidone

In one study the ratio of plasma level to dose of zonisamide was 29% lower in 11 patients also taking phenobarbital than in 28 patients taking zonisamide alone, suggesting that phenobarbital reduces zonisamide levels.\(^1\) Similarly, another study in healthy subjects found that pretreatment with phenobarbital increased the clearance of a single dose of zonisamide by about twofold.\(^13\) A further study found no changes in the serum levels of phenobarbital or primidone in 34 and 13 patients, respectively, who were also given zonisamide.\(^3\)

(e) Phenytoin

In one study the ratio of plasma level to dose of zonisamide was 39% lower in 14 patients also taking phenytoin than in 28 patients taking zonisamide alone, suggesting phenytoin modestly reduces zonisamide levels.\(^1\) In an early study in 2 groups of patients, one taking carbamazepine and the other phenytoin, it was noted that the zonisamide AUC following a single 400-mg dose was 40% higher in the carbamazepine group than the phenytoin group.\(^3\) However, in the first study, the reduction in zonisamide level-to-dose ratio was the same for phenytoin as for carbamazepine.\(^1\) Therefore the comparative effect of phenytoin and carbamazepine on zonisamide levels is unclear.

Zonisamide 300 to 600 mg daily did not affect the phenytoin serum levels in 10 patients.\(^6\) Another study found that zonisamide did not affect the serum levels of phenytoin in 9 children.\(^14\) A further study similarly found no change in the plasma level of phenytoin in 33 patients also given zonisamide.\(^3\) In contrast to these three studies, in a population pharmacokinetic analysis, the clearance of phenytoin at a given dose was 14% lower and the serum level 16% higher in 39 patients also taking zonisamide.\(^15\) Similarly, the preliminary results from 9 patients in another study showed that there was a 28% increase in the steady-state AUC of phenytoin when zonisamide 100 mg daily increased to 200 mg twice daily was given.\(^16\) However, a later study by the same authors, in 19 patients, found that zonisamide did not affect the pharmacokinetics of phenytoin to a clinically relevant extent.\(^17\)

(f) Valproate

In one study the ratio of plasma level to dose of zonisamide was about 20% lower in 24 patients also taking valproate than in 28 taking zonis-
mide alone, suggesting that valproate has little effect on zonisamide levels. Similarly, another study in 16 patients found that valproate did not affect the pharmacokinetics of zonisamide. Further, the steady-state pharmacokinetics of valproate did not change when zonisamide 100 mg daily increased to 200 mg twice daily was added to the therapy of 16 patients.

Another study found that zonisamide did not affect the serum levels of sodium valproate in 12 children. A further study similarly found no marked changes in the plasma level of valproic acid in 7 patients also given zonisamide.

Mechanism

Uncertain. It seems possible that phenobarbital, phenytoin and carbamazepine can induce the metabolism of zonisamide thereby reducing its serum levels. The plasma protein binding of zonisamide is unaffected by other antiepileptics (phenobarbital, phenytoin, carbamazepine, valproate).

Importance and management

None of these studies reported any major problems during concurrent use of zonisamide and these other antiepileptic drugs. Zonisamide serum levels are lower with phenobarbital, phenytoin and carbamazepine, and there is the possibility of carbamazepine or phenytoin level changes, so it would be prudent to monitor patients taking any of these combinations.

Antihistamines (histamine H 1-antagonists) vary in their interaction profiles by sedative potential, route of metabolism, and cardiotoxicity (QT interval prolongation).

(a) Additive sedative effects

The older antihistamines (e.g. chlorphenamine, diphenhydramine and hydroxyzine) are also referred to as sedating antihistamines or first-generation antihistamines. As the former name suggests they have the potential to cause additive sedative effects with other sedating drugs. This type of interaction is discussed elsewhere, see ‘CNS depressants + CNS depressants’, p.1253. The sedating antihistamines also tend to have antimuscarinic (also called anticholinergic) adverse effects and so therefore may interact additively with other antimuscarinic-type drugs. This is also discussed elsewhere, see ‘Antimuscarinics + Antimuscarinics’, p.674.

The newer (non-sedating antihistamines or second-generation antihistamines) have a low potential to cause sedative effects. This appears to be because they are substrates for P-glycoprotein, an efflux transporter found in many organs, which would have the effect of actively ejecting any drug molecules that crossed the blood-brain barrier. Nevertheless, sedation may occur on rare occasions and patients should be advised to be alert to the possibility of drowsiness if they have not taken the drug before. Any drowsiness is likely to become apparent after the first few doses, and would indicate that additive sedative effects with other sedating drugs might be expected. The antihistamines are listed, by sedative potential, in ‘Table 15.1’, (below).

(b) Metabolism

Some of the sedating antihistamines, such as diphenhydramine, are inhibitors of the cytochrome P450 isoenzyme CYP2D6. None of the non-sedating antihistamines are known to inhibit cytochrome P450 isoenzymes, but some are substrates for CYP3A4 including astemizole, desloratadine, ebastine, loratadine, mizolastine, and terfenadine, see ‘Table 15.2’, (p.583). This has important consequences for the potential cardiotoxicity of astemizole and terfenadine, see (c) below. Loratadine and desloratadine are also substrates for CYP2D6, and mizolastine is also metabolised by glucuronidation. Cetirizine, levocetirizine and fexofenadine are minimally metabolised. Where pharmacokinetic interactions occur with fexofenadine, these appear to be mediated via drug transporters such as P-glycoprotein and/or organic anion transport polypeptide (OATP). For more information see ‘Drug transporter proteins’, (p.8).

(c) QT interval prolongation and cardiac arrhythmias

Important drug interactions occur with the non-sedating antihistamines astemizole and terfenadine. Raised serum levels of these two antihistamines can block potassium channels, lengthening the QT interval and increasing the risk of potentially fatal cardiac arrhythmias (torsade de pointes). Therefore, dangerous interactions may result when other drugs reduce the metabolism of astemizole or terfenadine, usually by inhibition of the cytochrome P450 isoenzyme CYP3A4. Such drugs include the ‘macrolides’, (p.589) and the ‘azoles’, (p.584). Adverse interactions are also predicted when astemizole or terfenadine are used with drugs that prolong the QT interval, see ‘Antihistamines + Drugs that prolong the QT interval’, p.587. Due to these potentially fatal interactions, astemizole has been withdrawn from many countries, while terfenadine has been withdrawn in the US and reclassified as a prescription-only medicine in the UK. Apart from possibly ebastine, loratadine and mizolastine, where information is inconclusive, none of the other non-sedating antihistamines have been clearly shown to be associated with QT prolongation (see ‘Table 15.2’, (p.583)). Therefore, even when pharmacokinetic interactions result in increased levels, these are unlikely to be clinically important in terms of cardiotoxicity.

†The HERG (human ether-a-go-go related gene) channel is involved in cardiac action potential repolarisation and is known to be blocked by certain drugs. Blocking HERG channels results in prolongation of the QT interval.

Antihistamines + Azoles

The azole antifungals raise the levels of astemizole and terfenadine, which can result in life-threatening arrhythmias. Arrhythmias have been reported for astemizole with ketoconazole, and terfenadine with itraconazole, ketoconazole, and even topical oxiconazole. Consequently all azoles are contraindicated with astemizole and terfenadine.

Ketoconazole increases mizolastine levels, which resulted in some QT prolongation in one study, therefore all azoles are contraindicated. The manufacturers of ebastine advise caution with ketoconazole and itraconazole as ketoconazole raises ebastine levels. The manufacturers of acrivastine advise caution with azoles due to a lack of data.

The situation with loratadine and ketoconazole is unclear as one study found that concurrent use caused a small increase in the QT interval.

Ketoconazole raises the levels of desloratadine, emedastine, fexofenadine but as no adverse cardiac effects were seen these combinations are considered safe. No interaction occurs between ketoconazole and azelastine, cetirizine, intranasal levocabastine, and none is expected with levocetirizine.

Clinical evidence

The effect of various azole antifungals on the plasma levels of the non-sedating antihistamines, and their cardiac effects from controlled studies are summarised in 'Table 15.3', (p.585). The subsections below include data from case reports and further studies.

A. Astemizole

(a) Ketoconazole

A 63-year old woman developed torsade de pointes arrhythmia and was found to have a prolonged QT interval after taking astemizole and ketoconazole. These two drugs were withdrawn and she was successfully treated with a temporary pacemaker, magnesium sulphate and lidocaine. She was later discharged with a normal ECG.1

(b) Miconazole

An in vitro study using human liver microsomal enzymes and 14C-labelled compounds found that miconazole inhibits the metabolism of astemizole. On the basis of the values obtained it has been predicted that a clinically relevant interaction could occur in vivo.2

B. Desloratadine

A chemotherapy patient developed severe pruritus and was given desloratadine and clemastine. Because of a pyrexia of unknown origin she was treated with meropenem and then 48 hours later fluconazole was added. After about 36 hours severe hepatotoxicity was detected, and apart from the anti-infectives the other drugs were stopped. Liver parameters recovered over the following week. Because the patient had previously received clemastine and fluconazole without problems, this case was attributed to a possible interaction between fluconazole and desloratadine.3

C. Ebastine

One animal study showed that ebastine given with ketoconazole had a similar potential for QTc prolongation as terfenadine given with ketoconazole. The potential was greater than that for loratadine, which was not considered to have a significant effect.4 A review of the safety of ebastine cites two studies assessing the potential interaction between ebastine and ketoconazole. One, a single dose study, found that the combination did not affect the QTc interval, whereas in a multiple dose study the QTc interval was prolonged by 18.1 milliseconds by the combination.5

D. Fexofenadine

(a) Itraconazole

In a single dose study, administration of itraconazole 200 mg one hour prior to fexofenadine 180 mg increased the AUC of fexofenadine 2.3-fold, and 3-fold in two groups of subjects of different genotypes for the gene encoding P-glycoprotein. Itraconazole pretreatment increased the effect of fexofenadine on histamine-induced wheal and flare reaction.6

(b) Ketoconazole

Fexofenadine has no effect on the pharmacokinetics of ketoconazole.7

E. Loratadine

In one study8 the cardiac effects of loratadine were found to be similar to those of ebastine (see C. above), which caused a small increase in the QT interval. However, loratadine alone, given at 4 times the recommended dose for 90 days, had no effect on the QTc interval when compared with placebo,9 and animal studies suggest that the combination of ketoconazole and loratadine does not significantly affect the QTc interval.4 As at 1993, there had been no cases of torsade de pointes reported during worldwide clinical use of loratadine,9 but see also ‘Table 15.2’, (p.583).

F. Terfenadine

(a) Fluconazole

By January 1993 no clinically significant interactions between terfenadine and fluconazole had been reported to the FDA.10

(b) Itraconazole

A 26-year-old woman taking 60 mg terfenadine twice daily began to have fainting episodes on the third evening after starting to take itraconazole 100 mg twice daily for vaginitis. When admitted to hospital the next morning her ECG showed a QT interval of 580 milliseconds and her heart rate was 67 bpm. Several episodes of torsade de pointes were recorded, and she fainted during two of them. No arrhythmias were seen 20 hours after the last itraconazole dose, and her QT interval returned to normal after 3 days. She was found to have terfenadine levels of 28 nanograms/mL in the first sample of serum taken (normally less than 5 nanograms/mL) and she still had levels of 12 nanograms/mL about 60 hours after taking the last tablet.11,12 Two other similar cases have been reported,13,14 and the FDA has received four well-documented cases of severe cardiac complications due to this interaction.15

(c) Ketoconazole

A 39-year-old woman taking terfenadine 60 mg twice daily developed a number of episodes of syncope and light-headedness, preceded by palpitations, dizziness and diaphoresis, within 2 days of starting to take ketoconazole 200 mg twice daily. ECG monitoring revealed torsade de pointes and a QTc interval of 655 milliseconds. Her terfenadine serum levels were 57 nanograms/mL (levels expected to be 10 nanograms/mL or less). Other drugs being taken were cefaclor (stopped 3 to 4 days before the problems started) and medroxyprogesterone acetate. She had taken terfenadine and cefaclor on two previous occasions in the absence of ketoconazole without problems.16,17 Other cases of an interaction between terfenadine and ketoconazole have also been reported.18,19

(d) Oxiconazole

A 25-year-old woman complained of palpitations and chest pain radiating down her left arm, and was also found to be having frequent ventricular premature beats in a pattern of bigeminy. On questioning it turned out that she was taking terfenadine and using topical oxiconazole for ringworm on her arm. Both drugs were stopped and her symptoms disappeared the following week.20

Mechanism

In vitro studies have shown that ketoconazole inhibits the metabolism of astemizole.21 Ketoconazole, and to a lesser extent itraconazole and miconazole,21,22 also appear to reduce the metabolism of terfenadine by inhibition of the cytochrome P450 isozyme CYP3A.21–23 High serum levels of astemizole and terfenadine (but not its metabolites) block cardiac potassium channels leading to prolongation of the QT interval, which may precipitate the development of torsade de pointes arrhythmia (see ‘Table 15.2’, (p.583)). The risk of cardiac arrhythmias with other non-sedating antihistamines appears to be non-existent or very much lower (see ‘Table 15.2’, (p.583)), so any pharmacokinetic interactions do not result in clinically relevant cardiac toxicity. In fact, studies have shown that desloratadine at nine times the recommended dose,24 fexofenadine in overdose,25 and mizolastine at four times the recommended dose26 do not affect the QT interval. However, some questions remain about loratadine and ebastine. Additionally, some studies have reported that ketoconazole alone is associated with a small increase in QT interval,3 and at least one case of torsade de pointes has been reported for ketoconazole alone.27 Therefore the cardiac effects of ketoconazole may be additive with those of the antihistamines, and this may be important for ebastine and loratadine.

†Note that terfenadine levels are normally undetectable
‡QTc intervals calculated using the Fridericia cube route formula, rather than the more commonly used Bazett square root formula, which the authors suggest would lead to a 5 to 6 millisecond overestimation

Cases of torsade de points have been reported for this antihistamine

Fexofenadine is not metabolised by CYP3A4, but it is a substrate for P-glycoprotein and OATP, therefore azole antifungals may increase its levels by inhibiting drug transporter proteins.

Importance and management

The interactions of astemizole with ketoconazole, and terfenadine with itraconazole or ketoconazole are established and clinically important, although much of the evidence for them is indirect. Astemizole would also be expected to interact similarly with itraconazole. The risk of an interaction with terfenadine or astemizole and otherazole antifungals seems smaller.

The incidence of an interaction is probably low, but because of the potential severity and unpredictability of this interaction, the concurrent use of astemizole and terfenadine is contraindicated with allazole antifungals in all patients. This is a recommendation of the manufacturers and the CSM in the UK. The manufacturer of terfenadine extends this contraindication to the concurrent use of topical azoles.

The use of azole antifungals with mizolastine is also contraindicated, and the manufacturer of ebastine advises against the concurrent use of ketoconazole and itraconazole. Because there are no data on acrivastine with ketoconazole, the manufacturer advises caution.

Ketoconazole markedly raises loratadine levels. In one study, this was associated with a small increase in QT interval, but no obvious alteration in adverse event profile. No special precautions appear to have been recommended for the use of loratadine with azoles.

Desloratadine, emedastine and fexofenadine levels are raised by ketoconazole, and therefore probably
Antihistamines + Benzodiazepines and related drugs

Benzodiazepines impair psychomotor performance, but neither ebastine nor mizolastine (both non-sedating antihistamines) further impair this. An enhanced sedative effect would be expected if known sedative antihistamines are given with benzodiazepines. Diphenhydramine did not alter the pharmacokinetics of zaleplon.

Clinical evidence

(a) Diphenhydramine

A randomised single dose three-period crossover study in healthy subjects found that diphenhydramine 50 mg had no significant effect on the pharmacokinetics of a single 10-mg dose of zaleplon, despite the fact diphenhydramine is a moderate inhibitor of the primary metabolic pathway [aldehyde oxidase] of zaleplon.1

(b) Ebastine

Ebastine 20 mg daily did not impair the performance of a number of psychomotor tests in 12 healthy subjects, although body sway and flicker fusion tests were altered. When ebastine was given with a single 15-mg dose of diazepam, it did not further impair performance compared with diazepam alone, and did not alter plasma diazepam levels.2

(c) Mizolastine

Mizolastine appears to lack sedative effects, and does not have a detrimental effect on psychomotor performance.3 A single 2-mg dose of oral lorazepam was found to impair the performance of psychomotor tests in 16 healthy subjects, and caused some sedation and amnesia, but these effects were not changed when the subjects also took mizolastine 10 mg daily for 8 days.3

Mechanism, importance and management

In a number of older antihistamines cause sedation, and this would be expected to be increased by some of the benzodiazepines by the simple addition of their CNS depressant effects. Non-sedating antihistamines would not be expected to have this effect (but see also ‘Antihistamines’, (p.582)), and this has been confirmed for ebastine and mizolastine.

Antihistamines + Drugs that prolong the QT interval

Astemizole and terfenadine should generally not be used with other drugs that can also prolong the QT interval. The manufacturer of mizolastine issues the same advice. One early study found that hydroxyzine caused ECG abnormalities in high doses. The authors suggested that its use with other drugs that can cause cardiac abnormalities might increase the likelihood of arrhythmias and sudden death, but there is no published evidence of this.

Clinical evidence, mechanism, importance and management

(a) Non-sedating antihistamines

The manufacturers of astemizole1 and terfenadine2 contraindicated the concurrent use of any other drugs that can also prolong the QT interval (for a list, see ‘Table 9.2’, (p.257)). However, note that the primary risk of QT prolongation and torsade de pointes arrhythmia with astemizole and terfenadine appears to be from drugs that significantly inhibit their metabolism (e.g. ‘azoles’, (p.584) and ‘macrolides’, (p.589)). Clinically relevant QT prolongation has not yet been shown conclusively for any of the other antihistamines (see ‘Table 15.2’, (p.583)), although the manufacturers of mizolastine still contraindicate its use with drugs that prolong the QT interval. Isolated cases have been described with other antihistamines: a case of torsade de pointes has been attributed to the concurrent use of amidodarone and ‘loratadine’, (p.246); a case report of torsade de pointes with sotalol and ‘terfenadine’, (p.859) was attributed solely to additive effects of QT prolongation with these drugs; and a small additional QT-prolonging effect has also been shown when terfenadine was given with ‘sparfloxacin’, (p.593).
Consider also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

(b) Sedating antihistamines

A study, conducted in 1958, in 25 elderly psychotic patients taking high-dose hydroxyzine 300 mg daily over a 9-week period found that ECG changes were mild, except for an alteration in T waves, which were defined in 9 patients. In each case the T waves were lower in altitude, broadened and flattened and sometimes notched. The QT interval was usually prolonged. A repeat of the study in a few patients, at least one given hydroxyzine 400 mg, found similar effects, the most pronounced change being a marked attenuation of cardiac repolarisation. On the basis of these observations the authors suggest that other drugs that cause ECG abnormalities such as thioridazine might aggravate and exaggerate these hydroxyzine-induced changes and increase the risk of sudden death. However, note that in the decades of use of hydroxyzine since this study was conducted there appear to be only a few isolated reports of arrhythmias (tachycardia) associated with its use.\(^5,6\) Note also that some manufacturers do not give any warnings regarding the use of hydroxyzine in patients with cardiac disorders, nor are any cardiac adverse effects mentioned, even for overdose.\(^5\) However, one manufacturer does suggest that caution is necessary in patients pre-disposed to arrhythmias, or on drugs that may cause arrhythmias.\(^9\)

## Antihistamines + Grapefruit and other fruit juices

Grapefruit juice raises terfenadine levels, increasing the risk of QT interval prolongation and torsade de pointes arrhythmias. Grapefruit juice does not appear to alter the pharmacokinetics of astemizole and desloratadine. The absorption of fexofenadine is modestly reduced by grapefruit juice, orange juice and apple juice.

### Clinical evidence

(a) Astemizole

In a study in 12 healthy subjects the steady-state pharmacokinetics of astemizole (30 mg daily for 4 days, then 10 mg daily for the next 20 days), were unaffected by 800 mL of grapefruit juice (given as 200 mL every 4 hours).\(^1\)

(b) Desloratadine

The bioavailability of a single 5-mg dose of desloratadine was unaffected by 8 oz (240 mL) of double-strength grapefruit juice, which was given three times daily for 2 days preceding the desloratadine and then 5 minutes before and 2 hours after the dose.\(^2\)

(c) Fexofenadine

In a study in 23 healthy subjects the AUC of fexofenadine 60 mg was reduced by 30% by double-strength grapefruit juice (8 oz or 240 mL), which was given three times daily for 2 days before the fexofenadine and then 5 minutes before and 2 hours after the dose.\(^3\) Similarly, another study found that grapefruit juice at normal strength decreased the AUC of a single 120-mg dose of fexofenadine by 67%. Dilute grapefruit juice (25%) caused a smaller reduction of 23%. Normal strength orange juice and apple juice similarly decreased the AUC of fexofenadine by 72% and 77% respectively.\(^4\) In this study, 300 mL of juice was given with the fexofenadine, followed by 150 mL every half an hour to a total volume of 1.2 L. A subsequent study found that a single 300 mL dose of normal strength grapefruit juice reduced the AUC of a single 120-mg dose of fexofenadine by 42% when they were given simultaneously.\(^5\) An effect was apparent for 300 mL of grapefruit juice given up to 10 hours prior to fexofenadine 120 mg in at least some of 12 subjects involved in this study.\(^6\)

### (d) Terfenadine

Terfenadine 60 mg was given to 6 healthy subjects every 12 hours for 14 days, given simultaneously with 240 mL of double-strength grapefruit juice every 12 hours for the final 7 days. Terfenadine was only detectable in the plasma when grapefruit juice was taken. The mean QTc interval was found to have risen from 420 to 434 milliseconds,\(^6\) which is not of a magnitude usually considered to be clinically significant. The effects were less pronounced in a further 6 subjects who took the grapefruit juice 2 hours after the terfenadine.\(^7\) Several other reports confirm these pharmacokinetics findings, although some did not find any changes in the QTc interval.\(^8,9\)

### Mechanism

Not fully understood, but it seems likely that some component of grapefruit juice inhibits the metabolism of the terfenadine to its active metabolite (by the cytochrome P450 isoenzyme CYP3A4), so that the parent drug accumulates.\(^10\) Terfenadine, but not its metabolite, causes QTc prolongation. Increased QTc intervals are associated with the development of ventricular tachycardia and torsade de pointes arrhythmias, which are potentially life-threatening.

Fexofenadine is a substrate for P-glycoprotein, and organic anion transporting polypeptide (OATP), both of which affect fexofenadine uptake. OATP in particular may be inhibited by grapefruit juice, apple juice, and orange juice, so these juices may reduce fexofenadine levels by preventing its absorption.\(^3\)

### Importance and management

The interaction between terfenadine and grapefruit juice is established and potentially clinically important. However, the serious cardiac effects may only occur in a small subset of individuals. As of 1996 neither the FDA nor the CSM appeared to have reports of problems in patients that were attributable to the use of antihistamines and grapefruit juice,\(^11\) although in 1997 the CSM had one report of a probable interaction with terfenadine.\(^11\) Nevertheless because of the risk of serious cardiotoxicity (however small) it would be prudent for all patients taking terfenadine to avoid grapefruit juice. At least one manufacturer of terfenadine contraindicates grapefruit juice.\(^12\)

The evidence from healthy subjects suggests that astemizole does not interact, but it is possible that individuals predisposed to cardiac conduction disorders are at risk.

Further study is required to determine the clinical relevance, if any, of the reductions in fexofenadine bioavailability in the presence of grapefruit juice, orange juice, and apple juice. Consider this interaction as the cause if fexofenadine seems less effective than expected.

Desloratadine appears to be a safe alternative.

No pharmacokinetic interaction appears to occur when cimetidine is given with cetirizine, desloratadine, ebastine or terfenadine, or when ranitidine is given with terfenadine or chlorphenamine. However, an isolated case report describes torsade de pointes in one patient taking terfenadine with cimetidine. Cimetidine moderately raises hydroxyzine levels and considerably raises loratadine levels, but this is not thought to be of clinical significance. The renal clearance of fexofenadine was reduced by cimetidine in one study although there was no change in plasma pharmacokinetics.

Clinical evidence

A. Non-sedating antihistamines

(a) Cetirizine

Cetirizine 10 mg was given to 8 patients with chronic urticaria before and after they took cimetidine 600 mg every 12 hours for 10 days. The pharmacokinetics of cetirizine were statistically unaltered and its effects remained unchanged.1

(b) Desloratadine

In a parallel study in 18 healthy subjects, cimetidine 600 mg every 12 hours had little effect on the pharmacokinetics of desloratadine 5 mg daily. The desloratadine AUC increased by about 20% and the maximum level by about 10%,2 but there was no change in ECG parameters including the QTc interval.2

(c) Ebastine

In a study in 12 healthy subjects cimetidine had no significant effect on the conversion of single 20-mg doses of ebastine to its active metabolite carebastine, and there was no evidence of sedation or other adverse effects. In this study cimetidine was given as 2 g in divided doses the day before the ebastine dose and 400 mg four times daily both on the day of and the day after the ebastine dose.4

(d) Fexofenadine

Cimetidine 400 mg twice daily for 6 days did not cause any changes in the plasma pharmacokinetics of a single 120-mg dose of fexofenadine in 12 healthy subjects. However, the renal clearance of fexofenadine was decreased by 39%.5

(e) Loratadine

Loratadine 10 mg and cimetidine 300 mg every 6 hours were given alone and together to 24 healthy subjects for 10 days. The AUCs of loratadine and its metabolite were increased by 103% and 6% respectively, but the safety profile of the loratadine (clinical laboratory tests, vital signs and adverse events) were unchanged. Cardiac repolarisation and all other ECG measurements were unaltered, and no sedation or syncpe were seen.6

(f) Terfenadine

Cimetidine 1.2 g daily for 5 days had no effect on the pharmacokinetics of a single 120-mg dose of terfenadine in 12 healthy subjects.7 Another study in two groups of 6 healthy subjects confirmed that cimetidine 600 mg every 12 hours or ranitidine 150 mg every 12 hours had no effect on the pharmacokinetics of terfenadine 60 mg every 12 hours. No adverse ECG changes were seen.8 However, an isolated case report describes a 63-year-old woman who had 8 episodes of syncope (later identified as being due to torsade de pointes) and a convolution 2 days after starting terfenadine 60 mg twice daily and cimetidine 400 mg twice daily. She was also taking chlorphenamine and co-proxamol (paracetamol (acetaminophen) and dextrorropoxyphene (propxyphenec)).9

B. Sedating antihistamines

(a) Chlorphenamine

A study in healthy subjects found that the pharmacokinetics of a single 4-mg dose of racemic chlorphenamine were unaffected by ranitidine 75 mg twice daily for 6 days.10

(b) Hydroxyzine

In one study, 8 patients with chronic urticaria were given hydroxyzine 25 mg before and after taking cimetidine 600 mg every 12 hours for 10 days. The cimetidine increased the AUC of hydroxyzine by 33% and also increased its suppression of the wheal and flare response (although this was not statistically significant).1 A previous study in 7 patients found that cimetidine raised serum hydroxyzine levels.11

Mechanism

Cimetidine is a non-specific cytochrome P450 isoenzyme inhibitor, but it would seem that in most cases, with the exception of loratadine, these enzyme inhibitory effects do not significantly affect the metabolism of antihistamines. More recent evidence has shown cimetidine can also affect drug transporter proteins, in particular it may inhibit organic cation transporters. However, it probably does not affect anion transporter proteins since it does not affect the plasma pharmacokinetics of fexofenadine, which is a substrate of these transporters.2

Importance and management

There would seem to be no good reason for avoiding the concurrent use of either cetirizine, ebastine, fexofenadine, hydroxyzine, or loratadine with cimetidine, or chlorphenamine with ranitidine, nor would any of the other H1-receptor antagonists be expected to interact with any of these antihistamines.

The situation with terfenadine and cimetidine is not totally clear because of the isolated case report of toxicity cited here, but currently there is not enough evidence to advise against the use of these two drugs. The manufacturer of mizolastine recommends caution with concurrent cimetidine on the basis that cimetidine might increase mizolastine levels and prolong the QT interval.12 This is a cautious approach since a link between mizolastine and cardiac arrhythmias has not been proven.

Antihistamines + Macrolides

Erythromycin causes terfenadine and astemizole to accumulate in a few individuals, which can prolong the QT interval and lead to life-threatening torsade de pointes arrhythmias. Cases of torsade de pointes have been reported for astemizole with erythromycin, and terfenadine with erythromycin or troleandomycin. Other macrolides are believed to interact similarly, with the exception of azithromycin and possibly dirithromycin.

Erythromycin modestly raises mizolastine levels, although this had no effect on the QT interval. Nevertheless, the manufacturers of mizolastine contraindicate erythromycin. Erythromycin markedly raised ebastine levels, which caused a modest prolongation of the QT interval. The manufacturers of ebastine advise against the
concurrent use of erythromycin, clarithromycin and josamycin. Because there is no information for acrivastine, the manufacturer advises caution.

There is a case of torsade de pointes possibly due to spironolactone with the sedating antihistamine mequitazine. The situation with erythromycin and loratadine is unclear as one study found that the combination caused a very slight increase in QT interval. Both azithromycin and erythromycin raise fexofenadine levels, but this had no effect on the QT interval, or on adverse events. Azelastine, cetirizine, desloratadine, and intranasal levocabastine seem to be free of clinically relevant interactions with macrolides.

**Clinical evidence**

The effect of various macrolides on the plasma levels of the non-sedating antihistamines, and their cardiac effects from controlled studies are summarised in ‘Table 15.4’, (p.591). The subsections below include data from case reports and other studies.

(a) Azithromycin. The manufacturers of azithromycin report that an in vivo study has shown that azithromycin had a negligible effect on the bioavailability of astemizole.3

(b) Erythromycin. An 87-year-old woman collapsed suddenly in her kitchen 4 days after starting to take astemizole 10 mg daily and erythromycin twice daily [dose unknown]. An ECG showed her to be having multiple episodes of torsade de pointes arrhythmias, the longest of which lasted 17 seconds. Her QTc was 720 milliseconds and she was mildly hypokalaemic. She was given a temporary pacemaker and when she was eventually dischared with a normal sinus rhythm, her QTc had fallen to 475 milliseconds.7

(c) Mequitazine

A 21-year-old woman with a congenital long QT syndrome had several syncopal attacks, one at least of which was caused by torsade de pointes. This was attributed to the concurrent use of mequitazine and spiramycin over a 2-day period. The problem resolved when the drugs were withdrawn.4

(d) Terfenadine

1. Erythromycin. A 18-year-old girl who was taking terfenadine 60 mg twice daily and erythromycin 250 mg every 6 hours, fainted while at school and, when later hospitalised, was seen to have repeated episodes of ventricular tachycardia and ventricular fibrillation requiring resuscitation. Later she was also noted to have torsade de pointes. Her QTc interval was found to be prolonged at 630 milliseconds. The drugs were withdrawn and 9 days later, after a period in intensive care, she was discharged symptom-free with a normal QTc interval.5 In contrast, a retrospective report found no documented cardiac adverse events in 92 patients who had received erythromycin and terfenadine.6

2. Troleandomycin. The manufacturers of terfenadine have on record a case of a woman, with a history of aortic valve disease, who had an episode of torsade de pointes arrhythmia while taking troleandomycin. She had taken more than the maximum recommended dose of terfenadine.7 Another woman taking terfenadine 60 mg three times daily developed torsade de pointes arrhythmia and a prolonged QTc interval when troleandomycin 500 mg three times daily was added. She recovered when both were stopped, but again developed a significantly prolonged QTc interval when both were restarted.8

**Mechanism**

Some macrolides (particularly erythromycin and clarithromycin) appear to reduce the metabolism of terfenadine and astemizole by inhibition of the cytochrome P450 isoenzyme CYP3A.9,10 High serum levels of astemizole and terfenadine cause a prolongation of the QT interval and may precipitate the development of torsade de pointes arrhythmia, see ‘Table 15.2’, (p.583). The risk of cardiac arrhythmias with other non-sedating antihistamines appears to be non-existent or very much lower (see ‘Table 15.2’, (p.583)), so any pharmacokinetic interactions do not result in clinically relevant cardiac toxicity. In fact, studies have shown that fexofenadine in overdose,11,12 and mizolastine at four times the recommended dose13 do not affect the QT interval. However, some questions remain about mizolastine and ebastine. The increased levels of fexofenadine with erythromycin may be due to increased absorption and decreased biliary secretion,12 via an effect on drug transporters.

**Importance and management**

The interactions of terfenadine with erythromycin, clarithromycin, and troleandomycin; and astemizole with erythromycin are established, clinically important and potentially hazardous. From the reports above it does seem that only a very few individuals develop a clinically important adverse interaction with these macrolides, but identifying them in advance is not often practical or possible. Because of the unpredictability and potential severity of this interaction, the FDA,6 the CSM14 in the UK and the manufacturers of terfenadine15 and astemizole1 now contraindicate macrolides in anyone taking terfenadine or astemizole. The only exception to this is azithromycin with astemizole.1 The manufacturer of terfenadine extends this contraindication to the concurrent use of topical macrolides.15 The manufacturers of mizolastine also contraindicate the concurrent use of the macrolides,16 despite any evidence of a significant interaction. Erythromycin markedly raises ebastine levels causing a modest increase in QT interval. The manufacturer of ebastine advises against concurrent use of the macrolides erythromycin, clarithromycin and josamycin.17 Erythromycin also raises loratadine levels, which caused a very slight increase in QTc interval in one study. However, no special precautions appear to have been recommended for the use of loratadine with macrolides. Because there are no data on acrivastine with erythromycin, the manufacturer advises caution.18

Fexofenadine levels are raised by both azithromycin and erythromycin but because this does not result in adverse cardiac effects concurrent use is considered safe. Azelastine, cetirizine (and therefore probably its isomer levocetirizine) desloratadine and levocabastine seem to be free from clinically significant pharmacokinetic interactions, and have no cardiac effects, and so may therefore provide suitable alternatives if a non-sedating antihistamine is needed in a patient taking macrolides.

The isolated case of mequitazine is unlikely to be of general importance, since this sedating antihistamine is not usually associated with causing ventricular arrhythmias.

### Antihistamines + Nefazodone

Nefazodone inhibits the metabolism of terfenadine and thereby prolongs the QT interval. This combination should be avoided. There is also some evidence that the combination of nefazodone and loratadine increases the QT interval, although to a lesser extent than terfenadine. In vitro evidence suggests nefazodone will also inhibit the metabolism of astemizole.

#### Clinical evidence, mechanism, importance and management

(a) Astemizole

The manufacturers of nefazodone and astemizole say that an in vitro study suggests that nefazodone may increase astemizole levels, and so concurrent use is contraindicated. The advice to avoid the combination would seem prudent since raised levels of astemizole with other inhibitors of CYP3A4 such as the ‘macrolides’, (p.589), have been rarely associated with life-threatening torsade de pointes arrhythmias.

(b) Loratadine

A randomised, placebo-controlled study in healthy subjects found that when they were given nefazodone 300 mg twice daily with loratadine 20 mg once daily, the loratadine AUC was increased by 39%. Similarly, the QTc interval was increased by 21.6 milliseconds by the combination, which was about half the increase seen with terfenadine 60 mg twice daily given with the same dose of nefazodone. Neither nefazodone, loratadine nor terfenadine alone prolonged the QTc interval. The findings for loratadine in this study were unexpected, since this antihistamine was considered to have no clinically relevant effect on the QT interval (but see also ‘Table 15.2’, (p.583)). The use of the Bazett formula to calculate QTc has
been questioned, but this is the most commonly used formula, and any overestimation would also apply to terfenadine. This appears to be the only study to have directly compared loratadine with terfenadine, and although it shows that loratadine at twice the recommended dose has half the QT-prolonging effect of terfenadine (at the maximum recommended dose), it nevertheless raises questions about the cardiac safety of loratadine. Further study is needed.

(c) Terfenadine

In a randomised, placebo-controlled study, healthy subjects were given nefazodone 300 mg twice daily and terfenadine 60 mg twice daily, given alone and in combination. Nefazodone increased the AUC of terfenadine by about fivefold, which was associated with a mean increase in the QTc interval of 42.4 milliseconds. This was considered to result in a clinically significant, increase in the risk of torsade de points arrhythmias. Studies using human liver microsomes found that nefazodone is a moderately weak inhibitor of the CYP3A4-mediated N-dealkylation and C-hydroxylation of terfenadine. Nefazodone is contraindicated with terfenadine, and it has been suggested that this explains the lack of clinical reports.

3. Abernethy DR, Barbey JT, Franc J, Brown KS, Feirrera I, Ford N, Salazar DE. Loratadine and nefazodone 300 mg twice daily and terfenadine 60 mg twice daily, given together was additive, and no pharmacokinetic interaction was found. 6

Antihistamines + Protease inhibitors

Nelfinavir markedly increases terfenadine levels, which is expected to increase the risk of QT prolongation and torsade de points arrhythmias. Other protease inhibitors are predicted to interact similarly with both terfenadine and astemizole, and concurrent use is contraindicated. Ritonavir modestly increases cetirizine levels, and in vitro data suggests that saquinavir will have a similar effect, but this is not considered to be clinically relevant. Based on in vitro data, ritonavir is predicted to markedly raise fexofenadine levels, but this may not be of any clinical relevance.

Clinical evidence, mechanism, importance and management

(a) Astemizole

Protease inhibitors are inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which astemizole is metabolised. On the basis of the interaction of astemizole with other CYP3A4 inhibitors, such as the ‘azoles’, the concurrent use of astemizole with any protease inhibitor is contraindicated. This seems a sensible precaution.

(b) Cetirizine

In a study in 16 healthy subjects the concurrent use of cetirizine 10 mg daily and ritonavir 600 mg twice daily for 4 days (following steady-state ritonavir levels), increased the AUC of cetirizine by 42% with a slight 9% increase in maximum plasma levels. It was suggested that ritonavir may have decreased the renal excretion of cetirizine. The increase in cetirizine levels was not considered to be clinically relevant. Ritonavir pharmacokinetics were minimally affected by cetirizine.

(c) Fexofenadine

An in vitro study showed that ritonavir markedly reduced the transport of fexofenadine, thought to be via inhibition of P-glycoprotein. This would be predicted to markedly increase the bioavailability of fexofenadine, as occurs with verapamil, see ‘Calcium-channel blockers + Antihistamines’, p.861. However, the similar marked increases in fexofenadine levels that occurred with ‘erythromycin’, (p.589) and ‘ketonozolae’, (p.584) did not increase adverse effects and were not associated with any prolongation of the QT interval. This suggests that a clinically relevant interaction between ritonavir and fexofenadine is not expected.

(d) Terfenadine

Nelfinavir 750 mg every 8 hours for 5 days raised the levels of a single 60-mg dose of terfenadine from less than 5 nanograms/mL to a range of 5 to 15 nanograms/mL. The pharmacokinetics of nelfinavir were unaffected. This rise in terfenadine levels is predicted to prolong the QT interval, and to increase the risk of torsade de points arrhythmias. In an in vitro study, saquinavir was a potent inhibitor of the metabolism of terfenadine. Note that saquinavir is the least potent CYP3A4 inhibitor of the protease inhibitors. On the basis of in vitro studies and what is known about interactions with other inhibitors of CYP3A4 such as the ‘azoles’, (p.584), all protease inhibitors are predicted to raise terfenadine levels and consequently concurrent use is contraindicated. Because of the seriousness of this reaction, and the fact that it is not possible to predict which individuals will be affected, this seems a sensible precaution.

Antihistamines + Quinolones

Studies in healthy subjects showed that there was a small additive effect on the QT interval when terfenadine was given with sparfloxacin.

Clinical evidence, mechanism, importance and management

In a single-dose, placebo-controlled study in 8 healthy subjects, sparfloxacin 400 mg increased the QT interval by 14 milliseconds, terfenadine 60 mg increased the QT interval by 7.5 milliseconds (not statistically significant), and the combination caused an additive increase of 24.7 milliseconds.

The effects of the combination in this study were shown to be purely additive.

In a placebo-controlled study 22 patients were given sparfloxacin 400 mg on day 1 and 200 mg on days 2 to 4 with terfenadine 60 mg twice a day for 7 doses. The increase in the QT interval when the two drugs were given together was additive, and no pharmacokinetic interaction was found.

Since the effects of therapeutic doses of terfenadine on the QT interval are minimal, any additional effect with sparfloxacin would be small. Nevertheless, since torsade de points can cause sudden death, the combination of two drugs with the potential to prolong the QT interval is generally considered contraindicated (see ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257) and the manufacturer of terfenadine specifically contraindicates sparfloxacin.

If an antihistamine is required in a patient taking sparfloxacin, one that has no effect on the QT interval should be used, for example, cetirizine, see ‘Table 15.2’, (p.583). Other quinolones that cause QT prolongation include gatifloxacin and moxifloxacin, see ‘Table 9.2’, (p.257), and it would also be prudent to avoid use of antihistamines that prolong the QT interval (e.g. astemizole and terfenadine) with these quinolones.

Antihistamines + SSRIs

Two isolated reports describe cardiotoxicity, which was attributed to the concurrent use of terfenadine and fluoxetine, although other evidence suggests that an interaction is unlikely. Terfenadine does not appear to interact with paroxetine or sertraline. Nonetheless, the manufacturers of both astemizole and terfenadine contraindicate the concurrent use of SSRIs. There does not
appear to be a significant interaction between desloratadine and fluoxetine. An interaction between fluoxetine and loratadine is theoretically possible, but the clinical significance of this is unclear.

Clinical evidence

A. Astemizole

The manufacturer of astemizole contraindicates the concurrent use of SSRIs because there is a risk that they will inhibit astemizole metabolism, leading to a rise in its serum levels, which could result in QT interval prolongation and the development of torsade de pointes arrhythmias.1

B. Desloratadine

The concurrent use of desloratadine 5 mg daily and fluoxetine 20 mg daily for 7 days (after attainment of fluoxetine steady-state) had no clinically relevant effects on the pharmacokinetics of desloratadine or fluoxetine (changes in maximum levels and AUC were less than 15%). There was no change in ECG parameters including the QTc interval, and the combination did not increase the incidence of adverse effects.2 This study was placebo-controlled and in healthy subjects who were of extensive metaboliser phenotype for CYP2D6.

C. Loratadine

Fluoxetine is an inhibitor of the cytochrome P450 isozymes CYP3A4 (weak inhibitor) and CYP2D6 (moderate inhibitor), by which loratadine is metabolised. Fluoxetine may therefore moderately raise loratadine levels. One study suggests that high-dose loratadine does not cause adverse cardiac adverse effects.3 However, more recent case reports and studies have cast some doubt over the cardiac safety of loratadine (see ‘Table 15.2’, (p.583)).

D. Terfenadine

(a) Fluoxetine

A 41-year-old man with no previous history of heart disease awoke one night short of breath, with a sensation of his heart missing beats and beating irregularly. He also experienced orthostatic hypotension on a number of occasions. However, a later ECG showed a normal sinus rhythm. He was taking daily doses of terfenadine 120 mg, fluoxetine 20 mg (started a month previously), ibuprofen 2.4 g, misoprostol 400 micrograms, Midrin (paracetamol (acetaminophen), dichloralphenazone, isomeethene mutate) and ramitidine 300 mg. This reaction was attributed to an interaction between fluoxetine and terfenadine. However, a few days after stopping the terfenadine, and 12 days after this episode, his cardiac rhythm as recorded by a 24-hour Holter monitor showed some minor abnormalities (intermittent sinus tachycardia, isolated premature beats), although nothing approaching the previous alarming episode.4 A woman taking several drugs (topical aciclovir, beclometasone, pseudoephedrine, ibuprofen) had a prolonged QTc interval of 550 milliseconds two weeks after starting terfenadine and fluoxetine, but she remained asymptomatic. Within a week of stopping the terfenadine her QTc interval had returned to normal.5

In contrast, 12 healthy subjects who were given a single 60-mg dose of terfenadine before and after taking fluoxetine 60 mg daily for 8 days showed no significant changes in the pharmacokinetics of terfenadine or its acid metabolite.6 Other in vitro studies with human liver microsomal enzymes confirmed that fluoxetine has only a very slight inhibitory effect on the metabolism of terfenadine, which was considered to be clinically irrelevant.7

(b) Paroxetine

A two-period crossover study in 11 healthy subjects given terfenadine 60 mg twice daily found that paroxetine 20 mg daily for 8 days had no effect on the AUC of terfenadine or the QTc interval. A small, clinically unimportant reduction in the levels of carboxyterfenadine was seen. It was concluded that there is no clinically relevant interaction between terfenadine and paroxetine.8 In vitro studies with human liver microsomal enzymes confirmed that paroxetine has only a very slight inhibitory effect on the metabolism of terfenadine, which is not considered to be clinically significant.9

(c) Sertraline

Although the CSM in the UK initially stated that terfenadine should not be used with sertraline, they subsequently reviewed the data and now consider that an interaction is unlikely.8

Mechanism

Not understood. An in vitro model study using human liver microsomal enzymes, which accurately predicted a large and potentially hazardous interaction between terfenadine and ketoconazole or itraconazole (now clinically proven—see ‘Antihistamines + Azoles’, (p.584), found that six SSRIs (desmethylsertraline, fluoxetine, fluvoxamine, norfluoxetine, paroxetine, sertraline) at usual clinical doses were at least 20 times less potent than ketoconazole at inhibiting terfenadine metabolism.1 This suggests that all of these SSRIs are very unlikely to interact with terfenadine clinically, although the authors of the study warn that if high doses of SSRIs are used (particularly fluoxetine) some caution is appropriate.2 Astemizole is metabolised in part by the cytochrome P450 isoenzyme CYP2D6, which is inhibited to a variable extent by the SSRIs, and therefore interactions involving this isoenzyme are possible.

Importance and management

The interaction between the SSRIs and terfenadine is not adequately established, and there is little evidence regarding interactions between the SSRIs and astemizole, although it is possible that the contraindication with astemizole has contributed to minimal usage of the combination and therefore a lack of reported interactions. In addition to fluoxetine and paroxetine, the manufacturers of terfenadine list fluvoxamine and citalopram as drugs that are expected to increase terfenadine serum levels,10 but direct evidence of this seems to be lacking. Nonetheless, the manufacturer contraindicates the use of all these SSRIs with terfenadine.11 Due to the severity of the potential interaction, it would appear prudent to use caution if terfenadine is used with any SSRI (excepting perhaps sertraline), and consider an alternative antihistamine without cardiac effects (see ‘Table 15.2’, (p.583)), wherever possible. Desloratadine appears to be a non-interacting alternative.

The situation with loratadine is unclear, and currently all the evidence is theoretical.

Antihistamines + Terbinafine

Terbinafine does not interact with astemizole or terfenadine to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a large scale post-marketing survey of 25,884 patients taking terbinafine, over 40% were taking at least one other drug. From amongst this group, an unknown number of patients were taking astemizole or terfenadine. No adverse interactions were reported.1 A cross-over study in 26 healthy subjects given terbinafine 250 mg daily or placebo with terfenadine 60 mg twice daily for 7 days found that terbinafine reduced the trough levels of terfenadine acid metabolite by about 20% on the last day of concurrent use. Other terfenadine acid metabolite pharmacokinetic parameters were not affected. The AUC, and peak and trough plasma levels of terbinafine were increased by about 16%, 6.6%, and 22%, respectively, after 7 days of concurrent use. Although the incidence of ECG abnormalities was not significantly higher in any group, a 10% prolongation of the QT interval was found in those receiving terfenadine either alone or with
terbinafine. Concurrent use was well-tolerated and it was concluded that terbinafine could safely be given with terfenadine. 2

Antihistamines: Ocular + Miscellaneous

No specific interaction studies have been performed with eye-drop formulations of the antihistamines azelastine, emedastine, epinastine, or olopatadine. However, interactions are not anticipated since very little drug is expected to reach the systemic circulation.

Clinical evidence, mechanism, importance and management

The UK manufacturer of azelastine eye drops notes that interaction studies with high oral doses of azelastine bear no relevance to the eye drops, as systemic levels are only in the picogram range after administration of eye drops. 1 Similarly, the manufacturer of epinastine eye drops notes that no drug interactions are anticipated since systemic epinastine levels are extremely low after ocular use. They note that epinastine is also excreted mostly unchanged. 2 The manufacturer of olopatadine eye drops notes that in vitro studies showed that it was not an inhibitor of the common cytochrome P450 isoenzymes. 3 No drug interactions would be anticipated between these, or any other, antihistamine eye drops and systemically administered drugs.

The manufacturer of emedastine eye drops notes that an interval of 10 minutes should be allowed after the administration of the eye drops and other ophthalmically administered medicines, which is good practice for any ocular drugs.

Astellizole + Quinine

Quinine causes a marked but transient increase in plasma astemizole levels, and to avoid the possible risk of cardiac arrhythmias the manufacturers contraindicate this combination. Three case reports confirm that this is a clinically important interaction.

Clinical evidence

Astellizole 30 mg daily for 4 days followed by 10 mg daily for the next 20 days, was given to 12 healthy subjects. The steady-state pharmacokinetics of the astemizole were then examined after the subjects took quinine 20 mg every 4 hours for 12 hours (a total of 80 mg quinine), and after a single 430-mg dose of quinine. The smaller dose of quinine caused only a slight increase in the maximum plasma astemizole levels and AUC, but the larger single dose of quinine resulted in a transient threefold increase in both maximum plasma levels and AUC, especially of desmethylastemizole, the metabolite of astemizole. 1

A patient who had been taking astemizole 10 mg daily for 10 months with fluoxetine, alprazolam, isradipine, and diuretics with potassium had a syncopal episode one hour after taking the first dose of quinine sulphate 260 mg for leg cramp. The ECG showed recurrent episodes of torsade de pointes with a QT interval of greater than 680 milliseconds. The only electrolyte abnormality was slight hypomagnesaemia. Intravenous magnesium was given and the patient’s QT interval shortened to 420 milliseconds over 3 days. 2 The manufacturers have on record two other case reports 3 of cardiac arrhythmias possibly attributable to an interaction between astemizole and quinine.

Mechanism

Uncertain. One suggestion is that the interaction is not primarily due to inhibition of the metabolism of astemizole by the quinine, but rather to a transient quinine-induced displacement of both astemizole and its metabolite from its tissue binding sites. 4 Note that the desmethyl metabolite of astemizole causes QTc prolongation.

Importance and management

Information is very limited, but on the basis of the evidence cited above the manufacturers of astemizole contraindicate the concurrent use of quinine in order to avoid the risk of cardiac arrhythmias. 4 The case report that is cited here confirms that this is a potentially clinically hazardous drug combination. 2

The larger single dose of 430 mg of quinine used in the study approached the dosage used for the treatment of malaria, whereas the smaller dose of 80 mg was equivalent to the amount contained in 2 litres of a quinine-containing soft drink. 1 There would therefore appear to be no reason for those on astemizole to avoid moderate quantities of these quinine-containing drinks. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Cinnarizine + Phenylpropanolamine

Phenylpropanolamine 50 mg counteracted the mild sedation caused by cinnarizine 25 or 50 mg, and improved the performance of some skills related to driving in 12 healthy subjects. 1

Fexofenadine + Antacids or Omeprazole

An aluminium/magnesium hydroxide-containing antacid modestly reduced fexofenadine levels, and it is recommended that dosing should be separated by 2 hours. Omeprazole does not appear to interact with fexofenadine.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturer notes that when a single 120-mg dose of fexofenadine was given within 15 minutes of an aluminium/magnesium hydroxide antacid (Maalox), the fexofenadine AUC was decreased by 41% and the maximum level was decreased by 43%. Although the effect of these reductions on possible efficacy has not been assessed, the manufacturer recommends that it is advisable to leave 2 hours between the administration of fexofenadine and antacids containing aluminium and magnesium hydroxide. 2

(b) Omeprazole

The manufacturer notes that no interaction has been seen between fexofenadine and omeprazole. 2

Fexofenadine + Rifampicin (Rifampin)

Rifampicin increases the oral clearance of fexofenadine, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A single 60-mg dose of fexofenadine was given to 24 healthy subjects 2 days before and on the last day of a 6-day course of rifampicin 600 mg daily. The oral clearance of fexofenadine was increased 1.3– to 5.3-fold, with no effect on renal clearance or half-life. This was thought to be due to the effect of rifampicin on P-glycoprotein, which is involved in the up-
take of fexofenadine.1 The clinical significance of this interaction is un- clear, but until more is known it would seem prudent to monitor the efficacy of fexofenadine if it is given in combination with rifampicin.

Fexofenadine + St John’s wort (Hypericum perforatum)

Pretreatment with St John’s wort (Hypericum perforatum) had no clinically relevant effect on the plasma levels of single-dose fexofenadine in one study, but markedly reduced them in another.

Clinical evidence, mechanism, importance and management

A single 900-mg dose of St John’s wort (Hypericum perforatum) increased the maximum plasma level of a single 60-mg dose of fexofenadine by 45% and increased the AUC by 31% in 12 healthy subjects.2 Conversely, St John’s wort 300 mg three times daily for 14 days caused a slight 5 to 10% decrease in the maximum level and AUC of a single dose of fexofenadine 60 mg in the same subjects.1 In contrast, in another study, 12 days of pretreatment with St John’s wort increased the oral clearance of a single dose of fexofenadine by about 1.6-fold in healthy subjects.2 In both these studies St John’s wort was thought to be interacting via its effects on P-glycoprotein.

The findings from these two studies for multiple dose St John’s wort suggest that either no clinically relevant decrease in fexofenadine levels occurs, or that a decrease occurs that is possibly clinically important. Further study is needed. If fexofenadine becomes less effective in a patient taking regular St John’s wort, consider the St John’s wort as a possible cause.

Terfenadine + Atorvastatin

Atorvastatin does not appear to alter the pharmacokinetics of terfenadine.

Clinical evidence, mechanism, importance and management

A group of healthy subjects were given a single 120-mg dose of terfenadine on day 8 of a 10-day course of atorvastatin 80 mg daily. It was found that the atorvastatin caused some small to moderate changes in the pharmacokinetics of the terfenadine and its metabolite fexofenadine (AUC increased by 35% and decreased by 2% respectively, maximum serum levels decreased by 8% and decreased by 16% respectively), none of which reached statistical significance. More importantly there were no changes in the QTc interval, which indicates that atorvastatin does not increase the cardiotoxicity of the terfenadine.1 There would therefore appear to be no reason for avoiding concurrent use.

Terfenadine + Zileuton

In one study zileuton modestly increased terfenadine levels, without altering the QTc interval. Nevertheless, the combination is contraindicated.

Clinical evidence, mechanism, importance and management

Terfenadine 60 mg every 12 hours for 7 days was given to 15 healthy subjects with either zileuton 600 mg every 6 hours or a placebo. The mean AUC0-8h and the maximum plasma concentrations of terfenadine increased by 35% in the presence of zileuton, but the levels were still very low (less than 5 nanograms/mL). The maximum plasma concentration and AUC of carboxyterfenadine (a terfenadine metabolite) were increased by about 15% by zileuton. ECG measurements showed that the addition of zileuton did not increase the QTc interval nor cause any other significant changes.1 The authors concluded that the interaction was unlikely to be of clinical significance. However, the manufacturers of terfenadine currently contraindicate zileuton, on the basis that any drug that inhibits terfenadine metabolism may result in accumulation of terfenadine and prolongation of the QT interval with the risk of life-threatening arrhythmias.2 Because of the unpredictability of these interactions, this seems a sensible precaution.

Terfenadine + Paracetamol (Acetaminophen)

An isolated report describes the development of torsade de pointes arrhythmia in an elderly man on very large doses of paracetamol (acetaminophen) and amitriptyline when he began to take terfenadine.

Clinical evidence, mechanism, importance and management

An 86-year-old man taking amitriptyline 25 mg at night, prednisone 3 mg daily and excessive amounts of paracetamol (up to 1 g every 2 hours over a 6-month period) developed breathlessness and bradycardia shortly after starting to take terfenadine 60 mg twice daily. In hospital he became unconscious and was initially pulseless but recovered spontaneously. An ECG showed that he had AV block and a prolonged QT interval, which resulted in runs of self-limiting torsade de pointes arrhythmia.1 The reasons for this reaction are not known, but a suggested explanation is that overdosage with paracetamol produced large amounts of a metabolite (N-acetyl-p- benzoquinoneimine). This metabolite could have inhibited the metabolism of the terfenadine by the cytochrome P450 isoenzyme CYP3A4, thereby resulting in terfenadine accumulation and the development of its cardiotoxic effects.1 The amitriptyline may additionally have had some part to play because it can also (although rarely) cause torsade de pointes.

This is an isolated case and unlikely to be of general importance. There would seem to be little reason on the basis of this report for patients on terfenadine to avoid normal therapeutic doses of paracetamol (acetaminophen). There appear to be no other reports of this interaction.

Terfenadine + Venlafaxine

Venlafaxine does not appear to significantly alter the pharmacokinetics of terfenadine.

Clinical evidence, mechanism, importance and management

A study in 24 subjects given a single 120-mg oral dose of terfenadine before and after taking venlafaxine 75 mg every 12 hours for 9 days found that the pharmacokinetic profile of terfenadine was unchanged, although its acid metabolite concentrations were slightly decreased by about 25%.1 This study was undertaken to confirm that venlafaxine lacks inhibitory activity on the cytochrome P450 isoenzyme CYP3A4, but at the same time it also indicates that venlafaxine does not raise the serum levels of terfenadine, which are associated with serious cardiotoxicity. There would therefore seem to be no reason for avoiding concurrent use.

The drugs dealt with in this section are the ergot derivatives and the triptans (or more properly the serotonin 5-HT₁ agonists), whose main use is in the treatment of migraine. ‘Table 16.1’, (below) lists some of the drugs commonly used in migraine. Drugs such as propranolol, which are more commonly used in other conditions, are discussed elsewhere in the publication.

(a) Ergot derivatives

The main problem with the use of the ergot derivatives is that of ergotism. Drug interactions may result in additive effects or cause raised levels of ergot derivatives, which may result in the symptoms of ergot poisoning. This may include severe circulatory problems e.g. the extremities may become numb, cold to the touch, tingle, and muscle pain may result. In extreme cases there may be no palpable pulse. Ultimately gangrene may develop, and amputation may be required. Chest pain can also occur, and in some cases myocardial infarction has been reported. Since ergotamine and dihydroergotamine are metabolised in the liver by CYP3A4, drugs which inhibit this isoenzyme, particularly potent inhibitors, such as the ‘protease inhibitors’, (p.600), should generally be avoided due to the risk of precipitating ergotism.

(b) Triptans

Although the triptans would be expected to share a number of pharmacodynamic drug interactions, due to their differing metabolic pathways they will not all necessarily share the same pharmacokinetic interactions. For example, sumatriptan, which is metabolised mainly by monoamine oxidase A, is unlikely to interact with macrolide antibacterials, which are inhibitors of the cytochrome P450 isoenzyme CYP3A4. However, eletriptan, which is metabolised by CYP3A4 and possibly CYP2D6 could potentially interact (see ‘Triptans + Macrolides’, p.604, for full details). Frovatriptan and zolmitriptan are substrates for CYP1A2, and are affected by CYP1A2 inhibitors such as fluvoxamine, but zolmitriptan also inhibits CYP1A2 and may therefore be expected to have additional interactions. The picture with zolmitriptan becomes more complicated since it is also metabolised by monoamine oxidase A. Naratriptan appears unlikely to undergo significant pharmacokinetic interactions since half the dose is excreted unchanged and the rest metabolised by a variety of isoenzymes. A summary of the metabolic pathways of the triptans can be found in ‘Table 16.2’, (below).

Early in the development of triptans it was theorised that they might possibly add to the increased levels of serotonin caused by other serotonergic drugs, leading to excess serotonergic activity and increasing the risk of ‘the serotonin syndrome’, (p.9). Therefore sumatriptan was contraindicated in patients taking SSRIs, MAOIs, and lithium, but note, there is little evidence that this occurs in practice. However, there is also a pharmacokinetic interaction between some triptans and ‘MAOIs’, see (p.604) or ‘SSRIs’, (p.605).

| **Table 16.1** Antimigraine drugs |
|---|---|
| **Group** | **Drugs** |
| Antihistamines | Flunarizine, Pizotifen |
| Beta blockers | Atenolol, Metoprolol, Nadolol, Propranolol, Timolol |
| Ergot derivatives | Codergocrine, Ergotamine, Dihydroergotamine, Methysergide |
| Triptans (Serotonin (5-HT₁) agonists) | Almotriptan, Eletriptan, Frovatriptan, Naratriptan, Rizatriptan, Sumatriptan, Zolmitriptan |

| **Table 16.2** Interactions between drug metabolising enzymes and the triptans‡ |

‡ Other isoenzymes have been implicated, but not at clinically relevant concentrations of the triptans
**Ergot derivatives + Antidepressants**

One isolated report describes three cases in which patients developed symptoms indicative of the serotonin syndrome when they took amitriptyline, paroxetine/imipramine, or sertraline with dihydroergotamine.

**Clinical evidence**

A woman taking imipramine, paroxetine and lithium, who had a 3-week continuous headache, was treated with 300 micrograms of dihydroergotamine intravenously. Within 5 minutes of a subsequent 500-microgram dose she developed dysarthria, dilated pupils, diaphoresis, diffuse weakness, and barely responded to commands. She was diffusely hyperreflexic and showed occasional myoclonic jerks. She recovered after 90 minutes.

A woman with a history of migraine headaches responded well to amitriptyline, metoclopramide, and dihydroergotamine. Six weeks after the amitriptyline was replaced by sertraline, she was again successfully treated for acute migraine with 10 mg of intravenous metoclopramide and 1 mg of intravenous dihydroergotamine. However, 2 hours later she developed nausea, emesis, agitation, weakness, diaphoresis, salivation, chills, and fever. All of the symptoms subsided after 24 hours.

A woman with a history of migraines (treated prophylactically with amitriptyline and propranolol) was admitted to hospital in status migrainosus. She was given 1 mg of dihydroergotamine, 10 mg of prochlorperazine and 10 mg of metoclopramide (all intravenously). Within 20 minutes she became diaphoretic, tachycardic, diffusely hyperreflexic, agitated, confused, and briefly lost consciousness twice. Diazepam 8 mg given intramuscularly calmed her agitation, and all the symptoms resolved after 6 hours. A year later she was given 6 mg of subcutaneous sumatriptan while taking nortriptyline daily with no ill effects.

**Mechanism**

Not understood. All of these patients appeared to have developed symptoms similar to those of the serotonin syndrome, which is thought to be due to hyperstimulation of 5-HT receptors in the brain. Dihydroergotamine is a 5-HT agonist while paroxetine and sertraline are both serotonin (5-HT) reuptake inhibitors, all of which might be expected to increase 5-HT concentrations in the CNS, and thereby increase receptor stimulation.

**Importance and management**

These appear to be isolated cases and not of general importance, nevertheless they illustrate the potential for the development of the serotonin syndrome in patients given multidrug regimens that affect 5-HT receptors. The syndrome is rare and it may (so it has been suggested) sometimes be of an idiiosyncratic reaction.

**Ergot derivatives + CYP3A4 inhibitors**

The azole antifungals are predicted to raise the levels of ergot derivatives, which may lead to ergotism. Concurrent use is contraindicated. Methysergide is also contraindicated with cimetidine and NNRTIs such as delavirdine. Caution is also advised with other CYP3A4 inhibitors, including grapefruit juice and quinupristin/dalfopristin.

**Clinical evidence, mechanism, importance and management**

The azole antifungals are mainly metabolised by the cytochrome P450 isoenzyme CYP3A4. The manufacturers of ergotamine dihydroergotamine and methysergide therefore logically predict that their levels will be raised by CYP3A4 inhibitors and advise against their concurrent use. They specifically contraindicate ‘macrolides’, (p.599), and ‘protease inhibitors’, (p.600), which are potent CYP3A4 inhibitors and which have been shown to interact with these ergot derivatives in a number of cases. They also contraindicate the azole antifungals and the NNRTIs (delavirdine, efavirenz). Although there appear to be no studies or case reports, given the way other potent CYP3A4 inhibitors interact, this seems prudent. Note that, of the azoles, ketoconazole, itraconazole are the most potent CYP3A4 inhibitors, and would therefore be expected to interact to the greatest extent. The US manufacturers of ergotamine and dihydroergotamine specifically contraindicate these azoles, but advise caution with fluconazole and clotrimazole, which are less potent CYP3A4 inhibitors. The manufacturers of ergotamine also advise caution with the use of less potent CYP3A4 inhibitors including grapefruit juice, quinupristin/dalfopristin and cimetidine. The manufacturers of dihydroergotamine and methysergide give a similar list.

Given the rarity of cases of an adverse effect with the potent CYP3A4 inhibitors any clinically significant interaction with these drugs would be expected to be extremely rare indeed, but concurrent use should be well monitored so any adverse effect can be identified swiftly and appropriate treatment given.

**Ergot derivatives + Glycerol trinitrate (Nitroglycerin)**

The ergot derivatives such as dihydroergotamine would be expected to oppose the anti-anginal effects of glycerol trinitrate. Nevertheless, an animal study has not borne out this expectation.

**Clinical evidence, mechanism, importance and management**

There seem to be no clinical reports of adverse interactions between the ergot derivatives and glycerol trinitrate, but since ergot causes vasoconstriction and can provoke angina it would be expected to oppose the effects of glycerol trinitrate when used as a vasodilator for the treatment of angina. Nevertheless, a study in animals suggests that dihydroergotamine will not worsen exercise-induced angina pectoris, and that the antianginal efficacy of glycerol trinitrate will not be neutralised by pretreatment with dihydroergotamine.

However, glycerol trinitrate has also been shown to increase the bioavailability of dihydroergotamine (by up to 370% in one case) in subjects with orthostatic hypotension, which would increase its vasoconstrictor effects. The clinical outcome of concurrent use is therefore uncertain. Note that ergot derivatives are generally regarded as contraindicated in those with ischaemic heart disease.

**Ergot derivatives + Heparin**

The use of dihydroergotamine with heparin has resulted in ergotism. In some cases, amputation of the affected limb was necessary. The rate of absorption and peak levels of subcutaneous dihydroergotamine are reduced by heparin.

**Clinical evidence, mechanism, importance and management**

There have been several reports of ergotism following the combined use of dihydroergotamine and heparin for thromboembolic prophylaxis. In a retrospective review of 61 092 Austrian patients attending trauma units who received dihydroergotamine and heparin prophylaxis, complications attributable to ergotism were seen in 142 patients. In 7 patients amputation was necessary and in a further 7 cases immediate opening of the vessel and catheter dilatation was successful. Other published reports support this interaction, including a report of two patients who experienced fatal myocardial infarctions, attributed to coronary artery spasm as a complication of prophylaxis with dihydroergotamine and heparin.

It has been found that the use of heparin results in a 25% increase in the AUC of subcutaneously administered dihydroergotamine. Giving the
two drugs at the same site reduced the rate of dihydroergotamine absorption by 63%, the time to peak levels by 110%, and the peak levels by 15%.

**Dihydroergotamine** had no effect on the pharmacokinetics of heparin.2

Because of the risk of peripheral ischaemia, the combination of dihydroergotamine and heparin is no longer widely used for thrombembolic prophylaxis. If the combination is used, the patient must be closely observed for any sign of vascular spasm.

### Ergot derivatives + Macrolides

**Ergot toxicity can develop rapidly in patients taking ergotamine or dihydroergotamine if they are given erythromycin or troleandomycin. Three possible cases of toxicity have occurred with clarithromycin, and one case has been reported with each of josamycin and oleandomycin.** Toxicity is predicted to occur with midecamycin. No cases of toxicity appear to have been described with spiramycin, and none would be expected. There is no direct information about azithromycin but it would not be expected to interact.

**Clinical evidence**

**a) Clarithromycin**

A 59-year-old woman took ergotamine tartrate 2 mg for a typical migraine headache. After 2 hours her tongue became swollen, painful and bluish in colour. She showed some hypertension (BP 200/110 mmHg) and her fingers and toes were cold and cyanotic (blue). She had taken this dose of ergotamine many times previously without problems, but on this occasion she had been taking clarithromycin 500 mg twice daily for the last 5 days. This adverse reaction was diagnosed as ergotism. Other evidence suggests that this patient may possibly have been unusually sensitive to vascular occlusion.1 The authors of this report briefly quote another case, originating from the manufacturers of clarithromycin, of a possible interaction with dihydroergotamine, although this was complicated by the concurrent use of other medications (not named) used in the management of AIDS.1 A woman who had previously uneventfully taken Cafergot (ergotamine tartrate 1 mg, caffeine 100 mg) for migraine developed ergotism (leg pain, cold and cyanosed limbs, and impalpable pulses) within 3 days of starting to take clarithromycin (dosage not stated). The authors postulated that smoking and the use of oxymetazoline (both of which have vasoconstrictor effects) may also have had some part to play.2

**b) Erythromycin**

A woman who had regularly and uneventfully taken Migral (ergotamine tartrate 2 mg, cyclizine hydrochloride 50 mg, caffeine 100 mg) on a number of previous occasions, took one tablet during a course of treatment with erythromycin 250 mg every 6 hours. Within 2 days she developed severe ischaemic pain in her arms and legs during exercise, with a burning sensation in her feet and hands. When admitted to hospital 10 days later, her extremities were cool and cyanosed. Her pulse could not be detected in the lower limbs.3

Eight other cases of acute ergotism have been reported4–11 in which patients were taking ergotamine tartrate or dihydroergotamine and erythromycin. The reaction has been reported to develop within a few hours,7 but it may take several days to occur.10 One case appeared to occur when the erythromycin was started 3 days after the last dose of dihydroergotamine.5

**c) Josamycin**

An isolated report describes a 33-year-old woman who developed severe ischaemia of the legs within 3 days of starting to take josamycin 2 g daily and ergotamine tartrate 300 micrograms. Her legs and feet were cold, white and painful, and most of her peripheral pulses were impalpable.12

**d) Midecamycin diacetate (Mocamycin)**

After 12 healthy subjects took midecamycin diacetate 800 mg twice daily for 8 days, the peak concentrations of a single 9-mg dose of dihydroergotamine were raised 3 to 40-fold.13

**e) Oleandomycin**

A case of ergotism has been reported in a 45-year-old woman who had been taking ergotamine 4 mg daily for 5 years and recently also oleandomycin.14

**f) Troleandomycin**

A 40-year-old woman who had been taking dihydroergotamine, 90 days daily, for 3 years without problems, developed cramp in her legs within a few hours of starting to take troleandomycin 250 mg four times a day. Five days later she was admitted to hospital as an emergency, with severe ischaemia of her arms and legs. Her limbs were cold and all her peripheral pulses were impalpable.15

There are reports of several other patients who had taken normal doses of ergotamine tartrate or dihydroergotamine for months or years without problems, who then developed severe ergotism within hours or days of starting to take normal doses of troleandomycin.10–23 This resulted in a myocardial infarction in one patient.14

**Mechanism**

Erythromycin and troleandomycin are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of ergot derivatives.16 Clarithromycin and oleandomycin are also known to inhibit CYP3A4. As a result the ergot is poorly metabolised and accumulates in the body. This leads to increased vasoconstriction and ultimately ischaemia. Spiramycin, and josamycin normally do not inhibit CYP3A4 and are therefore not expected to interact,2 although a case has been reported.17

**Importance and management**

The interactions of ergot derivatives with erythromycin and troleandomycin are well documented, well established, and clinically important, whereas information about clarithromycin appears to be confined to three postmarketing reports and that relating to oleandomycin to one case. There are no adverse reports about midecamycin, but it is expected to interact similarly. The concurrent use of all of these macrolides and ergot derivatives should be avoided. Some of the cases cited were effectively treated with sodium nitroprusside or nifidiphenol oxalate, with or without heparin.1,3,7–9,23 Spiramycin, and josamycin would not be expected to interact because they do not inhibit CYP3A4. However, there is one unexplained and unconﬁrmed report of an interaction with josamycin.12

It has been suggested that ergot alkaloids should be avoided with azithromycin, because clinically important interactions have been seen between other drugs and other macrolide antibacterials related to azithromycin,26,27 and the UK manufacturers of both ergotamine and azithromycin contraindicate the combination.28,29 However, there seems so far to be no direct evidence of any adverse interactions between ergot alkaloids and azithromycin, and the US manufacturers say that concurrent use can be undertaken with careful monitoring.30
Another man treated for cluster headaches with left vertebral artery occlusion and right vertebral arterial spasm. These used use resulted in impaired pain, touch and temperature sensation over developed ischaemia of the right foot, with impalpable popliteal and pedal methysergide 2 mg, intramuscular.

Trinitrate relieved the pain,2 (but see also ‘Ergot derivatives + Glyceryl gotamine increases the risk of arterial spasm.

Parenteral ergot use elsewhere in the body, resulting in serious tissue ischaemia. Parenteral ergotamine increases the risk of arterial spasm.

The concurrent use of methysergide and other ergot derivatives can increase the risk of severe and persistent spasm of major arteries in some patients.

A man developed loss of temperature sensitivity over the right side of his face and arm, as well as vertigo, dysphagia and hoarseness 7 days after starting combined treatment with methysergide 2 mg three times daily and 500 micrograms of subcutaneous ergotamine tartrate at night. Continued use resulted in impaired pain, touch and temperature sensation over the right side of his face, shoulder and arm. Arteriography demonstrated left vertebral artery occlusion and right vertebral arterial spasm. These symptoms, apart from the loss of temperature sensitivity, resolved when the drugs were stopped.1 Another man treated for cluster headaches with methysergide 2 mg, intramuscular ergotamine tartrate and pizotifen developed ischaemia of the right foot, with impalpable popliteal and pedal pulses. Arteriography showed that blood flow to the arteries of the right leg was reduced.1

Another report describes prolonged myocardial ischaemia in a patient with cluster headaches when a single 2-mg dose of ergotamine tartrate was added to methysergide 2 mg three times daily. Sublingual glyceryl trinitrate relieved the pain,2 (but see also ‘Ergot derivatives + Glyceryl trinitrate (Nitroglycerin)’, p.598)

A further case is reported of a woman who developed gangrene of both extremities. After an initial period of recovery she again experienced paraesthesias, coldness, cyanosis and skin paleness of both arms, and a feeling of cold in her left foot after having taken three tablets of ergotamine tartrate for migraine. He took two doses on two consecutive days, and 5 days later presented in hospital with numbness and cyanosis of the toes of his left foot. The next day he complained of intermittent claudication of his left leg, and 6 days later was admitted to hospital because of worsening symptoms and night cramps. Examination showed a typical picture of ergotism, with vasospasm and reduced blood flow in the popliteal, tibial and femoral arteries. He was treated with heparin and buplomedil, and recovered after 3 days.1

See (c) ritonavir below for details regarding a fatality involving indinavir, ritonavir and ergotamine.

Ergot derivatives + Protease inhibitors

A patient receiving indinavir rapidly developed ergotism after taking normal doses of ergotamine. At least ten other patients taking ritonavir and ergotamine have had the same interaction. A patient taking nelfinavir developed peripheral arterial vasospasm after also taking ergotamine. Other ergot derivatives are predicted to interact similarly.

Clinical evidence

(a) Indinavir

An HIV-positive man who had been taking lamivudine, stavudine, co-trimoxazole and indinavir (2.4 g daily) for more than a year was given Gyn- ergene caféine (ergotamine tartrate 1 mg with caffeine 100 mg) for migraine. He took two doses on two consecutive days, and 5 days later presented in hospital with numbness and cyanosis of the toes of his left foot. The next day he complained of intermittent claudication of his left leg, and 6 days later was admitted to hospital because of worsening symptoms and night cramps. Examination showed a typical picture of ergotism, with vasospasm and reduced blood flow in the popliteal, tibial and femoral arteries. He was treated with heparin and buplomedil, and recovered after 3 days.1

(b) Nelfinavir

A 40-year-old HIV-positive woman twice took ergotamine 2 mg for a migraine while also taking nelfinavir, zidovudine and lamivudine. On the first occasion she developed pain and cyanosis in her toes, and on the second occasion she developed cyanosis and oedema in her hands and feet, causing pain so severe that she was unable to walk. On both occasions peripheral arterial pulses were not palpable. Although she recovered spontaneously on both occasions, the authors caution concurrent use due to the extremely severe potential effects.2

(c) Ritonavir

A 63-year-old man with AIDS, who had taken ergotamine tartrate 1 to 2 mg daily for migraine headaches over the last 5 years, had his treatment with zidovudine, zalcitabine and co-trimoxazole changed to zidovudine, didanosine and ritonavir (600 mg every 12 hours). Within 10 days he developed paraesthesias, coldness, cyanosis and skin paleness of both arms, and when admitted to hospital his axillary, brachial, radial and ulnar pulses were found to be absent. An arterial doppler test showed the absence of blood flow in both his radial and ulnar arteries and he was diagnosed as having ergotism. The ergotamine and ritonavir were stopped, and he recovered when treated with prostaglandin E1 and calcium nadroparin.3

Another man, aged 31 years, taking ritonavir 400 mg twice daily (and also taking pizotifen, nelfinavir, stavudine, lamivudine, co-trimoxazole and venlafaxine) developed severe burning and numbness in both feet, and paraesthesias in his hands after taking 4 tablets of ergotamine 1 mg and caffeine 100 mg, over 10 days. He was diagnosed as having ergotism. The drugs were stopped and he was treated effectively with intravenous alprostadil and heparin.4

A case report describes irreversible coma in a 34-year-old woman who was taking ritonavir 600 mg twice daily, lamivudine and stavudine. She presented with dizziness, loss of vision, headache, vomiting, diarrhoea and a feeling of cold in her left foot after having taken three tablets of ergotamine 1 mg in the preceding 4 days. Peripheral pulses were absent in her extremities. After an initial period of recovery she again experienced a loss of consciousness, with signs of stenosis and vasospasm with cere-
bral hypoperfusion. Despite treatment with alprostadil, and discontinuation of ritonavir her condition deteriorated, and 2 years after the initial presentation, she remained in coma vigil (a state of altered consciousness).5

A fatality has been reported in a 49-year-old man taking ritonavir 200 mg twice daily and indinavir 800 mg twice daily in addition to statin- dine and lamivudine. After taking three tablets of Cafergot (ergotamine tartrate 1 mg and caffeine 100 mg) his headache worsened, he developed progressive lower extremity weakness, severe peripheral vasocstriction, labile hypertension and livedo reticularis (skin discoloration due to underlying capillary changes). He lapsed into coma and on day 5 was de- clared “brain dead”.6

At least 6 other cases of ergotism have been reported in patients taking ritonavir after taking ergot derivatives,7,12 and one required surgical amputation of the toes.8 The ergotism developed in three of the patients within a few hours to 24 hours of taking a single 1- or 2-mg dose of ergotamine tartrate,7,9,11 and in the others within about 4 to 15 days.8,10,12 One was taking a combination drug (ergotamine tartrate 300 micrograms, belladonna extract 200 micrograms and phenobarbital 20 mg) twice daily for gastric discomfort,9 another took up to 2 mg of ergotamine daily,10 and a third received 10 mg of ergotamine rectally over 4 consecutive days.12

Mechanism
Protease inhibitors reduce the metabolism of ergotamine by inhibiting the cytochrome P450 isoenzyme CYP3A4 to varying degrees. Therefore ergotamine levels are increased, which may result in toxicity. Ergotamine poisoning causes arterial spasm, which reduces and even shuts down the flow of blood in arteries.

Importance and management
Information appears to be limited to these reports, but what happened is consistent with the way other drugs that are potent inhibitors of CYP3A4 can interact with ergot derivatives (see ‘Ergot derivatives + Macrolides’, p.599). This interaction would appear to be established, and is clearly clinically important. It would now be prudent for any patient taking indinavir or ritonavir, and probably nelfinavir, to avoid the concurrent use of ergotamine or any other ergot derivative, such as dihydroergotamine or methylsergide. Information about possible interactions between ergot derivatives and other protease inhibitors seems to be lacking. Even so to be on the safe side the manufacturers of most of the other protease inhibi- tors contraindicate concurrent use with ergot derivatives.

10. Vila A, Mykietiuk A, Bonvehì P, Temporiti E, Urueña A, Herrera F. Clinical ergotism associ- ated with interaction between doxycycline and ergotamine, and uneventfully for 16 years was given doxycycline and dihydroergot- amine 30 drops three times a day. Five days later her hands and feet be- came cold and reddened, and she was diagnosed as having a mild form of ergotism.1

Other cases of ergotism, some of them more severe, have been described in two patients taking ergotamine tartrate and doxycycline,2,3 and in 3 patients taking tetracycline-containing preparations.4,5

Mechanism
Unknown. One suggestion is that these antibacterials may inhibit the activity of the liver enzymes concerned with the metabolism and clearance of ergotamine, thereby prolonging its stay in the body and enhancing its activity.1 One of the patients had a history of alcoholism and two of them were in their eighties, so impaired liver function may have played a part.

Importance and management
Information is very limited indeed. The incidence and general importance of this interaction is uncertain, but it would clearly be prudent to be on the alert for signs of ergotism in any patient given ergot derivatives and a tetra- cycline. However, note that one of the manufacturers of ergotamine6 ac- tually recommends that the concurrent use of ‘tetracycline’ should be avoided. Impairment of liver function may possibly be a contributory fac- tor in this interaction.

Ergotamine + Antiepileptics
Limited evidence suggests that phenytoin and carbamazepine can reduce serum flunarizine levels. Flunarizine does not appear to alter phenytoin or carbamazepine levels.

Clinical evidence, mechanism, importance and management
A study found that flunarizine levels were lower in patients receiving multiple antiepileptics than in those receiving only one antiepileptic (statistically significant only for carbamazepine and sodium valproate). Flunarizine did not affect the serum levels of these antiepileptics.5 Similarly, in another study involving 12 patients, four of whom were taking phenytoin, four car- bamazepine and four both phenytoin and carbamazepine, there was no difference in the pharmacokinetics of a single 30-mg dose of flunarizine or of multiple-dose flunarizine between the three groups. However, the ap- parent clearance values of flunarizine were several fold greater in these pa- tients than previously observed in healthy volunteers. There were no differences identified in the mean steady-state levels of the antiepileptics before and during flunarizine therapy.2

Although not conclusive, these data suggest that enzyme-inducing antie- piletics increase the metabolism of flunarizine. There would seem to be no reason for avoiding concurrent use, but the outcome should be moni- tored.

Ketoconazole and fluconazole increase the AUC of eletriptan by about sixfold and twofold, respectively. Almotriptan is less affect- ed, and ketoconazole only raises its AUC by about 60%. Itraconoz- ole is predicted to interact in the same way as ketoconazole.

Ergot derivatives + Tetracyclines
Five patients taking ergotamine or dihydroergotamine developed ergotism when they also took doxycycline or tetracycline.

Clinical evidence
A woman who had previously taken ergotamine tartrate successfully and uneventfully for 16 years was given doxycycline and dihydroergot- amine 30 drops three times a day. Five days later her hands and feet be-
Clinical evidence

(a) Almotriptan

In a randomised, open-label, crossover study, 16 healthy subjects were given ketoconazole 400 mg daily on days 1 to 3, with a single 12.5-mg dose of almotriptan on day 2. Ketoconazole increased the AUC and maximum plasma levels of almotriptan by 57% and 61%, respectively. The renal clearance of almotriptan was also reduced by approximately 10%.1

(b) Eletriptan

A pharmacokinetic study by the manufacturers of eletriptan found that ketoconazole 400 mg increased the maximum serum levels of eletriptan 2.7-fold, the AUC 5.9-fold and prolonged its half-life from 4.8 to 8.3 hours. Fluconazole caused a lesser 1.4-fold increase in the maximum serum levels of eletriptan, and a twofold increase in its AUC.2

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which eletriptan is metabolised. Fluconazole is a less potent inhibitor of CYP3A4, and therefore has a more modest effect. Almotriptan is also metabolised by CYP3A4, but as this is not the only route of metabolism, and therefore inhibition of CYP3A4 by ketoconazole has a less dramatic effect on its levels.

Importance and management

Although studies are limited these interactions are established. In the study with almotriptan and ketoconazole adverse events were not significantly altered, and so no almotriptan dosage adjustment is considered necessary when using this combination.1 Ketoconazole dramatically raises eletriptan levels, and therefore the manufacturers advise that concurrent use should be avoided.

Itraconazole, which is also a potent inhibitor of CYP3A4, has been predicted to interact in the same way as ketoconazole.2-4 In addition, the US manufacturers recommend that eletriptan should not be given within 72 hours of itraconazole and ketoconazole.2 Fluconazole is a less potent inhibitor of CYP3A4 and therefore may be used with caution. Other triptans would be expected to have little or no interaction with the azoles as they are not predominantly metabolised by CYP3A4 (see ‘Table 16.2’, (p.597)).

Triptans + Beta blockers

No clinically important interaction occurs between most triptans and propranolol, but the plasma levels of zolmitriptan are almost doubled by propranolol.

Clinical evidence, mechanism, importance and management

(a) Almotriptan

Twelve healthy subjects were given propranolol 80 mg twice daily for 7 days followed by a single 12.5-mg dose of almotriptan. Although some small changes were noted in the pharmacokinetics of almotriptan, these were not considered to be clinically significant and concurrent use of the combination was well tolerated.1

(b) Eletriptan

In an interaction study, 12 healthy subjects were given a single 80-mg dose of eletriptan following pre-treatment with propranolol 80 mg twice daily for 7 days. It was found that the eletriptan AUC was increased 1.3-fold and the half-life increased from 4.9 to 5.2 hours. However, these changes were not considered to be clinically significant. No significant blood pressure changes or any adverse events were seen, when compared with taking eletriptan alone.2

The manufacturers say that in clinical trials where eletriptan was taken with beta blockers, no evidence of an interaction was seen.3

(c) Frovatriptan

A single 2.5-mg oral dose of frovatriptan was given to 12 healthy subjects after they had received pre-treatment with propranolol 80 mg twice daily for 7 days. The AUC and maximum levels of frovatriptan were increased by 25% and 23%, respectively. However, no changes occurred in the ECGs and vital signs of the subjects, and so the pharmacokinetic interaction was not thought to be of clinical significance.4

(d) Naratriptan

The manufacturers of naratriptan report that there is no evidence of interactions with beta blockers (none specifically named) so there would appear to be no problems with the concurrent use of propranolol with any other beta blocker.

(e) Rizatriptan

A series of double-blind, placebo-controlled studies were conducted in a total of 51 patients who were given a single 10-mg dose of rizatriptan after 7 days of pre-treatment with propranolol 60 or 120 mg twice daily, nadolol 80 mg daily, metoprolol 100 mg daily, or placebo.5 Nadolol and metoprolol had no effect on the pharmacokinetics of rizatriptan. However, propranolol raised the AUC and the maximum plasma concentration of rizatriptan by 1.67 and 1.75-fold, respectively. Adjusting the dose of propranolol and separating the admixture by 2 hours had little effect on this interaction.6 In vitro studies have shown that propranolol markedly inhibits the metabolism of rizatriptan, whereas atenolol, nadolol and timolol do not affect the metabolism of rizatriptan.5 The manufacturers recommend that a 5-mg dose of rizatriptan (rather than the more usual 10 mg) should be used in the presence of propranolol, with a maximum of two or three doses in 24 hours.7 In the UK, they also state that administration should be separated by at least 2 hours, although the rationale for this is less clear given the findings of the above study.8 No reduction in the rizatriptan dosage would seem to be needed in the presence of nadolol, metoprolol, atenolol or timolol.

(f) Sumatriptan

In a study in 10 healthy subjects, propranolol 80 mg twice daily for 7 days did not alter the pharmacokinetics of a single 300-mg dose of sumatriptan given on day 7. There was no significant effect on pulse rate or blood pressure.9

(g) Zolmitriptan

In a double-blind, randomised, crossover study, 12 healthy subjects were given propranolol 160 mg or a placebo daily for 7 days, with a single 10-mg oral dose of zolmitriptan on day 7. The propranolol increased the maximum serum levels and the AUC of the zolmitriptan by 56% and 37%, respectively, and reduced the extent of its conversion to its active metabolite, probably due to inhibition of, or competition for metabolism by, cytochrome P450 isoenzymes. However, it was concluded that no clinically important changes in the therapeutic effects of zolmitriptan are likely, nor are any adjustments in its dosage needed.10

Triptans + Ergot derivatives

Simultaneous use of the ergot derivatives is contraindicated with all the triptans because of the theoretical risk of additive vasoconstriction, although this has been demonstrated only in one study with sumatriptan, and there is one isolated case of myocardial in-
faction in a woman taking sumatriptan and methysergide. No
important additive effect has been seen in pharmacodynamic
studies with almotriptan, eletriptan, frovatriptan, naratriptan,
rizatriptan or zolmitriptan. Some of the manufacturers of the
tRIPTANS give recommendations for the number of hours that
should be allowed between administration of triptans and ergot
derivatives.

Clinical evidence
(a) Almotriptan
The manufacturers of almotriptan say that no additive vasospastic effects
were seen in a clinical study in 12 healthy subjects given almotriptan and
ergotamine. However, they do note that such effects are theoretically
possible.
(b) Eletriptan
The manufacturers report that when oral ergotamine with caffeine was
given 1 hour and 2 hours after eletriptan, minor additive increases in blood
pressure were seen.
(c) Frovatriptan
In a randomised, crossover study, 12 healthy subjects were given a single
5-mg dose of oral frovatriptan, a single 2-mg sublingual dose of ergot-
amine, or both drugs together. The ergotamine reduced the maximum
levels and AUC of frovatriptan by about 25%. However, the frovatriptan
had no effect on ergotamine pharmacokinetics, and no clinically signifi-
cant changes in the haemodynamics or the ECGs of the subjects were not-
ed.
(d) Naratriptan
A study in 12 healthy subjects found that 1 mg of intramuscular dihy-
droergotamine reduced the AUC and the maximum serum levels of a
single 2.5-mg dose of naratriptan by 15% and 20%, respectively, but this
was considered to be clinically irrelevant. Concurrent use was well toler-
ated and no clinically significant blood pressure, heart rate or ECG effects
were seen.
(e) Rizatriptan
Additive vasospastic effects were not observed in a pharmacodynamic
study in 16 healthy subjects given oral rizatriptan 10 mg and intravenous
ergotamine 250 micrograms.
(f) Sumatriptan
A study in 38 migraine sufferers found that 1 mg of intravenous dihy-
droergotamine alone caused maximum increases in blood pressure of
13/9 mmHg, while 2 or 4 mg of subcutaneous sumatriptan alone caused a
smaller rise in blood pressure of 7/6 mmHg. When given together the
blood pressure rises were no greater than with dihydroergotamine alone.
A clinical study of subcutaneous sumatriptan in patients taking oral dihy-
droergotamine found that the adverse event profile of sumatriptan was
not affected by concurrent use. However, another pharmacodynamic
study found that subcutaneous sumatriptan and intravenous ergotamine
had additive vasocostractive effects (as assessed by decreases in toe-arm
systolic blood pressure gradients).
Myocardial infarction has been reported in a 43-year-old woman after
she took two 2-mg doses of methysergide 12 hours apart, followed by su-
mitriptan 6 mg subcutaneously. Severe chest pain and tightness with
breathlessness began 15 minutes later, and results of various tests were
consistent with ‘coronary spasm on an area of atherosclerosis’.
(g) Zolmitriptan
In a randomised, double-blind, placebo-controlled study, 12 healthy sub-
jects were given 5 mg of oral dihydroergotamine or a placebo twice daily
for 10 days, with oral zolmitriptan 10 mg (four times the usual dose)
on day 10. No significant changes in blood pressure, ECGs, or zol-
mitriptan pharmacokinetics were seen. Concurrent use was well tolerat-
ed. Another randomised, double-blind, placebo-controlled study in 12
healthy subjects looked at the effects of oral zolmitriptan 20 mg (eight
times the usual dose) given with oral ergotamine 2 mg (contained in
Cafergot tablets; ergotamine 1 mg with caffeine 100 mg). Using a very
detailed and thorough range of techniques, no clinically relevant cardio-
vascular changes were found, even at this large dose of zolmitriptan, and
concurrent use was generally well tolerated. No important changes in the
zolmitriptan pharmacokinetics were seen.

Mechanism
Vasoconstriction is a well known adverse effect of ergot derivatives, and
coronary vasoconstriction may also occur rarely with the triptans. (Note
that in 1992, soon after the marketing of sumatriptan, the CSM in the UK
had received 34 reports of pain or tightness in the chest caused by su-
matriptan, possibly due to coronary vasoconstriction.13) It is therefore the-
oretically possible that the drugs may have additive vasoconstrictive
effects, although there is little evidence of this in practice.

Importance and management
Due to the theoretical risk of additive vasoconstriction, and possible sig-
nificant coronary vasoconstriction (see sumatriptan above) ergot derivati-
tives are generally contraindicated with the triptans (the exception being
naratriptan, where concurrent use is not recommended). The UK manu-
ufacturers of sumatriptan say that ergotamine should not be given less
than 6 hours after taking the triptan, and recommend that the triptan should not
be taken less than 24 hours after taking ergotamine. 
The same recom-
mendations are made by the UK manufacturers of almotriptan, riza-
triprant, and zolmitriptan, whereas the UK manufacturers of eletriptan
and frovatriptan, recommend that ergot derivatives are not given for a
minimum of 24 hours (not just 6 hours) after these triptans. In general, in
the US, it is recommended that triptans should not be taken within
24 hours of any ergotamine or ergot-type medication.

Additive

Triptans + Flunarizine

Flunarizine did not alter the pharmacokinetics or pharmacody-
namics of sumatriptan in one study. Flunarizine does not appear to
interact with eletriptan.

Clinical evidence, mechanism, importance and management
(a) Eletriptan
The manufacturer notes that although no formal interaction studies have
been carried out, there was no evidence of an interaction between elet-
triprant and flunarizine in clinical trials.
(b) Naratriptan
A double-blind study found that flunarizine 10 mg daily for 8 days had no
effect on the pharmacokinetics of a single dose of sumatriptan, and the

combination caused no significant changes in blood pressure, ECG or heart rate.\(^2\)

### Triptans + Macrolides

**Erythromycin** markedly raises the plasma levels of eletiptan. Clarithromycin, josamycin and troleandomycin are predicted to interact similarly. Almotriptan levels may be raised by erythromycin. Clarithromycin does not significantly alter the pharmacokinetics of sumatriptan.

**Clinical evidence**

(a) **Eletiptan**

A clinical pharmacokinetic study by the manufacturers of eletiptan\(^1\) found that **erythromycin** 1 g increased the maximum serum levels of eletiptan 2-fold, the AUC 3.6-fold and prolonged its half-life from 4.6 to 7.1 hours.

(b) **Sumatriptan**

A study in which 24 healthy subjects were given sumatriptan 50 mg on the morning of the fourth day of a course of clarithromycin 500 mg twice daily, found that **clarithromycin** did not significantly affect the pharmacokinetics of sumatriptan.\(^2\)

**Mechanism**

The macrolides are, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which eletiptan is metabolised. Therefore giving erythromycin raises eletiptan plasma levels. Sumatriptan is not metabolised by CYP3A4 and therefore does not interact.

**Importance and management**

Information is limited but an interaction between eletiptan and erythromycin appears to be established. Because of the elevated levels seen, the manufacturers advise against their concurrent use.\(^1,3\) Other drugs that are potent CYP3A4 inhibitors are predicted to raise serum eletiptan levels similarly. Such drugs include clarithromycin, josamycin, and troleandomycin.\(^3\) In addition, the US manufacturers recommend that eletiptan should not be given within 72 hours of clarithromycin or troleandomycin.\(^3\)

Other triptans would be expected to have little or no interaction with the azoles as they are not predominantly metabolised by CYP3A4 (see ‘Table 16.2,’ p.597). The exception to this is **almotriptan**, which is metabolised in part by CYP3A4. The US manufacturers\(^4\) therefore predict that its levels may be raised by erythromycin. However, note that, based on its interaction with ‘ketoconazole’, (p.601), dosage adjustments would not be expected to be necessary.

### Triptans + MAOIs

Moclobemide markedly inhibits the metabolism of rizatriptan, and approximately doubles the bioavailability of sumatriptan. The manufacturers contraindicate these triptans with moclobemide and non-selective MAOIs. Moclobemide modestly inhibited the metabolism of zolmitriptan but had no clinically significant effect on almotriptan or frovatriptan.

Selegiline does not interact with sumatriptan or zolmitriptan, and would not be expected to interact with any of the other triptans.

Non-selective MAOIs (e.g. phenelzine) are not expected to interact with eletiptan, frovatriptan, or naratriptan. Nevertheless, the manufacturer of frovatriptan contraindicates the concurrent use of MAOIs, based on a theoretical increased risk of serotonin syndrome.

**Clinical evidence, mechanism, importance and management**

(a) **Almotriptan**

In a study in 12 healthy subjects, moclobemide 150 mg twice daily for 8 days increased the AUC of a single 12.5-mg dose of almotriptan given on day 8 by 37%, decreased its clearance by 27% and increased the half-life by 24%, which was not considered clinically significant.\(^1\) These findings are consistent with the fact that less than half of a dose of almotriptan is metabolised by monoamine oxidase A,\(^4\) and it would seem therefore that concurrent use need not be avoided. There appears to be no direct clinical information about the use of non-selective MAOIs but it seems unlikely that a clinically relevant interaction will occur.

(b) **Eletiptan**

The manufacturer of eletiptan notes that it is not a substrate for monoamine oxidase, and therefore no interaction with MAOIs is expected.\(^3\) Because of this, they have not undertaken a formal interaction study.\(^3\)

(c) **Frovatriptan**

The manufacturer of frovatriptan notes that it is not a substrate for, or an inhibitor of, monoamine oxidase.\(^5\) Nevertheless, they say that a potential risk of serotonin syndrome or hypertension cannot be excluded when it is used with MAOIs, so concomitant use is not recommended\(^3\) (but see also ‘Antimigraine drugs’, (p.597)). A study in 9 healthy subjects given a single 2.5-mg oral dose of frovatriptan following pre-treatment with moclobemide 150 mg twice daily for 7 days did not find any pharmacokinetic changes, or any changes in the vital signs and ECGs of the subjects. Therefore no adverse interaction would be expected with concurrent use.\(^7\)

(d) **Naratriptan**

The manufacturer of naratriptan notes that it does not inhibit monoamine oxidase. Therefore interactions with MAOIs are not anticipated.\(^3\)

(e) **Rizatriptan**

In a double blind, randomised, crossover study, 12 healthy subjects were given moclobemide 150 mg or a placebo three times daily for 4 days, with a single 10-mg dose of rizatriptan on day 4. The moclobemide increased the AUCs of rizatriptan and its active (but minor) metabolite by 2.2- and 5.3-fold, respectively, and increased their maximum serum levels by 1.4- and 2.6-fold, respectively. MAO-A is the principal enzyme concerned with the metabolism of rizatriptan. Moclobemide inhibits this enzyme and therefore raises rizatriptan levels. Despite these rises, the concurrent use of these drugs was well tolerated and any adverse effects were mild and similar to those seen when rizatriptan was given with the placebo. However, because of the magnitude of the rises, the authors recommend avoiding the combination.\(^7\) The manufacturers of rizatriptan contraindicate its use both during, and 2 weeks after stopping an MAOI, the stated reasons being that similar or greater rises in serum levels may be expected with irreversible non-selective MAOIs than with moclobemide.\(^10,11\) In addition, the US manufacturers\(^11\) note that no interaction would be expected with selective inhibitors of MAO-A (namely selegiline and rasagiline).

(f) **Sumatriptan**

Three groups of 14 subjects were given a placebo, moclobemide 150 mg three times daily, or selegiline 5 mg twice daily for 8 days, with subcutaneous sumatriptan 6 mg on day 8. No statistically significant differences in pulse rates or in blood pressures were seen between any of the groups following the injection of the sumatriptan. However, the sumatriptan AUC of the moclobemide-treated group was approximately doubled (129% increase), its clearance was reduced by 56% and its half-life increased by 52%. The pharmacokinetic changes seen in the selegiline group were not consistent. There were no differences in the adverse events experienced by any of the three groups.\(^12\) An in vitro study of the metabolism of sumatriptan confirms that it is the MAO-A enzyme, not MAO-B, that is the major enzyme involved in the metabolism of sumatriptan.\(^13\)

A comprehensive search of the literature and reports from proprietary manufacturers, identified published reports of 31 patients taking sumatriptan and MAOs concurrently, but no adverse events were reported,\(^14\) and a patient taking moclobemide 300 mg three times daily had no adverse effects when given oral sumatriptan 100 mg on six occasions.\(^15\)
However, a patient had taken an overdose of *moclobemide*, together with sumatriptan, sertraline, and citalopram developed the serotonin syndrome.16 The interaction between moclobemide and sumatriptan appears to be established. The same interaction seems likely to occur with any RIMA or non-selective MAOI, but not with the selective MAO-B inhibitors like selegiline. However, the increased sumatriptan bioavailability appears not to be clinically important because, in the study cited, those subjects taking moclobemide did not experience any more adverse effects than those taking the selegiline or placebo. Despite this the UK manufacturers of sumatriptan quite clearly say that the concurrent use of sumatriptan and MAOIs is contraindicated both during and for 2 weeks after stopping an MAOI.17

**Zolmitriptan**

In a series of three-period, crossover, randomised studies, 12 healthy subjects were given selegiline 10 mg daily or moclobemide 150 mg twice daily for 7 days, with a single 10-mg oral dose of zolmitriptan on day 7.18 It was found that the AUC of the zolmitriptan was increased by 26% by the *moclobemide*. A threefold increase in the AUC of the active metabolite also occurred.19 It is likely that moclobemide inhibited the metabolism of zolmitriptan via monoamine oxidase A. Despite these increases, because of the good tolerability profile of zolmitriptan, no dosage reductions are thought to be needed if given with *moclobemide*, but a maximum in take of 5 mg in 24 hours is recommended by the UK manufacturers.19 However, the UK manufacturers contraindicate the use of zolmitriptan both during and for 2 weeks after the use of RIMAs.20

Selegiline on the other hand had no effect on the pharmacokinetics of zolmitriptan or its metabolites, apart from a small (7%) reduction in its renal clearance.14 This finding was expected, since *selegiline* is specific for monoamine oxidase B (but note that this specificity is lost at higher doses). No special precautions would therefore seem to be necessary if *selegiline* is given with sumatriptan.

15. Bler P, Bergeron R. The safety of concomitant use of sumatriptan and antidepressant treat-

**Clinical evidence**

(a) Sumatriptan

Pizotifen 500 micrograms three times daily for 8 days in 14 healthy subjects was found to have no significant effect on the pharmacokinetics of sumatriptan. In addition, there were no significant changes in blood pressure or heart rate.1 In a clinical study, the addition of pizotifen prophylaxis did not alter the efficacy of acute sumatriptan for migraine relief. In this study, the combination was associated with more weight gain than sumatriptan alone, an effect which was attributed solely to the pizotifen.2

(b) Zolmitriptan

In a double-blind, randomised study, 12 healthy subjects were given pizotifen 1.5 mg or a placebo once daily for 8 days, with oral zolmitriptan 10 mg on day 8. Pizotifen did not significantly alter the pharmacokinetics of zolmitriptan, and no clinically relevant changes in heart rates or ECGs or blood pressures were seen as a result of concurrent use.3

**Mechanism, importance and management**

Although the information is limited, it shows that no sumatriptan or zolmitriptan dosage adjustments are expected to be needed if used with pizotifen. On the basis of the information on sumatriptan and zolmitriptan it seems unlikely that any of the other triptans will interact.

1. Fowler PA, Lacey LF, Thomas M, Keene ON, Tanner RJN, Haber NS. The clinical pharmaco-

**Triptans + Protease inhibitors**

The manufacturers state that the concurrent use of eletriptan and ritonavir, indinavir, or nelfinavir should be avoided, because these protease inhibitors are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of eleptran. Concurrent use would therefore be expected to markedly increase levels of eletriptan.12 In addition, the US manufacturers recommend that eletriptan should not be given within 72 hours of ritonavir and nelfinavir.2 This predicted interaction is based on the known interaction with ‘erythromycin’, (p.604) and ‘ketonazole’, (p.601). Similar predictions are made by the manufacturers of almotriptan, and they advise caution with the use of rizatriptan.3

**Triptans + SSRIs and related antidepressants**

The SSRIs normally appear not to interact with the triptans, but there are a few rare cases of dyskinesias when sumatriptan was given with an SSRI, and there is some evidence to suggest that the serotonin syndrome may occasionally develop. Venlafaxine and duloxetine are predicted to interact similarly. Fluoxetine modestly inhibits the metabolism of frovatriptan, and may inhibit the metabolism of zolmitriptan.

1. Fluoxetine 60 mg daily was given to 14 healthy subjects for 8 days, with a single 12.5-mg dose of almotriptan on day 8. Fluoxetine raised the maximum plasma levels of almotriptan by about 18%. The combination was well tolerated and caused no ECG changes, so no dose alterations were considered necessary.1

**Triptans + Pizotifen**

Pizotifen did not alter the pharmacokinetics or pharmacodynamics of sumatriptan or zolmitriptan, and did not alter the efficacy of acute sumatriptan for migraine. It seems unlikely that any of the other triptans will interact.
The manufacturer notes that although no formal interaction studies have been done, there was no evidence of an interaction between eletriptan and SSRIs in clinical trials, and that SSRIs appeared unlikely to alter the pharmacokinetics of eletriptan.  

Fluvoxamine has been shown to increase the blood levels of frovatriptan by 27 to 49%. The manufacturer recommends caution with concurrent use of frovatriptan and fluvoxamine or other SSRIs.

(d) Naratriptan

The UK manufacturer of naratriptan notes that there is no evidence of interactions with SSRIs.

(e) Rizatriptan

A single 10-mg dose of rizatriptan was given to 12 healthy subjects after they took paroxetine 20 mg or a placebo daily for 14 days. The plasma levels of rizatriptan and its active metabolite were not altered by paroxetine, and no adverse effects were seen. Safety evaluations included blood pressure, heart rate, temperature and a visual analogue assessment of mood. There was no evidence of the serotonin syndrome.

(f) Sumatriptan

A study in 11 healthy subjects found that paroxetine 20 mg daily for 16 days had no effect on the response to a 6-mg dose of subcutaneous sumatriptan, as measured by prolactin levels. The sumatriptan levels remained unaltered, its cardiovascular effects were unchanged and no clinically significant adverse effects occurred. Other studies report that the concurrent use of sumatriptan and SSRIs (fluoxetine 20 to 60 mg daily, fluvoxamine 200 mg daily, paroxetine 20 to 50 mg daily, sertraline 50 to 100 mg daily) was successful and uneventful. No adverse effects have been noted in 148 other patients. However, a case report describes 50 to 100 mg daily) was successful and uneventful. No adverse effects showed good evidence, and another 4 cases that showed some, but not strong evidence, of reactions consistent with the serotonin syndrome in patients also taking sumatriptan. Other cases describe a decrease in the efficacy of sumatriptan with paroxetine, identified 2 cases that showed good evidence, and another 4 cases that showed some, but not strong evidence, of reactions consistent with the serotonin syndrome in patients also taking sumatriptan.

Sertraline, paroxetine, and citalopram are also "Antimigraine drugs", (p.597). Since fluvoxamine is predicted to have a pharmacokinetic interaction with zolmitriptan the manufacturers recommend a maximum dosage of 5 mg in 24 hours in the presence of fluvoxamine.  

Importance and management

The weight of evidence suggests that the concurrent use of the triptans and SSRIs is normally uneventful, but adverse reactions do occur occasionally. The authors of some of the references above concluded that their findings do not imply that concurrent use should be avoided, but that caution and close monitoring should be used. Many of the US manufacturers of the triptans generally advise that patients receiving a triptan and an SSRI or an SNRI (i.e. duloxetine or venlafaxine) should be monitored for any signs of weakness, hyperreflexia, and incoordination. However, see also ‘Antimigraine drugs’, (p.597). Since fluvoxamine is predicted to have a pharmacokinetic interaction with zolmitriptan the manufacturers recommend a maximum dosage of 5 mg in 24 hours in the presence of fluvoxamine.

References:

Triptans + St John’s wort (Hypericum perforatum)

The CSM in the UK noted that pharmacodynamic (potentiation) interactions have been identified between triptans and St John’s wort (Hypericum perforatum) leading to an increased risk of adverse effects. They suggest that patients taking triptans should not take St John’s wort preparations.

Triptans + Tobacco

The clearance of naratriptan and possibly frovatriptan is modestly increased by smoking. However, this is unlikely to be clinically relevant. There was no evidence of an interaction between smoking and sumatriptan.
Clinical evidence

(a) Frovatriptan
In a retrospective analysis of pharmacokinetic data from phase I studies, there was a trend for a lower frovatriptan AUC and maximum plasma level in smokers when compared with non-smokers. The clearance tended to be higher but the half-life did not differ.1

(b) Naratriptan
The manufacturer notes that smoking increased the clearance of naratriptan by 30%.2

(c) Sumatriptan
A prospective study of 12 339 individuals receiving sumatriptan by injection identified 18.3% of these (2262) who were current smokers. There was no evidence of an interaction between sumatriptan and tobacco smoking.3

Mechanism
Tobacco smoke is known to induce the cytochrome P450 isoenzyme CYP1A2, which metabolises both naratriptan and frovatriptan to some extent. Zolmitriptan is also a substrate of CYP1A2, but the effect of smoking does not appear to have been studied.

Importance and management
Although data are limited, the possible small changes in the pharmacokinetics of frovatriptan and naratriptan with smoking are unlikely to be clinically relevant. It should be noted that smoking is a recognised risk factor for cardiovascular disease. Patients with such risk factors should only use the triptans after careful evaluation.

Triptans + Verapamil

Verapamil inhibits the metabolism of eletriptan (AUC increased 2.7-fold) and almotriptan (AUC increased by 20%) but neither of these changes are considered to be clinically significant.

Clinical evidence, mechanism, importance and management

(a) Almotriptan
In a crossover study, 12 healthy subjects were given a single 12.5-mg dose of almotriptan, either alone or following a week of treatment with sustained-release verapamil 120 mg twice daily. The AUC and maximum plasma level of almotriptan were raised by about 20% and 24%, respectively, by verapamil. However, the only effect this caused was a slight increase in systolic BP (8 mmHg) 2 hours after the dose. It was suggested that verapamil may inhibit the metabolism of almotriptan via the cytochrome P450 isoenzyme CYP3A4. The authors suggest that changes of this magnitude do not warrant dosage adjustments.1

(b) Eletriptan
In a clinical study with verapamil 480 mg, the maximum plasma levels and AUC of eletriptan were markedly increased by 2.2-fold and 2.7-fold, respectively.2,3 However, the UK manufacturers state that these increases were not clinically significant as there were no associated increases in blood pressure or adverse events compared to eletriptan alone.5

Triptans; Sumatriptan + Butorphanol

Sumatriptan given by injection appears not to interact with butorphanol nasal spray, but if both drugs are given sequentially by nasal spray a modest reduction in butorphanol absorption may occur.

Clinical evidence, mechanism, importance and management
No pharmacokinetic interactions or change in adverse effects were found to occur between single 1-mg doses of butorphanol tartrate nasal spray and a 6-mg subcutaneous dose of sumatriptan succinate in 24 healthy subjects. It was concluded that concurrent use during acute migraine attacks need not be avoided.1

In another study, 19 healthy subjects were given a 1-mg dose of butorphanol nasal spray either 1 or 30 minutes following a 20-mg dose of sumatriptan nasal spray. When butorphanol was given 1 minute after sumatriptan the AUC and maximum plasma levels of butorphanol were reduced by about 29% and 38%, respectively. When butorphanol was given 30 minutes after sumatriptan no significant pharmacokinetic interaction was noted. It was suggested that sumatriptan may cause a transient vasoconstriction of nasal blood vessels, leading to reduced butorphanol absorption. It would therefore seem wise to separate administration to ensure the full effects of butorphanol are achieved.2

Triptans; Sumatriptan + Loxapine

An isolated report describes a woman taking loxapine who developed a severe dystonic reaction when she was given sumatriptan.

Clinical evidence, mechanism, importance and management
A woman was taking loxapine 10 mg twice daily for psychotic target symptoms, benztropine for the prophylaxis of extrapyramidal effects, carbamazepine for mood stabilisation, and Fliset (paracetamol (acetaminophen), caffeine, and butalbital) for migraine headaches. Two days after the loxapine dosage was raised to 35 mg daily she was given a single 6-mg subcutaneous dose of sumatriptan for a migraine headache. Within 15 minutes she developed torticollis, which was treated with intramuscular benztropine and intravenous diphenhydramine.

The authors of the report suggest that this reaction was possibly caused by the additive dystonic effects of the loxapine and sumatriptan, despite the presence of the benztropine. Dystonia is not an uncommon extrapyramidal reaction associated with antipsychotics, and neck stiffness and dystonia are recognised adverse effects of sumatriptan, but of low incidence.1 This seems to be the first and only report of this apparent interaction, and therefore its general significance is unclear.

Triptans; Sumatriptan + Naproxen

A study in 12 healthy subjects found that a single 500-mg dose of naproxen had no significant effect on the pharmacokinetics of a single 100-mg oral dose of sumatriptan.1

Triptans; Sumatriptan + Topiramate

Topiramate does not significantly affect the pharmacokinetics of oral or subcutaneous sumatriptan.

Clinical evidence, mechanism, importance and management
In a study 24 healthy subjects were given topiramate 50 mg every 12 hours increased to 100 mg every 12 hours for a total of 7 days, with a single 100-mg oral dose of sumatriptan on day 7. It was found that topiramate reduced the AUC of sumatriptan by 10%, but this was not considered
to be clinically relevant. Topiramate had no effect on the AUC of sumatriptan given as a 6 mg subcutaneous dose. The clearance of topiramate appeared to be reduced, when data from this study was compared with that from historical controls, but the magnitude of the effect was not stated.\(^1\) The clinical significance of this effect is unclear.

---

### Triptans; Zolmitriptan + Cimetidine

**Cimetidine raises the plasma levels of zolmitriptan.**

**Clinical evidence, mechanism, importance and management**

The manufacturer of zolmitriptan notes that the half-life of zolmitriptan was increased by 44% and the AUC by 48% when it was given after the use of cimetidine. They suggest that this may be because of the inhibitory effect of cimetidine on the cytochrome P450 isoenzyme CYP1A2, an enzyme involved in the metabolism of zolmitriptan. The UK manufacturer recommends a zolmitriptan dose reduction to a maximum of 5 mg in 24 hours in patients taking cimetidine.\(^1\) The US manufacturer makes no recommendation on dose.\(^2\)

---

### Triptans; Zolmitriptan + Metoclopramide

**Metoclopramide does not affect the pharmacokinetics of zolmitriptan.**

**Clinical evidence, mechanism, importance and management**

In a randomised, crossover study, 15 healthy subjects were given single 10-mg doses of zolmitriptan alone or with metoclopramide 10 mg. Metoclopramide had no effect on the pharmacokinetics of zolmitriptan, so there would appear to be no reason for avoiding concurrent use of these two drugs.\(^1\)

---

### Triptans; Zolmitriptan + Paracetamol (Acetaminophen)

**Paracetamol causes a slight increase in zolmitriptan levels and zolmitriptan causes a slight reduction in the rate and extent of paracetamol absorption, but this does not appear to be clinically relevant.**

**Clinical evidence, mechanism, importance and management**

In a randomised, crossover study, 15 healthy subjects were given single 10-mg doses of zolmitriptan, alone or with 1 g paracetamol. The paracetamol increased the zolmitriptan maximum plasma levels and AUC by 11%, while reducing its renal clearance by 9%. The paracetamol maximum plasma levels and AUC were reduced by 31% and 11%, and absorption was delayed (time to achieve maximum levels 3 versus 0.75 hours). The presence of oral metoclopramide 10 mg did not affect the interaction between zolmitriptan and paracetamol.\(^1\) It was suggested that zolmitriptan might have some inhibitory effect on gastric emptying thereby slowing the absorption of paracetamol. The authors considered that the small changes in pharmacokinetics seen were of no clinical relevance.\(^1\)

---

### Triptans; Zolmitriptan + Quinolones

**The UK manufacturer recommends a dose reduction of zolmitriptan to a maximum of 5 mg in 24 hours in patients taking quinolone antibacterials such as ciprofloxacin.** This is because these antibacterials are predicted to increase levels of zolmitriptan by inhibiting the cytochrome P450 isoenzyme CYP1A2, an enzyme involved in the metabolism of zolmitriptan.\(^1\) This is based on the known interaction with ‘cimetidine’, (above). However, the US manufacturer makes no comment on this theoretical interaction.\(^2\)

---

### Triptans; Zolmitriptan + Xylometazoline

**In a clinical study in 18 healthy subjects, there was no change in the rate or extent of absorption of intranasal zolmitriptan 5 mg given 30 minutes after xylometazoline nasal spray.**\(^1\) This suggests that nasal vasoconstriction does not affect absorption of intranasal zolmitriptan.

---

The antineoplastic drugs (also called cytotoxics or sometimes cytostatics) are used in the treatment of malignant disease alone or in conjunction with radiotherapy, surgery or immunosuppressants. They also find application in the treatment of a number of autoimmune disorders such as rheumatoid arthritis and psoriasis, and a few are used with other immunosuppressant drugs (cyclosporin, corticosteroids) to prevent transplant rejection. These other drugs are dealt with under the section on ‘immunosuppressants’, (p.1009).

Of all the drugs discussed in this publication, the antineoplastic drugs are amongst the most toxic and have a low therapeutic index. This means that quite small increases in their levels can lead to the development of serious and life-threatening toxicity. A list of the antineoplastic drugs that are featured in this section appears in ‘Table 17.1’, (below), grouped by their primary mechanism of action. This table also includes a number of hormone antagonists that are used in the treatment of cancer.

Unlike most of the other interaction monographs in this publication, some of the information on the antineoplastic drugs is derived from animal experiments and in vitro studies, so that confirmation of their clinical relevance is still needed. The reason for including these data is that the antineoplastic drugs as a group do not lend themselves readily to the kind of clinical studies that can be undertaken with many other drugs, and there would seem to be justification in this instance for including indirect evidence of this kind. The aim is not to make definite predictions, but to warn users of the interaction possibilities.

Altretamine (Hexamethylmelamine) + Antidepressants

Severe orthostatic hypotension has been described in patients given altretamine with either phenelzine, amitriptyline or imipramine.

Clinical evidence, mechanism, importance and management

Four patients experienced very severe orthostatic hypotension (described by the authors as potentially life-threatening) when they were given altretamine 150 to 250 mg/m² with either phenelzine 60 mg daily, amitriptyline 50 mg daily or imipramine 50 to 150 mg daily.1 They experienced incapacitating dizziness, severe lightheadedness, and/or fainting within a few days of taking both drugs concurrently. Standing blood pressures as low as 50/30 and 60/40 mmHg were recorded. The reasons are not known. One of the patients had no problems when imipramine was replaced by nortriptyline 50 mg daily. One other patient who had also been on altretamine with antidepressants reported dizziness, while another noted nonspecific discomfort. The incidence of this interaction is unknown, but it is clear that the concurrent use of altretamine and tricyclics or MAOIs should be closely monitored.

Altretamine (Hexamethylmelamine) + Pyridoxine (Vitamin B₆)

Pyridoxine reduced the neurotoxicity associated with altretamine, but also reduced its effectiveness.

Clinical evidence, mechanism, importance and management

In a large randomised study in women with advanced ovarian cancer the neurotoxicity associated with altretamine and cisplatin chemotherapy was reduced by pyridoxine, but the response duration was also reduced.1 In this study, cisplatin was given on day 1 (37.5 or 75 mg/m²) and altretamine 200 mg/m² daily was given on days 8 to 21, and the half the patients also received pyridoxine 100 mg three times daily on days 1 to 21. It is unclear how pyridoxine reduced the activity of this regimen, but the use of pyridoxine (vitamin B₆) should probably be avoided in patients receiving altretamine.

9-Aminocamptothecin + Antiepileptics

Enzyme-inducing antiepileptics can lower the serum levels of 9-aminocamptothecin.

Clinical evidence, mechanism, importance and management

A study in 59 patients with glioblastoma multiforme or recurrent high grade astrocytomas found that the steady-state plasma levels of 9-aminocamptothecin were reduced to about one-third in 29 of the patients also taking antiepileptics (carbamazepine, phenobarbital, phenytoin, sodium valproate). The incidence of myelosuppression was greater in those not taking antiepileptics.1 A further study also found that the clearance of 9-aminocamptothecin was increased by carbamazepine and phenytoin.2 The reason for the reduced 9-aminocamptothecin levels is not known, but it seems likely that it was due to the enzyme-inducing activity of carbamazepine, phenobarbital and phenytoin. These results suggest that higher than usual doses of 9-aminocamptothecin are possibly needed in the presence of enzyme-inducing antiepileptics. Related topoisomerase inhibitors are similarly affected, see ‘Irinotecan + Antiepileptics’, p.638, and ‘Topotecan + Phenytoin’, p.667.

Aminoglutethimide + Danazol

Danazol may reduce the efficacy of aminoglutethimide.

Clinical evidence, mechanism, importance and management

In a randomised clinical study, giving danazol with aminoglutethimide in women with breast cancer, reduced the response rate compared with aminoglutethimide alone. It was found that danazol suppresses sex hormone binding globulin leading to increased free oestriodiol, which counteracts the oestriodiol suppressive effect of aminoglutethimide.1 Danazol should probably not be combined with anti-oestrogenic treatments.

Aminoglutethimide + Diuretics

A single case report describes hyponatraemia, which occurred after a patient had taken aminoglutethimide and bendroflumethiazide for 10 months.

Clinical evidence, mechanism, importance and management

A woman who, for several years, had been taking bendroflumethiazide 10 mg daily and potassium chloride 578 mg for hypertension and mild cardiac decompensation, was given aminoglutethimide 1 g daily, and hydrocortisone 60 mg daily, for breast cancer. After 10 months of treatment she was hospitalised with severe hyponatraemia, which resolved on withdrawal of all the drugs. No significant changes in electrolytes occurred over 3 months when the aminoglutethimide and hydrocortisone were used alone, but serum sodium fell again when the diuretic was restarted. The serum sodium levels were subsequently maintained by the addition of fludrocortisone 100 micrograms daily.3 The hyponatraemia was thought to be caused by the combined inhibitory effect of the aminoglutethimide on aldosterone production (which normally retains sodium in the body) and the sodium loss caused by the diuretic. Plasma electrolytes should be monitored when aminoglutethimide is used, and this would seem particularly important if it is given with any diuretic.

5-Aminolevulinic acid + St John’swort (Hypericum perforatum)

An isolated case report describes a severe phototoxic reaction attributed to a synergistic effect of 5-aminolevulinic acid and St John’s wort.

Clinical evidence, mechanism, importance and management

A 47-year-old woman experienced a phototoxic reaction on skin areas exposed to light 6 hours after receiving 5-aminolevulinic acid 40 mg/kg. She developed a burning erythematous rash and severe swelling of the face, neck and hands. Treatment with oral corticosteroids resulted in complete resolution after skin desquamation. She was also taking St John’s wort. A 47-year-old woman experienced a phototoxic reaction on skin areas exposed to light 6 hours after receiving 5-aminolevulinic acid 40 mg/kg. She developed a burning erythematous rash and severe swelling of the face, neck and hands. Treatment with oral corticosteroids resulted in complete resolution after skin desquamation. She was also taking St John’s wort.

Anastrozole + Miscellaneous

Anastrozole does not appear to interact with aspirin, cimetidine, digoxin, oral antidiabetics or quinapril. It also appears to have no effect on cytochrome P450 enzymes, so it is unlikely to interact with drugs that are affected by enzyme inducers or inhibitors.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 10 elderly women with breast cancer were given anastrozole 1 mg daily for 10 weeks and 5 of them who also had hypertension were additionally given quinapril, after week 4, for 28 days. Quinapril did not affect plasma anastrozole levels and dose modification is not required during concurrent use.1 A clinical study with cimetidine has shown that it does not affect the pharmacokinetics of anastrozole,2 which suggests that anastrozole is unlikely to be affected by other drugs that inhibit cytochrome P450. Another clinical study showed that anastrozole does not affect the pharmacokinetics of antipyrine (phenazone),3 so that it is unlikely to interact with those drugs which are known to be affected by enzyme inducers and inhibitors.

The UK manufacturers also say that in clinical studies there was no evidence of any interactions between anastrozole and commonly used drugs: aspirin, digoxin, and oral antidiabetics were specifically mentioned in the early product information.5

Verapamil can increase the efficacy of doxorubicin in tissue culture systems and increase doxorubicin levels in patients. D-verapamil can alter the pharmacokinetics of epirubicin and possibly increase its bone marrow depressant effects.

Clinical evidence, mechanism, importance and management

(a) Doxorubicin

The efficacy of doxorubicin can be increased by verapamil and nifedipine in doxorubicin-resistant tissue culture systems,1 while nifedipine has only minimal activity. A study in five patients with small cell lung cancer given doxorubicin, vincristine, etoposide and cyclophosphamide showed that when they were given verapamil 240 to 480 mg daily the AUC of doxorubicin was doubled, its peak serum levels were raised and its clearance was reduced. No increased toxicity was seen in this study.2 However, although another study found no increase in non-cardiac toxicities, verapamil caused an unacceptable degree of cardiac toxicity.3 Be alert for this possibility if both drugs are used.

(b) Epirubicin

When used to reduce multidrug resistance in patients with advanced colorectal cancer receiving epirubicin, the D-isomer of verapamil appears to increase the bone marrow depressant toxicity of epirubicin.4 Another study found that D-verapamil halved the AUC and half-life of epirubicin, and increased its clearance,5 while yet another did not find these changes but found that the production of the metabolites of epirubicin was increased.6 These changes should be taken into account if both drugs are used. More study is needed to evaluate the possible advantages and disadvantages of giving these drugs together.

Antracyclines + Calcium-channel blockers

High-dose cyclosporin increases the serum levels and the myelotoxicity of doxorubicin. An isolated report describes severe neutropenia and coma in a patient who had taken cyclosporin and was then subsequently given doxorubicin. Cyclosporin can also increase daunorubicin, epirubicin, idarubicin and mitoxantrone serum levels.

Clinical evidence

(a) Daunorubicin

Eight patients with small cell lung cancer were given an initial course of doxorubicin (25 to 70 mg/m² over 1 hour) and a subsequent cyclosporin-modulated doxorubicin course (cyclosporin 6 mg/kg bolus then 16 mg/kg daily for 2 days) for multidrug resistant tumour modulation. All of the patients were also given cyclophosphamide and vincristine. Cyclosporin increased the AUC of doxorubicin by 48%, and that of its active metabolite doxorubicinol by 443%. The myelotoxicity was increased by concurrent use: the leucocyte count fell by 84% after doxorubicin and by 91% after doxorubicin with cyclosporin, and the platelet counts fell by 36% and 73%, respectively. The patients showed significant weight loss and severe myalgias.2

Three preliminary phase I studies3-5 are consistent with this report. In these studies, cyclosporin was found to increase the doxorubicin AUC by 40 to 73%, and the doxorubicinol AUC by 250 to 285%. However, no evidence of increased cardiotoxicity was found in a study of 23 patients given cyclosporin and doxorubicin.6

A cardiac transplant patient was given cyclosporin 2 mg/kg daily for 22 months. The cyclosporin was stopped and he was given doxorubicin 60 mg, vincristine 2 mg, cyclophosphamide 600 mg and prednisone 80 mg to treat Burkitt’s lymphoma stage IVB. Eight hours later he developed disturbances of consciousness which lead to stage I coma, from which he spontaneously recovered 12 hours later. A week later a similar course of chemotherapy was started, and 10 to 15 minutes later he lost consciousness and generalised tonic clonic seizures progressively developed. He died 8 days later without recovering consciousness.7

(b) Epirubicin

Preliminary evidence suggests that cyclosporin can markedly increase the AUC of epirubicin (up to about fourfold) and increase the bone marrow suppression.8 Cyclosporin did not increase the cardiotoxicity of epirubicin in 20 patients in one study.9

(c) Idarubicin

The concurrent use of cyclosporin and idarubicin increased the AUC of idarubicin and its active metabolite idarubicinol by 77% and 181%, respectively, in 9 patients, when compared with 11 patients receiving idarubicin alone.10 Unacceptable toxicity occurred when idarubicin 9 or 12 mg/m² daily was combined with cyclosporin 15–16 mg/kg daily, when compared with idarubicin 12 mg/m² alone: 3 of 7 patients treated with the combination died. Increases in the AUC of idarubicin and idarubicinol produced by cyclosporin have also been reported elsewhere.9

(e) Mitoxantrone

The pharmacokinetics of mitoxantrone 10 mg/m² daily were compared with mitoxantrone 6 mg/m² (a 40% reduction in dose) with high-dose cyclosporin in children. The cyclosporin recipients had a 42% reduction in mitoxantrone clearance, a 12% increase in mitoxantrone AUC, and similar toxicity.10
Mechanism

Uncertain. One reason may be that the ciclosporin affects the P-glycoprotein of the biliary tract so that the clearance of these anthracyclines in the bile is reduced. An additional reason may be that ciclosporin inhibits the metabolism of metabolites, such as doxorubicinol, so that it accumulates. The increased levels of both would explain the increases in toxicity. It is not clear why such severe neurotoxicity was seen in one patient.

Importance and management

An established and clinically important interaction. Ciclosporin alters the pharmacokinetics of the anthracyclines resulting in increased serum levels. This pharmacokinetic interaction has complicated study into the value of using ciclosporin to modulate multidrug resistance in tumours and thereby improve the response to chemotherapy. In the case of anthracyclines and 'etoposide', any benefit could just be attributed to dose intensification. Consequently, some have suggested reducing the dose of the anthracycline. The use of high-dose ciclosporin for multidrug resistant tumour modulation remains experimental and should only be used in clinical studies. Concurrent use should be very well monitored. More study is needed to find out the possible effects of low-dose ciclosporin.

The pharmacokinetics of doxorubicin were also increased and clearance was reduced by 71%. In 9 other patients given Caelyx with docetaxel 30 or 60 mg/m², the AUC of doxorubicin was increased by 12% and clearance reduced by only 16%. In a study, 627 patients with breast cancer were given either doxorubicin 50 mg/m² with docetaxel 75 mg/m², or doxorubicin 60 mg/m² with cyclophosphamide 600 mg/m² postoperatively for 4 courses to assess disease-free survival at 5 years. The study was terminated prematurely because of the high risk of life-threatening complications in those given doxorubicin with paclitaxel. A total of 22 deaths associated with drug toxicity and one case of perforated peritonitis in patients with febrile neutropenia). The incidence of febrile neutropenia was 40.8% and 7.1% in the doxorubicin-docetaxel and doxorubicin-cyclophosphamide groups, respectively.

A woman with recurrence of breast cancer developed pseudomembranous colitis (non-Clostridium difficile) and cholestatic jaundice 6 days after completing her first cycle of treatment with doxorubicin and docetaxel and again 4 days after the second cycle about one month later.

Anthracyclines + Taxanes

Toxicity associated with combinations of paclitaxel with doxorubicin or epirubicin depends on the order of administration. Some modest pharmacokinetic changes may occur when paclitaxel and epirubicin are given together. The combination of doxorubicin and paclitaxel is more cardiotoxic than doxorubicin alone: paclitaxel increases doxorubicin levels but doxorubicin does not alter paclitaxel levels. Docetaxel may modestly affect the pharmacokinetics of epirubicin and doxorubicin.

Clinical evidence

(a) Doxorubicin

Early studies in patients with breast cancer found a higher frequency of toxicity (particularly mucositis) when paclitaxel was given before doxorubicin (given as 24-hour and 48-hour infusions, respectively). A subsequent study with similar effects revealed that doxorubicin clearance was reduced by one-third if paclitaxel was given first. In another study the peak plasma levels of doxorubicin were increased when it was given by bolus injection 15 minutes after a 3-hour infusion of paclitaxel. The effect was non-linear and dependent on the dose of paclitaxel. The same authors had already shown that this regimen produced a higher than expected incidence of cardiac toxicity. Subsequent studies have shown this schedule to result in unacceptable cardiotoxicity when the total cumulative doxorubicin dose exceeds 340 to 380 mg/m². However, when paclitaxel and doxorubicin were given together as a 3-hour infusion the levels of doxorubicin were lower than when it was given before paclitaxel, and in another study the pharmacokinetics of each drug were found to be unchanged when they were given simultaneously as a 72-hour infusion.

In 10 patients the AUC of intravenous pegylated liposomal doxorubicin (Caelyx) 30 to 35 mg/m² was increased by a mean of 80% when it was given with intravenous paclitaxel 70 or 175 mg/m². Peak plasma levels of doxorubicin were also increased and clearance was reduced by 71%. In 9 other patients given Caelyx with docetaxel 30 or 60 mg/m², the AUC of doxorubicin was increased by 12% and clearance reduced by only 16%.

In a study, 627 patients with breast cancer were given either doxorubicin 50 mg/m² with docetaxel 75 mg/m², or doxorubicin 60 mg/m² with cyclophosphamide 600 mg/m² postoperatively for 4 courses to assess disease-free survival at 5 years. The study was terminated prematurely because of the high risk of life-threatening complications in those given doxorubicin with paclitaxel. In 22 deaths associated with drug toxicity and one case of perforated peritonitis in patients with febrile neutropenia). The incidence of febrile neutropenia was 40.8% and 7.1% in the doxorubicin-docetaxel and doxorubicin-cyclophosphamide groups, respectively.

A woman with recurrence of breast cancer developed pseudomembranous colitis (non-Clostridium difficile) and cholestatic jaundice 6 days after completing her first cycle of treatment with doxorubicin and docetaxel and again 4 days after the second cycle about one month later.

(b) Epirubicin

The pharmacokinetics of epirubicin were compared in 4 patients with breast cancer given intravenous epirubicin 90 mg/m² alone and 16 patients given the same dose followed immediately either by paclitaxel 175 mg/m² as a 3-hour infusion or docetaxel 70 mg/m² as a 1-hour infusion. Non-ethepidermic epirubicin levels was detected, but the concentrations of epirubicin metabolites (epirubicinol and deoxydoxorubicinol) were increased by both paclitaxel and docetaxel. In a subsequent study 21 patients were given the same regimen of epirubicin followed immediately by paclitaxel and 18 patients were given the drugs in the reverse order. Non-ethepidermic toxicity was unaffected by the order of administration but when paclitaxel was given first the neutrophil and platelet nadir was lower and neutrophil recovery was slower. The AUC for epirubicin was also higher when paclitaxel was given first but the pharmacokinetics of paclitaxel were unaffected. In one study, 21 women with breast cancer were given intravenous epirubicin 90 mg/m² followed 15 minutes later by a 3-hour intravenous infusion of paclitaxel 175 mg/m² (6 patients), 200 mg/m² (9 patients), or 225 mg/m² (6 patients). Six women were given paclitaxel 200 mg/m² 30 hours after epirubicin. A significant increase in the AUC of epirubicin occurred with paclitaxel 200 mg/m² (23%) and 225 mg/m² (34%) and increases in the AUC of the metabolite of epirubicin (epirubicinol) occurred at all dose levels of paclitaxel compared with those found when epirubicin was given 30 hours before paclitaxel.

In another study, exposure to epirubicin metabolites, but not epirubicin itself, was increased when it was given 15 minutes before a 3-hour infusion of paclitaxel, when compared to a regimen using a 24-hour interval between the two drugs. In addition, the neutrophil nadir was lower, and clearance of paclitaxel was 30% slower with the former regimen, but cardiac toxicity was uncommon. Conversely, a study of the combination of docetaxel and epirubicin did not find that the sequence of drug administration affected the pharmacokinetics of epirubicin, nor was there any difference in toxicity.

In another study, 16 patients with breast cancer had a transient but significant increase in epirubicin plasma levels during the subsequent infusion (after an interval of 1 hour) of docetaxel 75 mg/m², which was not seen if the docetaxel was given within 10 minutes of epirubicin.

Mechanism

Studies in mice have found that the taxanes docetaxel and paclitaxel, and the vehicle used for paclitaxel Cremophor, may all modify the distribution and metabolism of doxorubicin increasing its levels in the heart, liver and kidneys. This may contribute to the cardiac toxicity seen during use with paclitaxel. Similarly, in vitro studies in human myocardium showed that paclitaxel and docetaxel increased the conversion of doxorubicin to doxorubicinol, the metabolite that is thought to be responsible for cardiotoxicity.

An in vitro study on the effect of paclitaxel and Cremophor on epirubicin metabolism in human blood found that paclitaxel slightly decreased production of epirubicin. A marked inhibition of epirubicin production occurred in the presence of Cremophor, but because of the low
volume of distribution of Cremophor this is not likely to be of clinical significance. In addition, in vitro studies have shown that the taxanes may reduce the biliary excretion of doxorubicin and epirubicin by inhibiting P-glycoprotein, and inhibition of epirubicin excretion via competition for P-glycoprotein by paclitaxel and Cremophor may be significant.

The case of pseudomembranous colitis and cholestatic jaundice in one patient was attributed to the combination of docetaxel and doxorubicin, but the patient was also receiving long-term treatment with erythromycin and omeprazole which may have contributed to the interaction by inhibiting docetaxel metabolism by the cytochrome P450 isoenzyme CYP3A.

Importance and management

The effect of paclitaxel on doxorubicin appears to be established. It has been noted that when paclitaxel or docetaxel are given with pegylated doxorubicin, exposure to doxorubicin is increased by at least 50% and less than 20%, respectively and that this should be taken into account during concurrent use. Various strategies have been suggested to reduce the cardiotoxicity of the combination of doxorubicin and taxanes. These include giving doxorubicin at least 24 hours before paclitaxel; reducing the cumulative dose of doxorubicin; or adding the cytoprotective drug dexamethasone. Epirubicin is considered less cardiotoxic than doxorubicin, and may be an alternative in some situations. However, it still appears preferable to give the anthracycline before the taxane. Docetaxel appears to have little clinical relevance effect on epirubicin, but this requires confirmation. Further study is needed on the optimum scheduling of anthracyclines and taxanes to maximise efficacy and minimise toxicity.

Anthraclyclines; Aclarubicin + Other antineoplastics

The bone marrow depressant effects of aclarubicin can be particularly severe in patients who have previously been treated with nitrosoureas or mitomycin. Aclarubicin appears not to interact with cyclophosphamide, cytarabine, enocitabine (behenoyl cy tarabine), fluorouracil, mercaptopurine, tioguanine or vincristine.

Clinical evidence, mechanism, importance and management

Myelosuppression is among the adverse effects of aclarubicin. The concurrent use of other drugs with similar myelosuppressant effects may be expected to have additive effects. Previous treatment with nitrosoureas (not specifically named) or mitomycin has been shown to increase the severity of the myelosuppression.

Anthraclyclines; Doxorubicin + Barbiturates

The effects of doxorubicin may be reduced by the barbiturates.

Clinical evidence, mechanism, importance and management

A comparative study in patients given doxorubicin found that those also taking barbiturates had a plasma clearance that was 50% higher than those who were not (318 mL/minute compared with 202 mL/minute). This clinical study is in agreement with previous studies in mice. A possible explanation is that the barbiturate increases the metabolism of the doxorubicin. It seems possible that the dosage of doxorubicin will need to be increased in barbiturate-treated patients to achieve maximal therapeutic effects.

Anthraclyclines; Doxorubicin + Tamoxifen

Tamoxifen appears to have no significant effect on the pharmacokinetics of doxorubicin.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in patients with non-Hodgkin’s lymphoma receiving CHOP (cyclophosphamide, vincristine, prednisone and doxorubicin 37.5 to 50 mg/m²) found that the addition of tamoxifen 480 mg daily for 5 days had no significant effect on the AUC or total clearance of doxorubicin. For the possible additive thromboembolic effect of doxorubicin and tamoxifen, see ‘Antineoplastics + Tamoxifen’, p.616.

Anthraclyclines; Epirubicin + Citodetin

Citodetin can increase epirubicin serum levels.
Clinical evidence, mechanism, importance and management

In a study in 8 patients, cimetidine 400 mg twice daily increased the AUC of epirubicin by 50%. At the same time the AUCs of two metabolites of epirubicin, epirubincinol and 7-deoxyodoxorubicinol aglycone, increased by 41% and 357%, respectively. Liver blood flow also increased by 17%.1 The mechanism is unknown. More study of this interaction is needed but be aware of the possibility of cimetidine increasing the exposure to epirubicin; monitor the patient closely and adjust epirubicin dosage if needed. Cimetidine is available without a prescription in some countries so that patients may unwittingly increase the toxicity of epirubicin. Cimetidine has also increased the levels or toxicity of some other antineoplastics, see ‘Nitrosoureas + Cimetidine’, p.655, ‘Cyclophosphamide + H1-receptor antagonists’, p.626 and ‘Fluorouracil + H1-receptor antagonists’, p.633.

Antineoplastics + Aprepitant

Aprepitant had no effect on the pharmacokinetics of a single dose of docetaxel. The activation of cyclophosphamide and thiopeta was slightly lower in patients receiving aprepitant, but this was not clinically relevant. However, because of the possibility of increased toxicity the manufacturer recommends caution with antineoplastics principally metabolised by the cytochrome P450 isoenzyme CYP3A4, particularly irinotecan, and also etoposide, vinorelbine, paclitaxel, ifosfamide, imatinib, vinblastine and vincristine, although there appears to be some limited evidence of safe concurrent use.

Clinical evidence

(a) Cyclophosphamide

The rate of auto-induction of cyclophosphamid was 23% lower and exposure to the active metabolite 4-hydroxycyclophosphamide was 5% lower in 6 patients receiving aprepitant with a 4-day course of high-dose CTC (cyclophosphamide, thiopeta, carboplatin) when compared with 49 patients receiving high-dose CTC without aprepitant.1

(b) Docetaxel

Aprepitant 125 mg given one hour before docetaxel on day one, then 80 mg daily on days 2 and 3 had no effect on the pharmacokinetics of a single 60–100-mg/m2 infusion of docetaxel in 10 cancer patients, and did not alter the toxicity profile. Each subject acted as their own control.2

(c) Thiopeta

The formation clearance of thiopeta was 33% lower and exposure to the active metabolite TEPA (triethylenephosphamide) was 20% lower in 6 patients receiving aprepitant with a 4-day course of high-dose CTC (cyclophosphamide, thiopeta, carboplatin) when compared with 49 patients receiving high-dose CTC without aprepitant.1

Mechanism

In the short-term, aprepitant is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, and might therefore reduce the activation of antineoplastics activated by this isoenzyme (cyclophosphamide, thiopeta), or increase the toxicity of antineoplastics metabolised by this enzyme (docetaxel, irinotecan).

Importance and management

The UK manufacturer of aprepitant recommends caution when it is used with antineoplastics that are metabolised by CYP3A4, particularly irinotecan, because of the possibility of increased toxicity with this drug. They also mention that etoposide, vinorelbine, docetaxel, paclitaxel, ifosfamide, imatinib, vinblastine and vincristine, were given without dosage adjustment for potential interactions, but as this was not a formal interaction study they recommend caution. However, with intravenous docetaxel, it appears that no important changes in pharmacokinetics occur, and therefore dosage adjustments are unlikely to be needed for this drug, and possibly also other intravenous antineoplastics metabolised by CYP3A4.2 Similarly, the minor reductions in the activation of cyclophosphamide and thiopeta were considered small compared to total variability, and therefore unlikely to be clinically important.

Antineoplastics + Colon-stimulating factors

Because of the increased risk of myelosuppression, colony-stimulating factors such as filgrastim, lenograstim, and molgramostim should not be given at the same time as myelosuppressive cytotoxic antineoplastics.

Clinical evidence, mechanism, importance and management

Colony-stimulating factors such as filgrastim, lenograstim, and molgramostim promote the growth of myeloid cell lines. Since rapidly dividing myeloid cells have increased sensitivity to cytotoxic chemotherapy the manufacturers have advised that these drugs should not be used from 24 hours before until 24 hours after cytotoxic chemotherapy.1,2 In support of this, the manufacturer of filgrastim notes that preliminary evidence concerning the severity of neutropenia was exacerbated when patients were treated concurrently with fluorouracil and filgrastim.2 Note also that there is some evidence that colony-stimulating factors may potentiate the pulmonary toxicity of ‘bleomycin’, (p.618) and ‘cyclophosphamide’, (p.625).

Antineoplastics + 5-HT3-receptor antagonists

Some evidence suggests ondansetron may modestly affect the pharmacokinetics of cyclophosphamide and cisplatin but it does not appear to affect those of carmustine. Ondansetron did not affect the in vitro activity of epirubicin, bleomycin, cisplatin or estramustine. Cisplatin and fluorouracil do not affect the pharmacokinetics of ondansetron. In in vitro studies granisetron potentiated the cytotoxic effects of epirubicin, had an additive effect on bleomycin and estramustine activity and appeared not to affect the metabolism of docetaxel and paclitaxel.

Clinical evidence, mechanism, importance and management

(a) Granisetron

In an in vitro study, granisetron significantly potentiated the cytotoxic effects of epirubicin on fibroblasts, and the effect of granisetron on the cytotoxic effects of bleomycin and estramustine in lung cancer cells appeared to be additive. The clinical relevance of the effects of granisetron on epirubicin is not known.1 Another in vitro study found that granisetron did not affect the metabolism of docetaxel or paclitaxel.2

(b) Ondansetron

The pharmacokinetics of high-dose cyclophosphamide, cisplatin and carmustine in 23 patients given ondansetron, lorazepam and diphenylhydramine as antiemetics were compared with those in 129 patients who received prochlorperazine instead of ondansetron. It was found that the AUCs of cyclophosphamide and cisplatin, but not that of carmustine, were significantly lower (by 15% and 19%, respectively) in the ondansetron group.2 Similarly, in another study, the pharmacokinetics of antineoplastics were analysed in 54 patients with breast cancer who were receiving high-dose cyclophosphamide, cisplatin and carmustine with lorazepam and ondansetron with or without prochlorperazine and com-
pared with 75 matched control patients whose had been given prochloper-
azine and lorazepam. In those given ondansetron the median AUC of
cyclophosphamide was 17% lower, the cisplatin AUC was about 10% higher and the carmustine AUC was unchanged.\(^1\) In contrast, a study in
10 patients who received intravenous cyclophosphamide 600 mg/m\(^2\) and
epirubicin 90 mg/m\(^2\) and either oral ondansetron 16 mg or placebo found
that the pharmacokinetic parameters of cyclophosphamide or its metabo-
olite were not significantly altered by ondansetron although there was con-
siderable variation between subjects. It was concluded that ondansetron
can be safely given with cyclophosphamide.\(^5\) No significant changes in the pharmacokinetics of ondansetron occurred in 20 cancer patients taking
cisplatin 20 to 40 mg/m\(^2\) and/or fluorouracil 1 g/m\(^2\) for 5 days but the
clearance was lower than in healthy subjects.\(^6\)

An in vitro study found that ondansetron did not affect the cytotoxic ef-
efts of bleomycin, epirubicin, estramustine or cisplatin in fibroblasts and
lung cancer cells.\(^1\)

Information seems to be limited to these studies, and the interactions are not established. The clinical relevance of these possible modest changes in
AUC of cyclophosphamide (0 to 17% reduction) and cisplatin (19% reduc-
tion or 10% increase) remain to be determined.

Antineoplastics + Megestrol

There is some in vitro evidence to suggest that megestrol acetate
may antagonise the antitumour activity of cisplatin. In one clini-

cal study megestrol reduced the response rates to etoposide with
but in another had no effect on response rates to alter-

nating cycles of cyclophosphamide, doxorubicin and vincristine,
and etoposide with cisplatin.

Clinical evidence

A study in 243 patients with advanced small-cell lung cancer (SCLC)
treated with etoposide and cisplatin found that those who also received megestrol acetate 800 mg daily had increased non-fluid body-weight and
significantly less nausea and vomiting. Although the 1-year survival rate
was worse than use of meg-

diated drug resistance in the first-line management of small-cell lung carcinoma. Br J Cancer

Antineoplastics + Protopofol

There are two isolated reports of severe pain occurring when pa-
ients who had previously received intravenous chemotherapy
were given intravenous propofol via hand veins.

Clinical evidence, mechanism, importance and management

Although pain on injection of propofol is well known one group of work-
ers noted that on a number of occasions patients previously treated with
intravenous chemotherapy had marked pain, both at the site of injection
and up the arm, when given propofol via hand veins.\(^1\) This would seem to
link with a report of a 15-year-old girl with acute lymphoblastic leukaemia
who had been treated with several injections of cyclophosphamide, methotrexate and vincristine during the previous 6 months, and who was
hamulatted in her hand and given an infusion of Plasmapyte B. An injection
of 60 micrograms of fentanyl via this cannula was painful and 20 mg of
lidocaine helped, but 20 mg of propofol caused extreme pain. A further
20 mg of lidocaine was given and the propofol administration was stopped,
but the pain continued. The whole hand became blue and con-
gested, and blood began to move backwards up the drip tubing. The ve-

nous congestion gradually subsided over the next 15 minutes.\(^2\) The
authors recommended that propofol should be avoided in patients who
have recently had intravenous chemotherapy.\(^2\) The general applicability of
these reports remains to be determined. The use of propofol alone may
cause pain and it should be noted that the manufacturers of propofol rec-

commend that local pain associated with propofol during the induction
phase can be minimised by the use of the larger veins on the forearm and
antecubital fossa.\(^3\)

Antineoplastics + Protease inhibitors

Use of protease inhibitor-based regimens has been found to be as-

ociated with a higher incidence of infections and neutropenia in
patients receiving cyclophosphamide, doxorubicin and etoposide (CDE)
than use of a NNRTI-based regimen.

Clinical evidence, mechanism, importance and management

A study to compare the incidence of neutropenia and infection resulting
from protease inhibitor or NNRTI-based antiretroviral regimen given with
cyclophosphamide, doxorubicin and etoposide (CDE) chemotherapy
for AIDS-related non-Hodgkin’s lymphoma was carried out in 46 patients
wit h AIDS-related non-Hodgkin’s lymphoma. Eleven patients were tak-
ing protease inhibitor-based antiretroviral treatment. There was a higher
incidence of infections requiring hospitalisation in the group taking a pro-

tease inhibitor than in the NNRTI-based treatment group (48% compared
with 25%). There was a similar difference in the incidence of grade 4 neu-

tropenia (54% compared with 38%) and day 10 and day 14 neutrophil

counts were significantly lower in patients receiving protease inhibitors,
resulting in delays in giving chemotherapy in 16% of cycles (compared
with 9% when no protease inhibitor was given). Overall, however, there
was no difference in response rate, disease-free survival or overall survival

diated drug resistance in the first-line management of small-cell lung carcinoma. Br J Cancer
between the two groups. The authors suggested that the increase in myelosuppression may be caused by the protease inhibitors reducing the metabolism of CDE via inhibition of cytochrome P450 enzymes, or inhibition of P-glycoprotein. 

Inhibitors of CYP3A4 may increase toxicity with etoposide, see ‘Etoposide + CYP3A4 inhibitors’, p.631.

Antineoplastics + Semaxanib

The combination of semaxanib, cisplatin and gemcitabine has caused an unexpectedly high incidence of thromboembolic events.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of semaxanib (SU5416), cisplatin and gemcitabine were unaltered when they were given together in a phase I study but investigation of the combination was terminated after 8 of the 19 patients had thromboembolic events (transient ischaemic attacks, cerebrovascular accidents, deep vein thromboses). Gemcitabine 1250 mg/m² was given on day 1, immediately followed by cisplatin 80 mg/m², then semaxanib 85 mg/m² (escalated to 145 mg/m² in some patients). Gemcitabine then semaxanib were given on day 8, and semaxanib alone on days 4, 11, 15, and 18. The cycle was repeated every 3 weeks. 

The incidence of thromboembolic events in this study (42%) was much higher than that seen with cisplatin and gemcitabine (0%) or semaxanib alone (2.2%), and was thought to be a result of the drug combination. 

Cisplatin in particular, due to its effects on platelets and its vasoconstrictive effects, may be the drug interacting with the semaxanib. 

Preliminary results of other studies of semaxanib with: 

- irinotecan; 
- fluorouracil and folinic acid; 
- irinotecan, fluorouracil and folinic acid; 
- paclitaxel and carboplatin did not report this complication. 

The authors of the first study cautioned against further clinical trials of antineoplastics with angiogenesis inhibitors such as semaxanib until the exact cause of the thromboembolic events has been elucidated.

2. Marx GM, Steer CB, Harper P, Pavlakis N, Rice O, Khayat D. Unexpected serious toxicity of semaxanib, cisplatin and gemcitabine has caused an unexpectedly high incidence of thromboembolic events. The combination of semaxanib, cisplatin and gemcitabine has caused an unexpectedly high incidence of thromboembolic events. The combination of semaxanib, cisplatin and gemcitabine has caused an unexpectedly high incidence of thromboembolic events.

Antineoplastics + Vaccines

The immune response of the body is suppressed by cytotoxic antineoplastics. The effectiveness of vaccines may be poor and generalised infection may occur in patients immunosuppressed with live vaccines.

Clinical evidence, mechanism, importance and management

Since cytotoxic antineoplastics are immunosuppressant, they reduce the response of the body to immunisation. A study in 53 patients with Hodgkin’s disease showed that chemotherapy reduced the antibody response to a pneumococcal vaccine by 60% when measured 3 weeks after immunisation.

The patients were taking chlorothemine (methlocrethamine), vincristine, prednisone and procarbazine. A few of them had also been given bleomycin, vinblastine or cyclophosphamide. Subtotal radiotherapy reduced the response by a further 15%. The response to influenza immunisation in children with various malignancies was also markedly suppressed by chemotherapy. The regimen included prednisone and the cytotoxic drugs mercaptopurine, methotrexate, and vincristine. Some of them were also given dactinomycin and cyclophosphamide. In another study only 9 out of 17 children with leukaemia or other malignant diseases and taking methotrexate, cyclophosphamide, mercaptopurine and prednisone developed a significant response to immunisation with inactivated measles vaccine.

Furthermore, immunisation with live vaccines may result in a potentially life-threatening infection. For example, a woman taking methotrexate 15 mg once a month for psoriasis developed a generalised vaccinal infection after vaccination against smallpox. She died in meningitis given smallpox vaccine and confirmed that they were more susceptible to infection if they had been given methotrexate, mercaptopurine or cyclophosphamide. 

Extreme care should therefore be exercised when using live vaccines for immunisation of patients who are receiving cytotoxics or other immunosuppressant drugs (see also ‘Corticosteroids + Vaccines; Live’, p.1061, and ‘Immunosuppressants + Vaccines’, p.1064).

Bexarotene + Miscellaneous

Gemfibrozil raises bexarotene plasma levels. The manufacturers warn that, theoretically, inhibitors of CYP3A4 (azoles, grapefruit juice, protease inhibitors and some macrolides) may possibly raise bexarotene levels, whereas CYP3A4 inducers (phenytoin, phenobarbital, rifampicin (rifampin)) may possibly reduce them. They also suggest that the efficacy of oral contraceptives may be reduced, and increased blood glucose-lowering effects may occur with insulin or oral antidiabetic drugs. No interaction seems to occur between bexarotene and atorvastatin or levotryoxine.

Clinical evidence, mechanism, importance and management

(a) Effects of enzyme inducers and inhibitors

Because it is known that bexarotene is metabolised by the cytochrome P450 isozyme CYP3A4, the manufacturers point out that there is a theoretical risk that drugs that inhibit CYP3A4 might increase bexarotene levels. They list clarithromycin, erythromycin, itraconazole, ketoconazole, protease inhibitors and grapefruit juice as possible interacting drugs because of their known inhibitory effects on CYP3A4. They also list a number of known CYP3A4 inducers, namely dexamethasone, phenytoin, phenobarbital and rifampicin (rifampin), because they may theoretically increase the metabolism of bexarotene and reduce its levels.1,2

The manufacturers also say that because bexarotene can induce liver enzymes, it may theoretically increase the metabolism of other substances metabolised by CYP3A4 such as tamoxifen and the steroids in oral or other systemic contraceptives, thereby reducing both their serum levels and their efficacy. For this reason they advise the use of additional non-hormonal contraception (e.g. a barrier method) to avoid the risk of contraceptive failure. They point out that this is particularly important because if failure were to occur, the foetus might be exposed to the teratogenic effects of bexarotene.1,2

(b) Other possible drug interactions

A population analysis of patients with cutaneous T-cell lymphoma found that the concurrent use of gemfibrozil substantially increased the plasma levels of bexarotene. The reasons for this effect are unknown, although inhibition of CYP3A4 by gemfibrozil may be partially responsible.1 The US manufacturers state concurrent use is not recommended, but note that fibrates are not generally recognised as inhibitors of this isozyme, see ‘Lipid regulating drugs’, (p.1086). Under similar conditions, they say that bexarotene levels were not affected by atorvastatin or levothyroxine. Changes in thyroid function caused by bexarotene have been successfully treated with thyroid hormone supplements.1,3

The manufacturers recommend that because bexarotene is related to vitamin A, any vitamin A supplements should be limited to 15 000 units or less daily to avoid potentially additive toxic effects. They also say that although no cases of hypoglycaemia have been seen, because of the known mode of action of bexarotene it should be used with caution if given with insulin or drugs that enhance insulin secretion (e.g. sulfonylureas) or insulin sensitisers (e.g. thiazolidinediones).1,2 For a list of these drugs see ‘Table 13.1’, (p.469).

Bicalutamide + Phenazone (Antipyrine)

The results of an interaction study between bicalutamide and phenazone suggest that bicalutamide is unlikely to interact with other drugs through enzyme induction.

Clinical evidence, mechanism, importance and management

The pharmacokinetics and metabolism of phenazone (largely used as an investigational marker drug of enzyme induction or inhibition) were studied in two groups of patients with prostate cancer before and after they took either bicalutamide 50 mg daily (7 patients) or 150 mg daily (11 patients) for 12 weeks. Small changes in the phenazone pharmacokinetics were found (half-life reduced by 16.3% with the 50 mg bicalutamide dose, AUC reduced by 18.6% with the 150 mg bicalutamide dosage). Nevertheless it was considered that bicalutamide does not significantly induce the liver enzymes responsible for the metabolism of phenazone and is therefore unlikely to interact with any other drugs by causing enzyme induction.1

Bleomycin + Cisplatin

Cisplatin can increase the pulmonary toxicity of bleomycin by reducing its renal excretion. Digital ischaemia and arterial thrombosis have also been described in patients receiving both drugs.

Clinical evidence

Thirty patients with carcinoma of the cervix and 15 patients with germ cell tumours were given combination chemotherapy including bleomycin and cisplatin. Cisplatin was given by infusion on day 1, followed by bleomycin given intramuscularly every 12 hours for 4 days or by continuous infusion over 72 hours. Nine of the patients with normal renal function and no previous pulmonary disease developed serious pulmonary toxicity and 6 died from respiratory failure.1

In a study of 18 patients given cisplatin and bleomycin for the treatment of disseminated testicular non-seminoma, 2 patients developed pneumonitis, and it was found that the cisplatin-induced reduction in renal function was paralleled by an increase in bleomycin-induced pulmonary toxicity.2 Similar results were found in a much larger study of 54 patients by the same group.3 A study in 2 children showed that the total plasma clearance of bleomycin was halved (from 39 to 18 mL/minute/m²) when they were also given cisplatin in cumulative doses exceeding 300 mg/m². The renal clearance in one of the children fell from 30 to 8.2 mL/minute/m² although there was no evidence of severe bleomycin toxicity in either child.4 Two cases of fatal bleomycin toxicity have been described in patients with cisplatin-induced renal impairment.5,6

A case report describes arterial thrombosis associated with pathological vascular changes in the arteries of a man treated with cisplatin, bleomycin and etoposide.7 Another man developed fatal thrombotic microangiopathy (characterised by microangiopathic haemolytic anaemia, thrombocytopenia, renal impairment), which was attributed to the use of bleomycin and cisplatin.8

In an earlier study, digital ischaemia occurred in 41% of patients treated with cisplatin, bleomycin and vinblastine compared with 21% of patients treated with only cisplatin and vinblastine.9

Mechanism

Renal excretion accounts for almost half of the total body clearance of bleomycin. Cisplatin is nephrotoxic and reduces the glomerular filtration rate so that the clearance of bleomycin is reduced. The accumulating bleomycin apparently causes the pulmonary toxicity.

Importance and management

Pulmonary toxicity with bleomycin is an established reaction with a potentially serious, sometimes fatal, outcome. Concurrent use should be very closely monitored and renal function checked. One of the problems is that levels of creatinine may not accurately indicate the extent of renal damage both during and after cisplatin treatment. The renal toxicity of cisplatin may also develop rapidly. Other toxic effects on the vascular system can also occur.

Bleomycin + Colony-stimulating factors

The concurrent use of granulocyte-colony-stimulating factor or granulocyte-macrophage colony-stimulating factor has been linked with an increased occurrence of bleomycin-induced pulmonary toxicity.

Clinical evidence, mechanism, importance and management

Pulmonary toxicity that developed at low cumulative bleomycin doses (70 to 130 units/m²) in at least 3 of 5 patients given standard ABVD treatment (doxorubicin, bleomycin, vinblastine, and dacarbazine) was attributed by the author of the report to the synergistic action of concurrent treatment with G-CSF (granulocyte-colony-stimulating factor).1 In another report 8 out of 40 patients with malignant non-Hodgkin’s lymphoma given G-CSF developed drug-induced pneumonia. Three of these patients were treated with chemotherapy regimens including bleomycin (MACOB-B, COP-BLAM III), and all 3 died of respiratory failure. None of 35 other patients, similarly treated but without G-CSF, developed pneumonia.2 Non-infectious interstitial pneumonitis developed in a patient given doxorubicin, cyclophosphamide, bleomycin, vinblatine, methotrexate and prednisone with GM-CSF (granulocyte-macrophage colony-stimulating factor).3 Five further reports have identified a total of 23 other patients who developed bleomycin-pulmonary toxicity probably potentiated by G-CSF or GM-CSF, including at least 7 fatalities.4-8

In contrast, analysis of two placebo-controlled studies of the use of adjuvant G-CSF (filgrastim or lenograstim) with combination chemotherapy including bleomycin found no evidence of an increase in pulmonary complications. Overall 7 of 139 patients treated with placebo and 9 of 139 treated with the G-CSF had pulmonary complications possibly related to bleomycin.9,10 Similarly, another retrospective analysis, found that 34% of patients treated with bleomycin and G-CSF developed pulmonary toxicity, compared with 33% of those treated with bleomycin alone.11

These interactions are not firmly established, but good pulmonary function monitoring appears to be advisable when colony-stimulating factors are used with antineoplastics causing pulmonary toxicity, such as bleomycin. If interstitial pneumonia occurs, the drugs should be discontinued and high-dose corticosteroids started immediately.2 More study is needed.

Consider also ‘Cyclophosphamide + Colony-stimulating factors’, p.625.

Clinical evidence

Bleomycin + Oxygen

Serious and potentially fatal pulmonary toxicity can develop in patients treated with bleomycin who are exposed to conventional oxygen concentrations during anaesthesia.

Clinical evidence

Five patients treated with bleomycin, exposed to oxygen concentrations of 35 to 42% during and immediately following anaesthesia, developed a severe respiratory distress syndrome and died. Bleomycin-induced pneumonitis and lung fibrosis were diagnosed at post-mortem. Another group of 12 matched patients who underwent the same procedures but with lower oxygen concentrations (22 to 25%) had an uneventful postoperative course.1

Another comparative study2 similarly demonstrated that adult respiratory distress syndrome (ARDS) in patients receiving bleomycin was reduced by a technique allowing the use of lower oxygen concentrations of 22 to 30%. Bleomycin-induced pulmonary toxicity, apparently related to oxygen concentrations, has also been described in other case reports.3,7 Studies in animals have also confirmed that the severity of bleomycin-induced pulmonary toxicity is increased by oxygen.8,10 However, in two other series of patients treated with bleomycin and undergoing surgery there was no obvious increase in pulmonary complications despite the use of usual concentrations of oxygen.11,12

Mechanism

Not understood. One suggestion is that bleomycin-injured lung tissue is less able to scavenge free oxygen radicals, which may be present, and damage occurs as a result.3

Importance and management

An established, well-documented, serious and potentially fatal interaction. It is advised that any patient receiving bleomycin and undergoing general anaesthesia should have their inspired oxygen concentrations limited to less than 30%, and the fluid replacement should be carefully monitored to minimise the crystallloid load. This is clearly very effective because one author has treated 700 patients following these guidelines without a single case of pulmonary failure.13 It has also been suggested that reduced oxygen levels should be continued during the recovery period and at any time during hospitalisation.3 If an oxygen concentration equal to or greater than 30% has to be used, the short-term use of prophylactic corticosteroids should be considered. Intravenous corticosteroids should be given at once if bleomycin toxicity is suspected.3

Busulfan + Azoles

Itraconazole, but not fluconazole, modestly reduces the clearance of busulfan. There is some limited evidence to suggest that the use of busulfan with ketoconazole may increase the risk of hepatic veno-occlusive disease.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of busulfan in 26 bone marrow transplant patients, who had received busulfan without concurrent antifungal therapy, were compared with those in 13 similar patients given busulfan with itraconazole and in 13 given busulfan with fluconazole. The busulfan clearance was decreased by 20% by itraconazole (probably because itraconazole inhibits the metabolism of busulfan by the liver) but busulfan clearance
was not affected by the fluconazole. The expected rise in serum busulfan levels is only likely to be moderate, but until more information is available it would be prudent to monitor for any signs of increased busulfan toxicity if itraconazole is used, but no special precautions seem to be needed with fluconazole. Concurrent ketoconazole has been identified as a possible risk factor for hepatic veno-occlusive disease after high-dose busulfan.

Further study is needed to confirm this.

Mechanism

It seems likely that the phenytoin (a well recognised enzyme inducer) increases the metabolism of the busulfan by the liver, thereby decreasing its levels. In an animal study, phenytoin was found to reduce the myelo-suppressive effects of busulfan.

Importance and management

The authors of one study suggest that antiepileptics with fewer enzyme-inducing properties than phenytoin should be used as prophylaxis if busulfan is given for bone marrow transplant pretreatment. One UK manufacturer recommends prophylaxis with a benzodiazepine rather than phenytoin if high-dose busulfan is given. ‘Clobazam’, (p.619), has been suggested as a possible alternative to phenytoin.

The UK manufacturer of parenteral busulfan found no evidence that phenytoin increased its clearance. However, the US manufacturer of parenteral busulfan gives a dose assuming that phenytoin will also be given, and notes that if other antiepileptics are used instead, the busulfan plasma levels may be increased and monitoring is recommended.

To overcome the problem of reduced phenytoin levels, the authors recommended a loading dose of phenytoin 18 mg/kg on the day before the first dose of busulfan, then 300 mg daily until 48 hours after the last busulfan dose. A further loading dose was given if the phenytoin level was subtherapeutic 48 hours after the initial dose (required in 35% of patients).

2. Chan KW, Mullen CA, Worth LL, Choroszy M, Koontz S, Tran H, Slopis J. Lorazepam for seizure prophylaxis during high-dose busulfan treatment.2

Busulfan + Tioguanine

There is evidence that the long-term use of busulfan with tioguanine increases the risk of nodular regenerative hyperplasia of the liver, portal hypertension and oesophageal varices.

Clinical evidence, mechanism, importance and management

Five patients receiving continuous busulfan 2 mg and tioguanine 80 mg five days weekly for chronic myeloid leukaemia (CML) developed oesophageal varices and abnormal liver function tests. Three of them had gastrointestinal haemorrhages and one died. Liver biopsy of 4 of the patients showed nodular regenerative hyperplasia, which was the cause of portal hypertension and varices. A later analysis of the Medical Research Council study comparing busulfan with busulfan and tioguanine in 675 patients with CML, revealed a total of 18 cases of portal hypertension and oesophageal varices (including 4 described in the first report), all 18 of which occurred in patients receiving both drugs. In addition, there was no survival advantage with the combination. The risk of portal hypertension may be related to long-term use of tioguanine, or to its combination with busulfan. This drug combination should not be routinely used for long-term maintenance therapy of CML.

Cetuximab + Irinotecan

No pharmacokinetic interaction occurs between cetuximab and irinotecan.
An isolated report describes seizures in a patient, which were possibly caused by the use of chlorambucil with prednisone.

Cisplatin + Aminoglycosides

The renal toxicity of cisplatin is potentiated by aminoglycoside antibacterials such as gentamicin and tobramycin. Extra care is required in patients treated with cisplatin requiring these antibacterials. In one retrospective analysis in patients taking cisplatin, hearing loss was not associated with the concurrent use of ototoxic drugs, including tobramycin.

Clinical evidence

(a) Hypomagnesaemia

Both cisplatin and the aminoglycosides can cause excessive loss of magnesium, and it has been suggested that combined use increases this loss.

(b) Nephrotoxicity

Early after the introduction of cisplatin it became apparent that aminoglycosides could increase the nephrotoxicity of this drug. In one report, 4 patients treated with cisplatin, in dosages ranging from low to very high (eight doses of 0.5 mg/kg, one or two doses of 3 mg/kg or a single-dose of 5 mg/kg), and who were subsequently given gentamicin and cefalotin developed acute and fatal renal failure. Autopsy revealed extensive renal tubular necrosis.

Two similar cases of severe renal toxicity, attributed to the use of gentamicin and cefalotin in patients who had previously been given cisplatin, are described elsewhere. Another patient treated with cisplatin and gentamicin developed acute renal failure. A further 3 patients treated with cisplatin then gentamicin or tobramycin had greater decreases in creatinine levels than 12 others receiving cisplatin alone. A retrospective comparative study confirmed that the incidence of abnormal renal function was higher in patients who had received cisplatin and an aminoglycoside than in patients who had received cisplatin alone (12 of 17 versus 19 of 50 patients, respectively), but the renal impairment was described as usually mild and not clinically significant. Similarly, a brief report stated that aminoglycoside use was associated with a greater decline in renal function in children receiving high-dose cisplatin.

Conversely, in another study aminoglycosides were not found to be a significant factor in the development of renal impairment after the use of high-dose cisplatin-based therapy, and use of appropriate supportive care (hydration and mannitol diuresis) probably played a part in this.

There is also evidence from a study in children to show that previous treatment with cisplatin is a risk factor for the delayed elimination of aminoglycosides (gentamicin, amikacin, tobramycin).

(c) Otoxicity

In one small retrospective analysis of cancer patients, the risk of developing hearing loss after low-dose, low-infusion cisplatin did not correlate significantly with the concurrent use of other ototoxic drugs, such as furosemide or tobramycin. Enhanced renal toxicity and ototoxicity have been reported in guinea pigs given cisplatin and kanamycin for 2 weeks.

In another animal study gentamicin was given for 14 days. A single dose of cisplatin given early in the course enhanced the ototoxic effects of gentamicin but no increase in ototoxicity occurred when cisplatin was given at the end of the gentamicin course.

Mechanism

Cisplatin is nephrotoxic and it would appear that its damaging effects on the kidney are additive with the nephrotoxic effects of the aminoglycoside antibacterials. Both gentamicin and cisplatin may cause ototoxicity. Previous exposure to cisplatin caused a significant decrease in gentamicin clearance in rats.

Importance and management

An established and potentially serious interaction. However, aminoglycosides remain an important group of antibacterials for the empirical treatment of febrile neutropenia in patients receiving chemotherapy, including cisplatin-based regimens. However, in selecting an initial antimicrobial regimen, it has been suggested that concurrent use of some drugs, including cisplatin and aminoglycosides, should be avoided if possible because of additive renal toxicity. Good supportive care is required (e.g. pre and post-treatment hydration with mannitol diuresis), and renal function should be well monitored. Audimetric tests should be carried out when cisplatin is used, particularly when other ototoxic drugs are also given.

A single report describes the development of renal failure in a patient treated with furosemide and other antihypertensives during cisplatin therapy. However, note that furosemide can be used to promote diuresis during cisplatin therapy to reduce the risk of nephrotoxicity. Although animal studies show that the damaging effects of cisplatin on the ear can be markedly increased by the concurrent use of etacrynic acid or furosemide, a retrospective analysis in patients did not find this effect.

Clinical evidence, mechanism, importance and management

(a) Nephrotoxicity

Three hours after receiving intravenous cisplatin 70 mg/m² a patient experienced severe nausea and vomiting and his blood pressure rose from 150/90 to 248/140 mmHg. This was managed with furosemide 40 mg intravenously, hydralazine 10 mg intramuscularly, diazoxide 300 mg intravenously and propranolol 20 mg orally twice daily for 2 days. Nine days later the patient showed evidence of renal impairment (creatinine raised from about 88 micromol/L to 283 micromol/L), which resolved within 3 weeks. The patient was subsequently similarly treated on two occasions with cisplatin and again developed hypertension, but no treatment was given and there was no evidence of renal impairment.1

The reasons for the renal impairment are not known, but a study in rats2 indicated that kidney damage may possibly be related to the concentrations of cisplatin, and that furosemide can increase cisplatin levels in the kidney. However, another study in patients found that there was no difference in the toxicity or pharmacokinetics of cisplatin when furosemide was used to induce diuresis, compared with mannitol.3 Two other studies have also found that furosemide does not alter cisplatin pharmacokinetics.4,3 An other study showed that sodium chloride solution with or without furosemide was associated with less cisplatin nephrotoxicity than sodium chloride solution with mannitol.5

Information seems to be limited to the case cited and its general clinical importance is uncertain. Although mannitol is by far the more usual drug used to induce diuresis during the use of cisplatin in order to reduce the risk of nephrotoxicity, furosemide may also be used for this indication.7

(b) Ototoxicity

Both cisplatin and loop diuretics such as etacrynic acid and furosemide given alone can be ototoxic in man. A study in guinea pigs showed that when cisplatin 7 mg/kg or etacrynic acid 50 mg/kg were given alone their ototoxic effects were reversible, but when given together the damaging effects on the ear were profound, prolonged and possibly permanent. Similarly, while cisplatin-induced ototoxicity was potentiated by furosemide in guinea pigs,4,5 in one study6 another this was only seen when a very high dose of furosemide was used.10 In one small retrospective analysis of cancer patients, the risk of developing hearing loss after low-dose slow-infusion cisplatin did not correlate significantly with concurrent use of other ototoxic drugs, such as furosemide.9 Audiometric tests should be carried out when cisplatin is used, and this is of particular importance when other ototoxic drugs are also given.

Cisplatin + Probenecid

The available clinical data suggest that the nephrotoxicity of cisplatin is reduced by probenecid, but uncertainty remains.

Cisplatin + H₂-receptor antagonists

Cimetidine and ranitidine probably do not have a clinically relevant effect on the renal clearance of cisplatin.

Clinical evidence, mechanism, importance and management

Some animal studies have shown that organic cations such as cimetidine and ranitidine may compete with the renal tubular transport of cisplatin and thus could be useful in reducing cisplatin nephrotoxicity.8,9 However, in a study of 10 children receiving cisplatin, ranitidine had no effect on the total body disposition or renal clearance of cisplatin. This finding and further studies in dogs showed that cisplatin may not share transport systems with organic cations to a clinically relevant extent.8 Although information is limited, it appears that there is no interaction between cisplatin and cimetidine or ranitidine. Note that cimetidine has increased the levels or toxicity of some other antineoplastics, see ‘Nitrosoureas + Cimetidine’, p.565, ‘Cyclophosphamide + H₂-receptor antagonists’, p.626, ‘Anthracyclines; Epirubicin + Cimetidine’, p.613, and ‘Fluorouracil + H₂-receptor antagonists’, p.633.

Clinical evidence, mechanism, importance and management

In a randomised study in cancer patients, probenecid 2 to 4 g daily reduced the fractional clearance of free platinum after a single 60- to 100-mg/m² dose of cisplatin given as a 24-hour infusion, and no cases of renal impairment were seen.1 Similarly, in a further phase I dose-escalation study no renal impairment was seen in patients given cisplatin at doses from 100 to 160 mg/m² when they were also given probenecid 1 g every 6 hours for 12 doses (beginning 24 hours before the cisplatin infusion, and continuing for 24 hours after).2 It was concluded that probenecid may protect against cisplatin-induced renal toxicity. An earlier study in rats had also suggested that giving probenecid before cisplatin reduced nephrotoxicity, as assessed by blood urea levels and serum creatinine.3 Subsequently, a study in dogs has found that probenecid decreases the renal clearance of free cisplatin,4 and another in mice found that probenecid reduces the renal tubular damage seen with cisplatin alone.5

Conversely, some researchers have suggested that the combination of probenecid and cisplatin is potentially more toxic than cisplatin alone. They found that probenecid increased the fractional clearance of free platinum from cisplatin in rats, and that pretreatment with probenecid increased nephrotoxicity, as assessed by blood urea levels.6 Other authors similarly reported that probenecid increased cisplatin clearance in rats.7 It is unclear why some animal studies show that probenecid increases cisplatin-induced nephrotoxicity whereas others show a decrease. Although the available clinical data suggest that there is a decrease, some uncertainty remains. The combination should be used with caution.

Cyclophosphamide + Allopurinol

There is some evidence to suggest that the incidence of serious bone marrow depression caused by cyclophosphamide can be increased by allopurinol, but this was not confirmed in a controlled study. Allopurinol may prolong the half-life of cyclophosphamide and increase the levels of its cytotoxic metabolites.

Clinical evidence

A retrospective epidemiological survey of patients in four hospitals who, over a 4-year period, had been treated with cyclophosphamide, found that the incidence of serious bone marrow depression was 57.7% in 26 patients who had also received allopurinol, and 18.8% in 32 patients who had not.1 A pharmacokinetic study in 9 patients with malignant disease and 2 healthy subjects showed that while taking allopurinol 600 mg daily the concentration of the cytotoxic metabolites of cyclophosphamide increased by an average of 37.5% (range 1.5 to 110%).2 Another pharmacokinetic study reported that the half-life of cyclophosphamide was more than two-fold longer in 3 children also receiving allopurinol 300 mg/m², when compared with that in children not given allopurinol.3 However, another study found that although allopurinol pre-treatment increased the half-life of cyclophosphamide, the plasma alkylating activity and urinary metabolite and cyclophosphamide excretion were unchanged.4 Moreover, a randomised controlled study, designed as a follow-up to the survey cited above,1 failed to confirm that allopurinol increased the toxicity of cyclophosphamide in 81 patients with Hodgkin’s or non-Hodgkin’s lymphoma. In this study, there was no difference in nadirs for white blood cells and platelets during 3 cycles of cyclophosphamide-containing chemotherapy in 44 patients receiving allopurinol and in 37 patients not receiving allopurinol.5

Mechanism

Not understood. Cyclophosphamide itself is inactive, but it is converted by the liver into cytotoxic metabolites.4 Allopurinol or its metabolite oxypurinol may inhibit their renal excretion, or may alter hepatic metabolism.2,3

Importance and management

This interaction is not established with any certainty. The authors of the randomised study consider that, if necessary, allopurinol can be used safely to prevent hyperuricemia with the chemotherapy regimens used for lymphomas.5 However, the other data introduce a note of caution. Be alert for increased cyclophosphamide toxicity if allopurinol is given.

Cyclophosphamide + Azathioprine

Early-onset pulmonary toxicity occurred in one patient taking amiodarone after high-dose cyclophosphamide was given. Fatal pulmonary toxicity occurred in another patient taking amiodarone after a single dose of cyclophosphamide.

Clinical evidence

A patient with dendritic cell carcinoma who had been taking amiodarone for 18 months, and who had received 6 cycles of chemotherapy including cyclophosphamide over the previous 12 months, was admitted to hospital with progressive shortness of breath 18 days after being given a single 4000-mg/m² dose of cyclophosphamide. He was found to have interstitial pneumonitis and a lung biopsy indicated drug-induced pulmonary toxicity. The patient’s condition improved rapidly over the following 10 days with discontinuation of amiodarone and treatment with prednisolone 60 mg daily. Over the previous year he had also received vincristine, etoposide and prednisone, cisplatin, cytarabine and dexamethasone as part of his chemotherapy.1 A patient with non-Hodgkin’s lymphoma who had been taking amiodarone 300 mg twice daily for 4 years, developed acute respiratory distress 2 days after being given a single dose of cyclophosphamide. This was eventually fatal. Autopsy revealed lung damage consistent with the effects of amiodarone and cyclophosphamide, with the cyclophosphamide the major cause. Other drugs used as part of the chemotherapy regimen were rituximab, doxorubicin, vincristine and prednisone.2

Mechanism

Pulmonary toxicity may occur in about 10% of patients given amiodarone.3,4 Pulmonary toxicity due to cyclophosphamide may occur between 1 to 6 months after exposure or occur as a more insidious form after about 6 months. The early onset of symptoms in the patients described above suggests accelerated mechanisms of pulmonary toxicity. Both cyclophosphamide and amiodarone pulmonary toxicity appear to be enhanced by oxygen and the combination of cyclophosphamide with amiodarone may enhance oxidative stress and therefore pulmonary toxicity.

Importance and management

Although information seems to be limited to the two case reports cited, the potential for both cyclophosphamide and amiodarone to cause pulmonary toxicity is established. Be alert to the possibility of enhanced pulmonary toxicity if these drugs are given together.

Fluconazole and itraconazole inhibit the metabolism of cyclophosphamide. There is some evidence that, compared with fluconazole, itraconazole might increase cyclophosphamide toxicity. Ketoconazole inhibits the metabolism of ifosfamide. This did not improve the ratio of active to inactive-toxic metabolites, and the possibility remains that ifosfamide efficacy could be reduced.

Cyclophosphamide or Ifosfamide + Azoles

A report describes liver damage in four patients given cyclophosphamide and who had previously taken azathioprine. However, another study found that liver function improved when cyclophosphamide was substituted for azathioprine in 29 patients.

Clinical evidence, mechanism, importance and management

Four patients (two with systemic lupus erythematosus, one with Sjogren’s syndrome, and one with Wegener’s granulomatosis) developed liver injury when given cyclophosphamide and 3 of them had liver cell necrosis. All had previously been treated with azathioprine and 2 of them had received cyclophosphamide previously without apparent liver damage. It was suggested that azathioprine and cyclophosphamide may have interacted.1 However, in a retrospective study of cardiac transplant recipients, substitution of cyclophosphamide for azathioprine was associated with improvement in liver function tests in 29 patients with suspected azathioprine-induced liver impairment.2

Evidence suggests that neither the toxicity nor the therapeutic effects of cyclophosphamide and ifosfamide are significantly altered by the concurrent use of barbiturates. However, an isolated report describes a girl taking phenobarbital who developed encephalopathy when given ifosfamide.

Clinical evidence

(a) Cyclophosphamide

In 4 patients phenobarbital 180 mg daily in divided doses for 10 days increased the mean plasma levels of cyclophosphamide total metabolites by 50% and increased their rate of urinary excretion.1 Similarly, another study in 11 patients given cyclophosphamide reported that the peak level of normustard-like substances was 1.5 times higher after pretreatment with phenobarbital.2 Similar changes in cyclophosphamide pharmacokinetics have been described in animal studies, and these have generally also shown that phenobarbital has no effect on the antitumour activity of cyclophosphamide3 although some have shown a reduction in its effects.4

Cyclophosphamide was reported to inhibit the clearance and increase the effects of pentobarbital in a study in rats.5 Another study found auto-induction of cyclophosphamide clearance in a patient taking phenobarbital with subsequent chemotherapy courses similar to that in patients not taking phenobarbital.6

(b) Ifosfamide

A 15-year-old girl who had been taking phenobarbital for epilepsy since infancy developed confusion and gradually became unconscious 6 hours after being given a first dose of ifosfamide for metastatic rhabdomyosarcoma. Her chemotherapy regimen was ifosfamide 3 g/m², mesna 3.6 g/m², vincristine 2 mg and dactinomycin. An EEG revealed signs of severe diffuse encephalopathy. She remained unconscious for 24 hours but was asymptomatic after 48 hours.7 In a pharmacokinetic study, phenobarbital 60 mg daily for 3 days had no effect on the pharmacokinetics of high-dose ifosfamide (4 g/m² over 1 hour each day for 3 days). The AUC for ifosfamide decreased from day one to day 3 irrespective of phenobarbital administration.8

Mechanism

Cyclophosphamide and ifosfamide are prodrugs that undergo hepatic metabolism, and it seems that they are able to induce their own metabolism. Cyclophosphamide appears to be hydroxylated by the cytochrome P450 subfamilies CYP2B and CYP2C, in particular, to form active metabolites, whereas ifosfamide appears to be principally hydroxylated by CYP3A. Both drugs also undergo dechloroethylation to produce inactive but neurotoxic metabolites, which can cause encephalopathy. For cyclophosphamide, this seems to be primarily catalysed by CYP3A, whereas for ifosfamide both CYP3A and CYP2B appear to be involved. Ifosfamide has a higher incidence of encephalopathy than cyclophosphamide.7 Phenobarbital and other barbiturates are inducers of both CYP2B and CYP3A. Therefore it is unlikely that barbiturates will generally alter the balance between dechloroethylation and hydroxylation for cyclophosphamide,3 although there is some evidence from animal studies they may do so for ifosfamide.10

Importance and management

The relationship between the case of encephalopathy and the use of ifosfamide with phenobarbital is not established, but it serves to emphasise the need for particular caution and good monitoring if concurrent use is undertaken. More study is needed. Although barbiturates can cause an increase in the rate of metabolism of cyclophosphamide, this does not appear to alter the AUC and efficacy of this drug.

References

Cyclophosphamide or Ifosfamide + Benzodiazepines

Animal studies suggest that the benzodiazepines may possibly increase the metabolic activation and the toxicity of high doses of cyclophosphamide and ifosfamide. However, diazepam did not alter the pharmacokinetics of high-dose cyclophosphamide in a clinical study. Note also that lorazepam is widely used for chemotherapy-induced nausea and vomiting.

Clinical evidence, mechanism, importance and management

Studies in mice found that pretreatment with benzodiazepines (chlordiazepoxide, diazepam, oxazepam) increased the levels of the active metabolites and the lethality of high-dose cyclophosphamide1 and similarly increased the levels of active metabolites and enhanced the toxicity of high-dose ifosfamide.2 However, a clinical study found that the prophylactic use of diazepam 5 mg daily as an antiepileptic had no effect on the pharmacokinetics of very high-dose cyclophosphamide (60 mg/kg intravenously over 2 hours for 2 days) or its neurotoxic (dechloroethylated) metabolites in 3 patients receiving cyclophosphamide and busulfan before bone marrow transplantation.3 In the animal studies, it was suggested that benzodiazepines may induce the liver enzymes concerned with the metabolism of cyclophosphamide and ifosfamide to its active cytotoxic products. There are very limited data on this potential interaction. The widespread use of the benzodiazepine lorazepam in antimetic regimens for chemotherapy-induced nausea and vomiting suggest that a significant increase in toxicity or alteration in efficacy of cyclophosphamide and ifosfamide does not occur clinically, but there do not appear to be any studies directly addressing this question.

Cyclophosphamide + Busulfan

The levels of cyclophosphamide may be increased, and those of its active metabolite decreased, if it is given within 24 hours of busulfan treatment.

Clinical evidence, mechanism, importance and management

In one study, the ratio of the AUC of cyclophosphamide and that of its active metabolite hydroxycyclophosphamide was higher in patients also receiving phenytoin and busulfan than in those receiving irradiation (suggesting reduced cyclophosphamide activation), but variability between patients was high.1 In a similar study, 23 bone marrow transplant patients were pretreated with busulfan 4 mg/kg/day for 4 days, followed by cyclophosphamide 60 mg/kg/day for 2 days. The interval between the last dose of busulfan and starting cyclophosphamide was 24 to 50 hours in 12 patients [group A] and 7 to 15 hours in the remaining 11 [group B]. Nine others pretreated with cyclophosphamide and total body irradiation acted as the controls. In group A the AUCs of cyclophosphamide and hydroxy-cyclophosphamide were similar to those in the controls but in group B the AUC of cyclophosphamide was more than doubled and the AUC of hydroxy-cyclophosphamide significantly lower (representing a reduced ratio of hydroxy-cyclophosphamide to cyclophosphamide). In addition group B had greater toxicity.2 Busulfan may directly inhibit the hepatic activation of cyclophosphamide or may act indirectly by depleting glutathione. Phenytoin induces the metabolism of cyclophosphamide (see ‘Cyclophosphamide or Ifosfamide + Phenytoin’, p.627).

It seems therefore that if the cyclophosphamide is given at least 24 hours after the last busulfan dose, its serum levels will not be greatly affected, whereas if the interval is short, activation may be decreased and toxicity increased. Further study is required to determine the optimum timing to achieve maximum efficacy and minimum drug toxicity while taking into account other concurrent medication such as phenytoin.

Cyclophosphamide + Chloramphenicol

Some limited evidence suggests that chloramphenicol may reduce the production of the active metabolites of cyclophosphamide. Whether this reduces its therapeutic efficacy remains to be determined.

Clinical evidence, mechanism, importance and management

Cyclophosphamide itself is inactive, but after administration it is metabolised to active alkylating metabolites. A study in animals found that pretreatment with chloramphenicol reduced the effects of cyclophosphamide and reduced the production of its active metabolites. Although another animal study also found a reduction in lethality of cyclophosphamide with chloramphenicol, the immunosuppressive effect of cyclophosphamide was unchanged. A study in 4 patients found that chloramphenicol 1 g twice daily for 12 days prolonged the mean serum half-life of a single intravenous dose of cyclophosphamide from 7.5 to 11.5 hours, but did not significantly affect the AUC of the metabolites.

Chloramphenicol is an inhibitor of the cytochrome P450 isoenzyme subfamily CYP2B, which is partially responsible for the activation of cyclophosphamide. It therefore seems possible that a reduction in the activity of cyclophosphamide may occur, but the extent to which this affects treatment with cyclophosphamide is uncertain. Concurrent use need not be avoided, but be alert for evidence of a reduced response. More study is needed.

Cyclophosphamide or Ifosfamide + Cisplatin

The renal toxicity of ifosfamide may be greater when used with cisplatin or in those who have had prior treatment with cisplatin. Ifosfamide may increase the hearing loss due to cisplatin.

Clinical evidence

(a) Nephrotoxicity

A comparative study in 36 children with malignant solid tumours taking a range of drugs including some known to be potentially nephrotoxic (high dose methotrexate, aminoglycosides, cyclophosphamide), indicated that previous treatment with cisplatin increased their susceptibility to ifosfamide toxicity (nephrotoxicity, severe leucopenia or acute tubular damage).1

Similarly, in another study the cumulative cisplatin dose given before high-dose ICE (ifosfamide, carboplatin, and etoposide) was found to be a strong risk factor for the development of nephrotoxicity.2 The nephrotoxicity may not be reversible; 3 cases requiring long-term haemodialysis have been described.3 Other studies also suggested that the concurrent use of ifosfamide with cisplatin appeared to increase nephrotoxicity; one showed an increase in depletion of phosphate reabsorption,4 whereas the other showed increased microglobulin excretion.5

(b) Ototoxicity

A retrospective comparative study found that when ifosfamide was added to cisplatin, the hearing loss caused by cisplatin was exacerbated.6

Mechanism
Both cisplatin and ifosfamide are commonly associated with nephrotoxicity. It is thought that concurrent or possibly previous treatment with cisplatin damages the kidney tubules so that the clearance of the ifosfamide metabolites is reduced and their toxic effects are thereby increased. Damaged kidney tubules may also be less capable of converting mesna to its active kidney-protecting form. The increase in the hearing loss is not understood.

Importance and management
These interactions appear to be established. The authors of the paper cited pointed out that the majority of patients who develop toxicity have persistently high urinary NAG concentrations (N-acetyl-β-D-glucosaminidase, an enzyme released by renal tubular cells), even though serum creatinine levels remain within the acceptable range for ifosfamide treatment. They suggest that evidence of subclinical tubular damage should be sought for by monitoring the excretion of urinary NAG. Note that cisplatin and ifosfamide are widely used in combination, and the related drug cyclophosphamide is also routinely used with cisplatin. Amifostine may be useful in reducing the nephrotoxicity of this combination. The authors who reported on hearing loss advised that serial audiograms should be done in patients treated with both drugs.

Clinical evidence, mechanism, importance and management
A 1-year-old boy with a neuroblastoma Evans stage III died of respiratory failure following treatment with filgrastim (a G-CSF) and normal doses of cyclophosphamide and doxorubicin. The authors of the report suggest that the pulmonary toxicity of the cyclophosphamide (normally only seen with high cumulative doses) is potentiated by filgrastim. Six of 53 patients treated with CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone) and G-CSF developed pulmonary toxicity, which was considered to be of higher incidence than usually seen with CHOP alone. The development of toxicity correlated with the mean peak leucocyte count. Another 10 cases of interstitial pneumonitis have occurred with cyclophosphamide-based regimens (not including bleomycin or methotrexate) and G-CSF. There is some evidence that the pulmonary toxicity of bleomycin might possibly also be increased by colony-stimulating factors used in combination chemotherapy with or without amifostine in patients with solid tumors. There are reports of increased frequency of toxicity in patients treated with both drugs.

Cyclophosphamide or Ifosfamide + Corticosteroids
There is limited and conflicting evidence on the effect of prednisone and prednisolone on the metabolic activation of cyclophosphamide. Synergistic increases in enzyme induction may occur if cyclophosphamide is given with dexamethasone. Dexamethasone does not appear to alter ifosfamide metabolism.

Clinical evidence
(a) Dexamethasone
In an in vitro study it was noted that the combination of cyclophosphamide with dexamethasone resulted in a greater induction of the cytochrome P450 isoform CYP3A4 than with cyclophosphamide alone; the extent of induction being dependent on baseline CYP3A4 activity. In rats, dexamethasone pretreatment caused a fourfold increase in the AUC of the inactive, neurotoxic, dechloroethylated metabolite of cyclophosphamide, and caused a 60% decrease in the AUC of the active, hydroxylated metabolite. In another study in patients receiving high-dose cyclophosphamide and dexamethasone for 2 days, total clearance of both cyclophosphamide and dexamethasone was higher on the second than the first day, with higher concentrations of cyclophosphamide metabolites. In rats, dexamethasone pretreatment had no net impact on the fraction of ifosfamide undergoing activation. Similarly, in a clinical study, ifosfamide metabolism was no different when patients were given dexamethasone 4 mg every 8 hours with ifosfamide for 3 days than when they received ifosfamide alone.

(b) Prednisone or Prednisolone
In an early study, single doses of prednisone were shown to inhibit the metabolic activation of cyclophosphamide, whereas another study briefly mentioned that massive single doses of prednisolone given just before cyclophosphamide did not inhibit cyclophosphamide metabolism. Longer-term prednisone treatment (50 mg daily for 1 to 2 weeks) increased the rate of activation of cyclophosphamide in the first study. Conversely, another study in 7 patients with systemic vasculitis given prednisone 1 mg/kg daily and cyclophosphamide 600 mg/m² intravenously every 3 weeks for 6 cycles found that, by the last cycle, the AUC of cyclophosphamide had significantly increased while that of its active metabolites had significantly decreased.

Mechanism
Cyclophosphamide and ifosfamide are prodrugs that undergo hepatic metabolism to active and inactive-neurotoxic metabolites, and it appears they induce their own metabolism (see also ‘Cyclophosphamide or Ifosfamide + Barbiturates’, p.623). Corticosteroids are inducers of the cytochrome P450 isoforms CYP3A4. For cyclophosphamide, the CYP3A subfamily is thought to be principally involved in production of inactive-neurotoxic metabolites, whereas, for ifosfamide, CYP3A catalyses both the production of active and inactive-neurotoxic metabolites. On this basis, corticosteroids might be expected to decrease the efficacy and increase the neurotoxicity of cyclophosphamide (although this does not take account of auto-induction), whereas for ifosfamide, they would not be expected to alter the balance between efficacy and toxicity.

Importance and management
The documentation is very limited. It appears that dexamethasone does not have any appreciable effect on the metabolism of ifosfamide. The information on cyclophosphamide is conflicting, and the clinical importance of any changes remains to be established. However, it should be noted that...
prednisone and prednisolone have a long established use as part of chemotherapy regimens including cyclophosphamide and are also often combined in various autoimmune diseases, and dexamethasone is widely used as an antiemetic with cancer chemotherapy.

Cyclophosphamide + H2-receptor antagonists

Ranitidine, and probably famotidine, appear not to increase the bone marrow toxicity of cyclophosphamide. Animal studies suggest that cimetidine might.

Clinical evidence, mechanism, importance and management

A study in 7 cancer patients found that although oral ranitidine 300 mg daily significantly prolonged the half-life and increased the AUC of intravenous cyclophosphamide 600 mg/m2, it did not significantly affect the AUCs of the two major alkylating metabolites of cyclophosphamide, nor did it affect its bone marrow toxicity (leucopenia, granulocytopenia). The authors of the study conclude that ranitidine can safely be given with cyclophosphamide.1 The same authors previously reported that cimetidine, when given with cyclophosphamide, increased the AUC of total alkylating metabolites of cyclophosphamide, and resulted in greater toxicity to normal bone marrow, but increased survival in leukemia-bearing mice.2,3 Other studies in mice have shown that cimetidine, but not famotidine, increases the toxicity of cyclophosphamide to normal bone marrow cells.4

Cimetidine inhibits the cytochrome P450 isozyme CYP2C9, which has a minor role in the activation of cyclophosphamide (see ‘Cyclophosphamide or Ifosfamide + Barbiturates’, p.623). These results suggest that no special precautions are likely to be needed when ranitidine or famotidine are given with cyclophosphamide. The relevance of the findings with cimetidine is uncertain. Cimetidine has also increased the toxicity of several other antineoplastic, as ‘Nitrosoureas + Cimetidine’, p.655, ‘Anthracyclines; Epirubicin + Cimetidine’, p.613, and ‘Fluorouracil + H2-receptor antagonists’, p.633.

Cyclophosphamide + Indomethacin

A single case report describes acute water intoxication when a patient taking indomethacin was given low-dose intravenous cyclophosphamide.

Clinical evidence, mechanism, importance and management

A patient with multiple myeloma taking indomethacin 50 mg every 8 hours, developed acute water intoxication and salt retention after being given a single bolus intravenous injection of cyclophosphamide 500 mg (less than 10 mg/kg). The reasons are not understood, but it is suggested that it was due to the additive or synergistic effects of the two drugs, since water intoxication had not been noted before with this low-dose of cyclophosphamide.1 There do not appear to be any further reports or studies on this potential interaction but water intoxication has subsequently been reported with low-dose intravenous cyclophosphamide alone.2 The evidence does not justify any special precautions when both drugs are used.

Cyclophosphamide + Metronidazole

A case report describes encephalopathy in a girl treated with cyclophosphamide and metronidazole.

Clinical evidence, mechanism, importance and management

After the fourth dose of pulse intravenous cyclophosphamide, a 9-year-old girl developed pancytopenia and gastrointestinal bleeding. She was then given metronidazole for presumptive Clostridium difficile colitis. Within 6 hours she developed encephalopathy with seizures and visual hallucinations, requiring antipsychotic therapy. Metronidazole is thought to cause disulfiram-like reactions by inhibiting aldehyde dehydrogenase (see ‘Alcohol + Antibacterials; Metronidazole’, p.44), and it was suggested that inhibition of this enzyme may cause toxic metabolites of cyclophosphamide to accumulate (see also ‘Cyclophosphamide or Ifosfamide + Barbiturates’, p.623). This appears to be the only report of this potential interaction, and its general relevance is unclear. Further study is required.

Cyclophosphamide + Pentostatin

Acute and fatal cardiovascular collapse developed in two patients when pentostatin was added to high-dose cyclophosphamide treatment. Some recent studies have found the combination to be effective and safe in patients with chronic lymphocytic leukaemia.

Clinical evidence, mechanism, importance and management

A clinical study that was started to find out if pentostatin would improve the immunosuppressive effects of cyclophosphamide, carmustine and etoposide in bone marrow transplant patients was stopped when acute and fatal cardiovascular collapse developed in the first 2 patients. Both patients had been given cyclophosphamide 800 mg/m2 and etoposide 200 mg/m2, both every 12 hours for 8 doses, and carmustine 112 mg/m2 daily for 4 doses. On day 3 pentostatin 4 mg/m2, given over 4 hours, was added. Within 8 to 18 hours after completion of chemotherapy both patients developed confusion, hypothermia, hypotension, respiratory distress, pulmonary oedema, and eventually fatal ventricular fibrillation within 45 to 120 minutes of the first symptoms. A later study in rats similarly found that pentostatin markedly increased the acute toxicity of cyclophosphamide. The reasons for this cardiotoxicity are not understood. Neither of the 2 patients had previously shown any evidence of cardiac abnormalities.1

However, in a more recent study in patients with previously treated chronic lymphocytic leukaemia (CLL), pentostatin 4 mg/m2 with cyclophosphamide 600 mg/m2 was found to be safe and effective.2 Another study found that pentostatin 4 mg/m2 and cyclophosphamide 600 mg/m2 with or without rituximab 375 mg/m2 was safe and effective for patients with Waldenstrom’s macroglobulinaemia.3 Other studies in patients with previously treated or untreated CLL found that cyclophosphamide 600 mg/m2 with pentostatin 4 or 2 mg/m2 and rituximab 375 mg/m22 was effective and was either well-tolerated or had only modest toxicity.4,5

Phenytoin increases the metabolism of cyclophosphamide and ifosfamide, but the clinical relevance of this is uncertain. Both unchanged and increased efficacy has been suggested.

Clinical evidence

A child taking phenytoin and also given ifosfamide and etoposide had a neurotoxic reaction. The plasma levels of the dechloroethylated metabolite of ifosfamide were subsequently found to be markedly altered compared with those previously seen in 14 other children receiving the same chemotherapy but not taking phenytoin. The child recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin). The child recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin). She recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin). She recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin). She recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin). She recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin). She recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin). She recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to chemotherapy but not taking phenytoin).

Mechanism

The alteration in the pattern of ifosfamide metabolites suggested that phenytoin had induced the activity of the cytochrome P450 isozyme CYP2B6, and to a lesser extent CYP3A4.1 The pattern of the increase in cyclophosphamide clearance is also consistent with induction of CYP2B and CYP3A.2 See also ‘Cyclophosphamide or Ifosfamide + Barbiturates’, p.623.

Importance and management

The alteration in the metabolism of cyclophosphamide and ifosfamide caused by phenytoin is not surprising, but the clinical importance of any changes remains to be established. The authors of the study from the 1970s concluded that phenytoin was unlikely to have much effect on the antitumour and toxic effects of cyclophosphamide.4 Conversely, the authors of the more recent studies suggest that phenytoin may increase the therapeutic efficacy of cyclophosphamide and ifosfamide.1,2 Further study is needed.

Note that reduced phenytoin levels and seizures have been reported in a patient receiving chemotherapy including cyclophosphamide, see ‘Table 14.1’, (p.519).

Cyclophosphamide or Ifosfamide + Rifampicin (Rifampin)

Rifampicin induced the metabolism of cyclophosphamide and ifosfamide. For ifosfamide, this did not improve the ratio of active to inactive-toxic metabolites, and the possibility remains that efficacy could be reduced.

Clinical evidence, mechanism, importance and management

In a clinical study, rifampicin increased the clearance of ifosfamide by about 100%. In this study, patients were given rifampicin 300 mg twice daily for 3 days before ifosfamide and for 3 days concurrently for one cycle, then for another cycle they were given the ifosfamide alone. The fraction of ifosfamide metabolised to the inactive-neurotoxic, dechloroethylated metabolite was increased, but elimination of this metabolite was also increased resulting in reduced exposure. The fraction metabolised to the active, hydroxylated metabolite, and its exposure, were not altered appreciably.1

An in vitro study in human liver cells showed that rifampicin was a potent inducer of the activation (hydroxylation) of cyclophosphamide and ifosfamide.2

Rifampicin is an inducer of the cytochrome P450 isozymes CYP3A4 and CYP2B6, which are involved in the metabolism of cyclophosphamide and ifosfamide (see also ‘Cyclophosphamide or Ifosfamide + Barbiturates’, p.623). In the clinical study cited,1 rifampicin did not have a positive effect on the proportion of ifosfamide undergoing activation. In addition, since rifampicin increased metabolism overall, there is the possibility of decreased efficacy,1 although this remains to be shown.

Cyclophosphamide + Sulfonamides

Some very limited evidence suggests that sulfaphenazole may modestly inhibit the metabolism of cyclophosphamide to its active metabolite, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

A study in 7 patients given a 50-mg dose of cyclophosphamide and sulfaphenazole 1 g twice daily for 9 to 14 days showed that the half-life of cyclophosphamide was unchanged in 3 patients, longer in 2 and shorter in the remaining 2 patients.1 Sulfaphenazole and sulfamethoxazole are inhibitors of the cytochrome P450 isozyme CYP2C9, which shows genetic polymorphism (i.e. some people produce very little, while others produce larger quantities). This enzyme has a minor role in the metabolism (and therefore activation) of cyclophosphamide, and the extent of its involvement varies between patients. For example, an in vitro study showed that sulfaphenazole inhibited cyclophosphamide activation by 17 to 27% in one human liver sample, but insignificant inhibition occurred in two others.2 Thus, sulfonamides such as sulfaphenazole and sulfamethoxazole may moderately inhibit the activation of cyclophosphamide in some patients, but the clinical relevance of this is uncertain. Note that co-trimoxazole is sometimes used for prophylaxis of infection in patients receiving chemotherapy. One study showed that this use did not increase the myelotoxicity of CAE (cyclophosphamide, doxorubicin, and etoposide).3

Cyclophosphamide or Ifosfamide + Taxanes

The clearance of ifosfamide is higher when it is given after docetaxel. This results in less toxicity, but the effect on efficacy is unknown. Ifosfamide did not alter the pharmacokinetics of docetaxel. The sequence of ifosfamide followed by paclitaxel was antagonistic in vitro.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

The AUCs of ifosfamide and its metabolites were lower when ifosfamide was given immediately after docetaxel than when it was given 24 hours before docetaxel, due to increased clearance. Docetaxel pharmacokinetics were unaltered by ifosfamide. This supports the evidence that the maximum tolerated dose is greater when ifosfamide is given after docetaxel. The mechanism is unknown, but it has been suggested that docetaxel may competitively inhibit the activation of ifosfamide by the cytochrome P450 isozyme CYP3A4. These results show that the toxicity, and possibly efficacy, of the combination are schedule dependent. More study is needed. Cyclophosphamide does not appear to alter docetaxel pharmacokinetics. For full details see also ‘Taxanes + Cyclophosphamide’, p.661.

(b) Paclitaxel

In vitro studies in human liver microsomes found that additive or synergistic cytotoxicity occurred when activated ifosfamide (hydroxyifosfamide) and paclitaxel were given together or when paclitaxel was given first followed by hydroxyifosfamide. In contrast pronounced antagonism was seen when hydroxyifosfamide was given before paclitaxel. The mechanism is unknown. These results suggest that the scheduling of this combination may be important for efficacy. More study is needed. There is some evidence that toxicity associated with combinations of paclitaxel and cyclophosphamide is sequence-dependent. For full details see also ‘Taxanes + Cyclophosphamide’, p.661.

Cyclophosphamide + Thiopeta

Pretreatment with thiopeta may inhibit the metabolism of cyclophosphamide to its active metabolite and decrease both its efficacy and toxicity. Cyclophosphamide appears not to affect the metabolism of thiopeta.

Clinical evidence, mechanism, importance and management

(a) Effect on cyclophosphamide

The proportion of cyclophosphamide excreted unchanged in the urine (i.e. never metabolically activated) was found to be higher when cyclophosphamide was given as a 96-hour infusion with thiopeta and novobiocin than when it was given alone. The authors suggested that the possibility that thiopeta inhibited the metabolism of cyclophosphamide should be investigated. Later, other authors observed that the concentration of the active metabolite of cyclophosphamide, 4-hydroxycyclophosphamide, decreased sharply after thiopeta was given to 20 patients. In a study to investigate this effect further, 3 patients were given high-dose cyclophosphamide 1000 or 1500 mg/m² as a 1-hour infusion, followed by carboplatin and thiopeta for 4 days. The order of infusion was reversed on one treatment day in each of 4 courses. Giving thiopeta 1 hour before cyclophosphamide resulted in decreases in the peak plasma levels and AUC of 4-hydroxycyclophosphamide of 62% and 26%, respectively, when compared with thiopeta given 1 hour after cyclophosphamide. In human microsomes, thiopeta was found to inhibit the conversion of cyclophosphamide to hydroxycyclophosphamide. These results suggest that thiopeta can decrease both the efficacy and toxicity of cyclophosphamide, and that the order of administration may be of critical importance. The authors question the practice of giving cyclophosphamide and thiopeta simultaneously.

(b) Effect on thiopeta

In an in vitro study using human microsomes, cyclophosphamide had no effect on the metabolism of thiopeta to TEPA (triethylphosphamide) by cytochrome P450 at therapeutic concentrations.

Erlotinib + Miscellaneous

The metabolism of erlotinib is markedly affected by other drugs that are potent inhibitors (e.g. ketoconazole) or inducers (e.g. rifampicin) of the cytochrome P450 isozyme CYP3A4. Alternatives to these drugs should be used where possible; if not, alteration of the dose of erlotinib is required. The concurrent use of temozolomide may either reduce or increase erlotinib levels, depending on the dose of erlotinib. Smoking increases the metabolism of erlotinib.

Clinical evidence, mechanism, importance and management

(a) Antiepileptics, enzyme-inducing

As part of a study in 33 patients with glioma, the pharmacokinetics of erlotinib 100 mg daily increasing to 500 mg daily was compared between patients taking enzyme-inducing antiepileptics and those not. There was a 33 to 71% lower exposure to erlotinib when it was given with an enzyme-inducing antiepileptic drug, thought to be due to increased activity of the cytochrome P450 enzymes. Antiepileptics drugs taken were carbamazepine, oxcarbazepine, phenytoin, fosphenytoin, phenobarbital and primidone. Patients taking these drugs tolerated a higher dose of erlotinib, and for further studies in this disease it was recommended that the dose of erlotinib should be at least 500 mg daily in those taking enzyme-inducing antiepileptics and 200 mg daily in those patients not taking these drugs. However, note that the manufacturer of erlotinib recommends using alternatives to these enzyme-inducing antiepileptics if possible, see CYP3A4 inducers, below.

(b) CYP3A4 Inhibitors

The AUC of erlotinib has been found to be increased by 66% when given with ketoconazole 200 mg twice daily for 5 days. The manufacturers advise caution with concurrent use, and recommend that the dose of erlotinib should be reduced if severe adverse reactions occur when given with strong CYP3A4 inhibitors. They specifically name atazanavir, clarithromycin, erythromycin, grapefruit and grapefruit juice, indinavir, itraconazole, ketoconazole, nefazodone, nelfinavir, ritonavir, saquinavir, telithromycin, troleandomycin and voriconazole.

(c) CYP3A4 inducers

Pretreatment with rifampicin 600 mg once daily for 7 days reduced the AUC of erlotinib by about 66%. In another study, the AUC of a single 450-mg dose of erlotinib, taken after 11 days treatment with rifampicin was about 57% of that of erlotinib 150 mg taken without rifampicin. The manufacturers advise that alternative treatments with no cytochrome P450 enzyme-inducing activity should be considered. If this is not possible, the starting dose of erlotinib should be adjusted to 300 mg (UK) with close monitoring, and, if tolerated, further increased after 2 weeks, in 50 mg increments, to 450 mg. They also advise caution with other CYP3A4 inducers, and specifically name barbiturates, carbamazepine, phenobarbital, phenytoin, rifabutin, rifapentine, and St John’s wort,
and recommend the use of alternative non-inducing drugs when possible.2,3 For enzyme-inducing antiepileptics, see also (a) above.

(d) Drugs that affect gastrointestinal pH

Drugs, such as antacids, H₂-receptor antagonists or proton pump inhibitors, that increase the pH of the gastrointestinal tract may reduce the solubility of erlotinib, which the manufacturers,2,3 state has a decreased solubility above pH 5. The manufacturers therefore recommend caution with concurrent use of these drugs during treatment with erlotinib as they cannot exclude that these drugs will reduce erlotinib efficacy.2

(e) Gemcitabine

There was no change in the pharmacokinetics of gemcitabine or erlotinib on concurrent use in a phase 1 study.2

(f) Temozolomide

As part of a phase 1 study, 16 patients with glioma were given erlotinib 100 mg daily increasing to 250 mg daily alone, and 14 were given erlotinib and temozolomide 150 mg/m² increasing to 200 mg/m² for 5 days in each 28 day cycle. At the lowest dose of erlotinib, the group also taking temozolomide had a 49% lower maximum plasma level of erlotinib, and almost 50% lower AUC of both erlotinib and its metabolite OSI-420. As the dose of erlotinib increased to 250 mg daily, this difference was reversed with temozolomide group showing a 45% higher AUC of erlotinib. The reason for these paradoxical findings is unclear, and their clinical relevance is uncertain.1

(g) Tobacco

Twelve cigarette smokers and 14 non-smokers were given oral erlotinib 150 mg on day 1 and 300 mg on day 15 of a study. The subjects who smoked had lower maximum plasma levels of erlotinib; 35% lower after the 150 mg dose and 20% lower after the 300 mg dose. The AUC was also reduced by 65% and 57%, respectively. Cigarette smoking induces CYP1A1 and 1A2, which are involved in the metabolism of erlotinib. Consideration should therefore be given to the smoking status of a patient when planning treatment with erlotinib.4 The manufacturer says that these decreases are likely to be clinically important, and that patients should be encouraged to stop smoking.2,3

(h) Warfarin

Raised INRs and infrequent bleeding have been reported in patients taking warfarin with erlotinib. Patients taking these drugs, and other coumarins, should be closely monitored for INR changes.2,3

Clinical evidence, mechanism, importance and management

Estramustine bioavailability in 12 patients was increased by about 80% when cladronate 800 mg four times daily was given with estramustine 280 mg twice daily for 5 days. The serum levels and AUC of cladronate were not changed by estramustine.1 Documentation appears to be limited to this study. However, the efficacy and toxicity of estramustine should be monitored if cladronate is also given. The effects of other bisphosphonates do not appear to have been studied.1

Clinical evidence

A randomised three-way crossover study in 6 patients with prostate cancer showed that the absorption of single-doses of estramustine disodium (equivalent to 140 mg of estramustine) was reduced by 59% when taken with 200 mL of milk, and by 33% when taken with a standardised breakfast (2 pieces of white bread with margarine, ham, tomato, marmalade and water). Peak serum estramustine levels were reduced by 68% and 43%, respectively.1

Mechanism

In vitro studies suggest that estramustine combines with calcium ions in milk and food to form a poorly-soluble complex that is not as well absorbed as the parent compound.1

Importance and management

An established interaction although the information is limited. The manufacturers recommend that estramustine should be taken not less than 1 hour before or 2 hours after meals, and that it should not be taken with milk, milk products, calcium-rich foods,2,3 or drugs (such as calcium-containing antacids).3

Etoposide + Antiepileptics

Etoposide clearance appears to be increased by phenobarbital, phenytoin, and probably carmamazepine, and this may result in reduced efficacy.

Clinical evidence, mechanism, importance and management

The clearance of etoposide was found to be highly variable in children given etoposide 320 to 500 mg/m² over 6 hours on alternate days for a total of 3 doses. However, it was 77% higher in 7 children taking antiepileptics (phenobarbital, phenytoin or both) than in 22 others not taking antiepileptics.1 In a retrospective survey, long-term antiepileptic use (phenytoin, phenobarbital, carmamazepine, or a combination) was associated with worse event-free survival, and greater haematological and/or CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. The authors considered that the increased clearance of etoposide induced by the antiepileptics was a likely factor in these findings.2,3 Be alert for the possible need to give larger doses of etoposide if these antiepileptics are used. More study is needed.

Etopeoside + Atovaquone

The concurrent use of atovaquone with etoposide may modestly increase exposure to etoposide catechol. The clinical relevance of this is unclear.

Clinical evidence, mechanism, importance and management

A study in 9 children with acute lymphoblastic leukaemia or non-Hodgkin’s lymphoma found that the AUC of etoposide and its metabolite etoposide catechol were slightly increased, by 8.6% and 28.4%, respectively, following atovaquone 45 mg/kg daily, when compared with co-trimoxazole 150/750 mg/m² daily. The mechanism by which this occurs is unclear, but atovaquone may affect the metabolism of etoposide by the cytochrome P450 isoenzyme CYP3A4 or its transport by P-glycoprotein.1 The authors considered that an interaction with co-trimoxazole was unlikely, so used it as a control, however, ideally this requires confirma-
tion. The relevance of the minor changes seen is unclear. The authors note that the risk of etoposide-related secondary acute myeloid leukaemia has been linked to minor changes in therapy, therefore, they advise caution if atovaquone is given with etoposide, particularly if it is used with other substrates of CYP3A4 or P-glycoprotein. They also say it may be possible to avoid the interaction by separating the administration by 1 to 2 days, but this requires confirmation.  

**Etoposide + Ciclosporin**

High-dose ciclosporin markedly raises etoposide serum levels and increases the suppression of white blood cell production. Severe toxicity has been reported in one patient.

### Clinical evidence

In a comparative study, 16 patients with multidrug-resistant advanced cancer were given 20 paired courses of etoposide, alone or with ciclosporin. Ciclosporin levels were measured at the end of a 2-hour infusion: ciclosporin levels of greater than 2000 nanograms/mL were defined as high-dose and those less than 2000 nanograms/mL as low-dose. High and low-dose ciclosporin, respectively, increased the etoposide AUC by 80% and 50%, decreased the total clearance by 38% and 28%, increased its half-life by 108% and 40%, reduced the leucocyte count nadir by 64% and 37% and altered the volume of distribution at steady state by 46% and 1.4%. The patients were given 150 to 200 mg/m² of etoposide daily as a 2-hour intravenous infusion for 3 consecutive days and ciclosporin in doses ranging from 5 to 21 mg/kg daily as a 3-day continuous infusion. In another study, 18 children with recurrent or refractory tumours who had previously received etoposide were given high-dose ciclosporin (either a continuous infusion of 15 mg/kg per 24 hours for 60 hours (13 patients) or 30 mg/kg over 3 hours on 3 consecutive days (5 patients) and etoposide 150 mg/m² over 1 hour for 3 days, starting 1 hour after the beginning of the ciclosporin infusion. The AUC and half-life of etoposide were increased by 89% and 78%, respectively, and the clearance was decreased by 48%. In a further study in children, the pharmacokinetics of etoposide 100 mg/m² daily were compared with etoposide 60 mg/m² (a 40% reduction in dose) with high-dose ciclosporin. Despite the dose reduction, recipients of ciclosporin had a 71% reduction in etoposide clearance and a 47% increase in the etoposide AUC, although toxicity was similar. The leukaemic cells in the bone marrow of a patient with acute T-lymphocyte leukaemia were totally cleared when ciclosporin 8.3 mg/kg orally twice daily was given with etoposide 100 to 300 mg daily for 2 to 5 days, but the adverse effects were severe (mental confusion, renal and hepatic toxicity). The patient died from respiratory failure precipitated by a chest infection.  

A patient with chronic myeloid leukaemia who had responded poorly to treatment with etoposide, mitoxantrone and cytarabine for blast crisis, returned to the chronic phase when given etoposide with ciclosporin. An in vitro study by the same authors showed that etoposide was partially toxic to blast cells but that its effect on blast cells was increased sixfold when it was given with ciclosporin.

### Mechanism

It is suggested that the ciclosporin decreases the metabolism of the etoposide by inhibiting its metabolism by cytochrome P450 isoenzymes and inhibiting P-glycoprotein-mediated efflux from the hepatocyte, as well as inhibiting some unknown non-renal clearance mechanism. The total effect is to cause the retention of etoposide in the body, thereby increasing its effects.

### Importance and management

An established interaction. Ciclosporin alters the pharmacokinetics of etoposide resulting in increased serum levels. This pharmacokinetic interaction has complicated the study of the value of using ciclosporin to modulate multidrug resistance in tumours to improve the response to chemotherapy. In the case of ‘anthracyclines’, (p.611) and etoposide, any benefit could just be attributed to dose intensification. Consequently, some, including one manufacturer, have suggested reducing the dose of etoposide by 40% or 50% in the presence of ciclosporin. In one study, a continuous infusion of ciclosporin was better tolerated than an intermittent regimen, but it was associated with similar hepatic and renal impairment as the short schedule (transient hyperbilirubinaemia, and elevated creatinine or urea). The use of high-dose ciclosporin for multidrug-resistant tumour modulation remains experimental and should only be undertaken in clinical studies. Concurrent use should be very well monitored. More studies are needed to find out the possible effects of low-dose ciclosporin.

The clearance of etoposide may be modestly reduced by carboplatin and cisplatin, but this is probably unlikely to be clinically relevant.

### Clinical evidence, mechanism, importance and management (a) Carboplatin

In one study in 4 patients, the pharmacokinetics of etoposide were unchanged when carboplatin was also given. However, in another study of 14 young patients receiving etoposide and carboplatin the clearance of etoposide was lower than in previous reports in adults and children. They had been given an escalating dosage regimen starting with etoposide 960 mg/m², and increasing to 1200, and 1500 mg/m², given in three divided doses on alternate days, with carboplatin 400 to 700 mg/m² given on the other days, followed by autologous marrow rescue. The authors point out that the dose and the timing of carboplatin may be important determinants for any interaction. In yet another study, carboplatin did not affect the pharmacokinetics of etoposide during the first cycle of chemotherapy (etoposide was given on days 1, 2 and 3, and carboplatin on day 2, and the AUC of etoposide was compared for days 1 and 2). However, during a second cycle of chemotherapy, the etoposide AUC was 8% higher on day 2 than day 1. These changes were considered unlikely to be clinically important.

### (b) Cisplatin

A study in 17 children with neuroblastoma found that when intravenous cisplatin 90 mg/m² was given immediately before etoposide, the clearance of etoposide 780 mg/m² fell by 20% and the serum levels rose. But after a cumulative dose of cisplatin of 360 mg/m² it had no effect on the clearance of etoposide. In another study, cisplatin did not affect the pharmacokinetics of etoposide during the first cycle of chemotherapy (etoposide was given on days 1, 2 and 3, and carboplatin on day 2, and the AUC of etoposide was compared for days 1 and 2). However, during a second cycle of chemotherapy, the etoposide AUC was 28% higher on day 3 than day 1. These changes were considered unlikely to be clinically important.

Etoposide + CYP3A4 inhibitors

In vitro studies show that some CYP3A4 inhibitors may possibly increase the effects and toxicity of etoposide. In one clinical study, etoposide clearance was increased by prednisone.

Clinical evidence, mechanism, importance and management

In vitro studies using human liver microsomes show that ketoconazole, prednisolone, troldenamidon, verapamil and vincristine can inhibit the metabolism (3′-demethylation) of etoposide by the cytochrome P450 isoenzyme CYP3A4. The implications of this fact that are concurrent use with these drugs might increase both the efficacy and the toxicity of etoposide.

However, in a study, 102 children with acute lymphoblastic leukaemia were given prednisone 40 mg/m² daily for 28 days with etoposide 300 mg/m² on day 29. Forty-eight of them with high risk disease were given continuation therapy and received etoposide 300 mg/m² at week 54, two weeks or more after the last prednisone dose. Etoposide clearance was 62% higher on day 29 than at week 54 and the AUC for the catechol metabolite was significantly lower (27%) on day 29 compared with week 54.

There seems to be little clinical confirmation that the potential interactions with the drugs listed above, other than corticosteroids (which found the opposite of the predicted effect) have clinical relevance, but good monitoring would be a prudent precaution. See also ‘Antineoplastics + Protease inhibitors’, p.615.

Etoposide + Food

In 8 patients with extensive small cell lung carcinoma the pharmacokinetics of a 100-mg oral dose of etoposide were unaffected when it was taken with a full breakfast, when compared with the fasting state. However, the manufacturer recommends that etoposide should be taken on an empty stomach.

Etoposide + Other antineoplastics

Doxorubicin and cyclophosphamide have no clinically relevant effects on the pharmacokinetics of oral or intravenous etoposide. Methotrexate and procarbazine do not affect the pharmacokinetics of oral etoposide.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 7 patients with small-cell lung cancer (SCLC) treated with cyclophosphamide 800 mg/m², doxorubicin 40 mg/m² and etoposide 100 mg/m² (all given intravenously) found that the protein binding, metabolism and renal clearance of etoposide were unaffected by the other antineoplastics. Similarly, another study found only modest changes in the pharmacokinetics of intravenous etoposide when it was given with cyclophosphamide and doxorubicin, compared with use alone, and these changes were considered unlikely to be clinically relevant. Specifically, the AUC of etoposide was 9% higher and the clearance was 10% lower on day 1 of the CAE cycle (cyclophosphamide, doxorubicin, and etoposide) compared with days 2 and 3 (etoposide alone). This is a commonly used regimen, and these data suggest there is no pharmacokinetic interaction.

Similarly, no changes in etoposide pharmacokinetics were seen when oral etoposide 100 mg was given immediately after oral cyclophosphamide 100 mg/m² and methotrexate 12.5 mg/m² in 8 patients with SCLC. In addition, no changes were seen when the same dose of oral etoposide was given 15 minutes after intravenous doxorubicin 35 mg/m² and oral procarbazine 60 mg/m². Oral etoposide pharmacokinetics appear not to be affected by these antineoplastics.

For the lack of effect of platinum derivatives, see ‘Etoposide + Cisplatin or Carboplatin’, p.630.

Exemestane + CYP3A4 inducers and inhibitors

Ketoconazole appears not to interact with exemestane, whereas rifampicin reduces exemestane levels.

Clinical evidence, mechanism, importance and management

The manufacturers say that in vitro evidence shows that while exemestane is metabolised by both the cytochrome P450 isoenzyme CYP3A4 and aldokeetoreductases, a clinical study found that ketoconazole (a specific inhibitor of CYP3A4) had no significant effects on the pharmacokinetics of exemestane. The manufacturers therefore suggest that interactions with CYP3A4 enzyme inhibitors are unlikely. However, in an interaction study the potent enzyme inducer rifampicin reduced the AUC and maximum plasma levels of exemestane by 54% and 41%, respectively.

The manufacturers therefore caution the use of exemestane with CYP3A4 inducers such as carbamazepine, phenobarbital, phenytoin and St John’s wort. The clinical relevance of these potential interactions is unknown, but it would seem prudent to monitor the outcome of concurrent use to ensure exemestane efficacy.

Fludarabine + Dipyridamole

Because fludarabine phosphate is an analogue of adenine, the UK manufacturers warn that drugs that are adenosine uptake inhibitors, such as dipyridamole, may prevent the uptake of fludarabine into cells and reduce its efficacy. Dipyridamole should probably therefore be avoided in patients receiving fludarabine.

Fludarabine + Pentostatin

When fludarabine phosphate and pentostatin were used in the treatment of chronic lymphoid leukaemia, 4 out of 6 patients de-
Fluorouracil + Alopurinol

Alopurinol has been studied as a modulator of the effects of fluorouracil, but has not gained an established clinical use in this setting.

Clinical evidence, mechanism, importance and management

Some early studies showed that alopurinol 300 mg twice to four times daily allowed the usual maximum tolerated dose of fluorouracil to be increased by up to twofold.1,2 The hope was that alopurinol would prove useful to decrease the toxicity and/or improve the activity of fluorouracil. However, most studies have shown no increase in response rates in colorectal cancer with alopurinol,3,4 even when the fluorouracil dose was escalated,1,2 and some have shown no reduction in toxicity.3,5 These are by no means all the studies, and are just cited as examples. Alopurinol mouthwash has also been investigated to reduce the incidence of stomatitis with fluorouracil. Some controlled studies have shown a benefit,6 whereas others have not.9 Alopurinol clearly modulates some of the effects of fluorouracil; however, this has not been shown to be obviously beneficial or harmful in the clinical setting.

5. Merimsky O, Inbar M, Chaitchik S. Treatment of advanced colorectal cancer by 5-fluorouracil + aminoglycosides; Oral

Neomycin can delay the gastrointestinal absorption of fluorouracil, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Some preliminary information from a study in 12 patients treated for metastatic adenocarcinoma found that with the use of oral neomycin 500 mg four times daily for a week delayed the absorption of fluorouracil, but the effects were generally too small to reduce the therapeutic response, except possibly in one patient.1 It seems probable that this interaction occurs because neomycin can induce a malabsorption syndrome. If neomycin, and most probably paromomycin or kanamycin are used in patients receiving fluorouracil, the possibility of this interaction should be borne in mind.

Fluorouracil + Cisplatin or Oxaliplatin

Giving low-dose cisplatin with a fluorouracil infusion markedly increased toxicity in one study. Cardiotoxicity may possibly be increased if higher doses of cisplatin are given with fluorouracil. Oxaliplatin appears to moderately raise fluorouracil levels, without increasing its toxicity.

Clinical evidence, mechanism, importance and management

(a) Cisplatin

Giving low-dose cisplatin 20 mg/m² once a week with continuous ambulatory fluorouracil infusions of 300 mg/m² daily considerably increased the toxicity (nausea, vomiting, anorexia, diarrhoea, stomatitis, myelosuppression) in 18 patients with advanced cancers. More than half developed multiple toxicities, and severe toxicity occurred in two-thirds. Leucopenia occurred in 28% given both drugs whereas it was virtually nonexistent with fluorouracil alone. Toxicity requiring treatment interruption or dose reduction was seen in 55% of patients receiving fluorouracil alone, and this rose to 94% in the presence of cisplatin.1 In another study, signs of cardiotoxicity (chest pain, ST-T wave changes, arrhythmias) were seen in 12 of 80 patients given fluorouracil with cisplatin for carcinoma of the head, neck, oesophagus and stomach.2 Studies in humans and rats have shown that there is prolonged elevation of filterable platinum levels associated with concurrent use of cisplatin and fluorouracil.3 The combination of a platinum derivative and fluorouracil is widely used, but the optimum schedule to improve activity and reduce toxicity is not firmly established. In one study of bolus cisplatin and continuous infusion fluorouracil, modifying the dose of fluorouracil based on AUC reduced toxicity while still maintaining response rates.4 In another study, cisplatin pharmacokinetics were said to be optimum when it was given as a continuous infusion with a continuous infusion of fluorouracil.5 Further study is needed.

(b) Oxaliplatin

In one study, 28 patients with advanced or metastatic colorectal cancer were given fluorouracil alone, or immediately following an 85 mg/m² dose of oxaliplatin given over 2 hours. Oxaliplatin did not significantly affect the pharmacokinetics of fluorouracil (either 2 cycles of a 400 mg/m² bolus followed by a 46-hour infusion of 2400 mg/m² given to 10 patients, with pharmacokinetic sampling over 46 hours, or a single cycle of a 400 mg/m² bolus followed by 600 mg/m² over 22 hours given to 18 patients, with pharmacokinetic sampling over 22 hours).6 However, in another study 29 patients with advanced colorectal cancer were given fluorouracil in a dose adjusted to give levels of between 2.5 and 3 mg/L (dose range 750 to 3500 mg/m² per week) either alone, or immediately following a 2-hour infusion of oxaliplatin 130 mg/m². In this study pharmacokinetic samples were taken on days 1 and 8 and 15. Oxaliplatin raised the plasma levels of fluorouracil by about one-third, with the effect appearing to last for 15 days, however, fluorouracil toxicity was not increased.7 The combination of fluorouracil and oxaliplatin is widely used, but one of the studies cited here suggest that the schedules could still be adjusted to optimise efficacy and minimise toxicity.8

Fluorouracil + Dipyridamole

One study suggested that intravenous dipyridamole may reduce the steady-state plasma levels of fluorouracil, whereas others found that oral dipyridamole caused no important changes in fluorouracil pharmacokinetics.
Clinical evidence, mechanism, importance and management

Numerous preclinical studies found that dipyridamole enhanced the activity of fluorouracil, leading to its investigation as a biomodulator. However, unexpectedly, in one phase I study of the combination, the use of dipyridamole was associated with lower steady state plasma level of fluorouracil, suggesting an approximately 30% increase in total body clearance or volume of distribution of fluorouracil. In this study, 47 patients with advanced cancer were given fluorouracil in escalating doses ranging from 185 mg/m² daily to 3600 mg/m² daily with or without dipyridamole as a continuous infusion of 7.7 mg/kg per day for 72 hours. In contrast, in a later randomised study, oral dipyridamole 75 mg three times daily for 5 days did not significantly alter the pharmacokinetics of fluorouracil, except for prolonging the half-life and slightly increasing the dose-intensity: over 5 cycles the average dose of fluorouracil was 479 mg/m² alone, compared with 533 mg/m² in the presence of dipyridamole. In this study, oral dipyridamole did not improve the antineoplastic activity of fluorouracil and folinic acid. Similarly, another clinical study found that oral dipyridamole did not significantly alter the pharmacokinetics of fluorouracil. Thus, despite the promise of preclinical studies, the benefits of combining dipyridamole with fluorouracil have not been realised clinically.

Fluorouracil + Multivitamin Preparations

Two patients developed severe fluorouracil toxicity while taking multivitamin preparations containing folic acid.

Clinical evidence

A woman who underwent surgery for carcinoma of the rectum was, a month later, given intravenous fluorouracil 500 mg/m² daily for 5 days. At the end of this chemotherapy cycle she was admitted to hospital with anorexia, severe mouth ulceration, bloody diarrhoea and vaginal bleeding, which was interpreted as fluorouracil toxicity. Her concurrent medication included folic acid 5 mg daily (in Multi-B forte) along with loperamide, sulphasalazine, vitamins B₁₂ and K, and HRT. A month later, when she was again given fluorouracil, but without the folic acid, her treatment was well tolerated and without toxicity. A man similarly treated with fluorouracil for colon cancer was admitted to hospital 2 days later with severe mouth ulceration and bloody diarrhoea. He too was found to be taking a multivitamin preparation, containing folic acid 500 micrograms (amount taken daily not known). Subsequent courses of fluorouracil at the same dosage but without the folic acid were well tolerated. For a report of fatal toxicity associated with the concurrent use of folic acid and capecitabine, see ‘Fluorouracil prodrugs; Capecitabine + Folinates’, p.635.

Mechanism

It would seem that folic acid increases fluorouracil inhibition of thymidine formation which is important for DNA synthesis, and thereby increases fluorouracil toxicity.

Importance and management

Direct information seems to be limited to these two cases and a case of fatal toxicity associated with concurrent folic acid and capecitabine, a prodrug of fluorouracil (see ‘Fluorouracil prodrugs; Capecitabine + Folinates’, p.635) but the interaction would appear to be established. What happened is consistent with the way folinic acid, another source of folate, is used therapeutically to increase the potency of fluorouracil. Patients treated with fluorouracil should therefore not be given folic acid, and should be told to avoid multivitamin preparations containing folic acid to prevent the development of severe fluorouracil adverse effects.

Fluorouracil + Folinate Preparation

Pharmacokinetic analysis has shown that folinate enhances systemic exposure to fluorouracil in patients with pancreatic carcinoma given folinic acid, fluorouracil, and gemcitabine. In addition, in vitro, gemcitabine increases the accumulation of fluorouracil and its cytotoxicity. Further study is needed.

Fluorouracil + H₂-receptor antagonists

Some data indicate that 4 weeks, but not 1 week, of treatment with cimetidine can markedly increase plasma fluorouracil levels. The combination may have increased activity in colorectal cancer.

Clinical evidence, mechanism, importance and management

A study in 6 patients with carcinoma given fluorouracil (15 mg/kg daily for 5 days, repeated every 4 weeks) found that cimetidine 1 g daily for 4 weeks increased the peak plasma fluorouracil levels by 74% and the AUC by 72% when fluorouracil was given orally. When fluorouracil was given intravenously the AUC was increased by 64% and the total body clearance was reduced by 28% by cimetidine. In this small group, no increased toxicity was noted. The pharmacokinetics of fluorouracil were unaltered when cimetidine was given for only one week. Cimetidine had similar effects in animal studies but ranitidine had no effect on fluorouracil metabolism. It is suggested that cimetidine reduces the hepatic metabolism of fluorouracil. At least three clinical studies have shown some treatment benefits from giving fluorouracil with long-term cimetidine in colorectal cancer. However, this benefit has been attributed to immunomodulation or inhibition of adhesion, rather than any pharmacokinetic interaction. Whatever the mechanism, it appears that cimetidine can increase the activity of fluorouracil. Concurrent treatment should be undertaken with care. Cimetidine can be obtained without a prescription in some countries so that patients may unwittingly increase the toxicity of fluorouracil. Ranitidine does not appear to interact.

Fluorouracil + Interferon alfa

Interferon alfa has increased plasma fluorouracil levels in some, but not other, studies.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study 26 patients with colorectal cancer were given a 5-day continuous infusion of fluorouracil 750 mg/m² daily repeated in week 4 followed by a bolus intravenous injection of 750 mg/m² once a week with or without subcutaneous interferon alfa-2a (Rofeneron) 9 million units three times a week. There was considerable within-patient variation but no significant differences in steady-state plasma levels were found between the two groups. Similarly, others have also reported that interferon alfa does not significantly alter fluorouracil pharmacokinetics; however, other studies have found a significant increase in peak fluorouracil levels and/or AUC when interferon alfa is given. Despite...
promising early pre-clinical and clinical data indicating that interferon may improve the response to fluorouracil, this has not yet been demonstrated in randomised studies. A study in 27 patients with metastatic melanoma treated with fluorouracil 1000 mg/m² every 28 days and interferon alfa 2a in doses of up to 9 million units daily for 70 days and then 3 million units three times a week for up to a year, found that the response rate was similar to that obtained in other studies using interferon alone. The most frequent adverse effects were related to the interferon, and no patients were withdrawn from the study due to toxicity.

**Fluorouracil + Metronidazole**

The toxicity, but not the efficacy of fluorouracil, is increased by metronidazole.

**Clinical evidence**

A marked increase in fluorouracil toxicity was noted in 27 patients with metastatic colorectal cancer when they were given intravenous metronidazole 750 mg/m² one hour before receiving intravenous fluorouracil 600 mg/m² 5 days per week, every 4 weeks. Granulocytopenia occurred in 74% of patients, nausea and vomiting in 48%, anaemia in 41%, stomatitis and oral ulceration in 34%, and thrombocytopenia in 19%.

A pharmacokinetic study in 10 patients found that metronidazole reduced the clearance of fluorouracil by 27% over the 5-day period and increased the AUC by 34%. In vitro studies with human colon cancer cells failed to show any increased efficacy.

Studies using another nitroimidazole, misonidazole, in patients with colorectal cancer also found an increased incidence and severity of gastrointestinal toxicity with concurrent use, and a slightly increased incidence of leucopenia and a reduction in the clearance of fluorouracil.

**Mechanism**

Metronidazole reduces the clearance of fluorouracil, thereby increasing its toxic effects.

**Importance and management**

Information is limited but the interaction between fluorouracil and metronidazole appears to be established. It was hoped that metronidazole or misonidazole (no longer in clinical use) might increase the efficacy of fluorouracil. However, the studies above show that the toxicity of fluorouracil is increased without an obvious increase in its therapeutic efficacy. Care should be taken if metronidazole is required for its antimicrobial effects.

**Fluorouracil + Miscellaneous**

A retrospective analysis of studies in a total of 250 patients given fluorouracil for the treatment of gastrointestinal cancer found that chlorprothixene, cinnarizine, prochlorperazine, sodium pentobarbital, thiethylperazine, trimethobenzamide (in antiemetic doses) did not significantly increase toxicity or decrease therapeutic effects, when compared with a placebo.

**Fluorouracil prodrugs + Sorivudine**

Marked and rapidly fatal toxicity, attributed to fluorouracil toxicity, has been seen in patients given tegafur or other fluorouracil prodrugs with sorivudine. Fluorouracil is expected to interact similarly.

**Clinical evidence**

In 1993, the Japanese Ministry of Health reported that 15 Japanese patients with cancer and a viral disease died several days after being given a fluorouracil prodrug (e.g. tegafur) and sorivudine. Before death most of them developed severe toxicity including severe anorexia, marked damage to the bone marrow with decreases in white cell and platelet counts, and marked atrophy of the intestinal membrane, with diarrhoea and loss of blood. Eight other patients given both drugs developed symptoms of severe toxicity.

**Mechanism**

Sorivudine appears to be converted in the gut into a metabolite (BVU or bromovinyluracil) that is a potent inhibitor of dihydropyrimidine dehydrogenase (DPD), an enzyme involved in the metabolism of fluorouracil (which is derived from tegafur and other fluorouracil prodrugs). There is some evidence that DPD activity is genetically determined, and that there are poor fluorouracil metabolisers with low DPD activity, who would be expected to be more susceptible to this interaction.

**Importance and management**

Information appears to be limited to these reports but the interaction appears to be established and of clinical importance. The concurrent use of inhibitors of DPD (such as sorivudine and brivudine) and oral fluoruracil prodrugs such as capecitabine and tegafur is contraindicated. Note that sorivudine was withdrawn from the market following confirmation of this interaction.

**Fluorouracil prodrugs; Capecitabine + Allopurinol**

The activity of capecitabine is predicted to be decreased by allopurinol.

**Clinical evidence, mechanism, importance and management**

Capecitabine is a prodrug, which is activated by several enzymatic steps to produce active fluorouracil within the body. Because allopurinol is reported to modulate fluorouracil, it is possible that capecitabine, with possible decreased efficacy (see
The absorption of capecitabine was not affected by an aluminum/magnesium hydroxide antacid.

Clinical evidence, mechanism, importance and management

A study in 12 patients found that 20 mL of an aluminum/magnesium hydroxide antacid (Maalox) caused a small increase in the plasma levels of a single 1250-mg/m² oral dose of capecitabine and one metabolite (5'-DFCR) but it had no effect on the other 3 major metabolites (5'-DFUR, 5'-FU and FBAL). There would therefore seem to be no reason for taking special precautions if capecitabine and an antacid of this type are used concurrently.

Fluorouracil prodrugs; Capecitabine + Antacids

A patient died after treatment with capecitabine possibly because the concurrent use of folic acid enhanced capecitabine toxicity. The maximum tolerated dose of capecitabine is decreased by folic acid.

Clinical evidence, mechanism, importance and management

(a) Folic acid

A 51-year-old woman with metastatic breast cancer started treatment with capecitabine 2500 mg/m² daily for 14 days every 21 days. Treatment was stopped after 8 days because she developed diarrhea, vomiting and hand-foot syndrome. She improved with parenteral hydration and symptomatic treatment, but 3 weeks later still had diarrhea, leg oedema and a hand-foot syndrome. She was found to have been taking folic acid 15 mg daily for several weeks before starting capecitabine and had continued to take it during and after capecitabine treatment. The patient’s condition improved when the folic acid was stopped, but she then developed diarrhea and fever followed by necrotic colitis and she died from septic shock and vascular collapse. It is possible that the concurrent use of folic acid enhanced the toxicity of capecitabine.

(b) Folinic acid

Studies in patients with refractory advanced cancer have shown that folinic acid 30 mg twice daily does not have a major effect on the pharmacokinetics of capecitabine. However, the pharmacodynamics of capecitabine were affected as determined by the more frequent occurrence of dose-limiting gastrointestinal disorders or hand-foot syndrome. The UK manufacturers say that the maximum tolerated dose of capecitabine when used alone in the intermittent regimen is 3000 mg/m², but it is reduced to 2000 mg/m² if folinic acid 30 mg twice daily is also given.

Clinical evidence, mechanism, importance and management

(b) Folinic acid

Studies in patients with refractory advanced cancer have shown that folinic acid 30 mg twice daily does not have a major effect on the pharmacokinetics of capecitabine. However, the pharmacodynamics of capecitabine were affected as determined by the more frequent occurrence of dose-limiting gastrointestinal disorders or hand-foot syndrome. The UK manufacturers say that the maximum tolerated dose of capecitabine when used alone in the intermittent regimen is 3000 mg/m², but it is reduced to 2000 mg/m² if folinic acid 30 mg twice daily is also given.

Clinical evidence, mechanism, importance and management

The concurrent use of gemcitabine and doxorubicin or epirubicin does not appear to affect the pharmacokinetics of either drug. An in vitro study found that the efficacy of the combination of gemcitabine and epirubicin may be schedule-dependent.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of gemcitabine and doxorubicin did not differ when they were given on the same day, when compared with when they were given alone in patients with breast cancer. Similarly, gemcitabine pharmacokinetics were unchanged by the concurrent use of epirubicin and paclitaxel in patients with breast cancer, and gemcitabine did not alter the interaction between epirubicin and paclitaxel (see ‘Anticyclines + Taxanes’, p.612).

An in vitro study using human bladder cancer cells found that both gemcitabine and epirubicin alone exerted a cytotoxic effect but the efficacy of the combination of epirubicin and gemcitabine depended on the schedule.
Gemcitabine + Platinum derivatives

The toxicity and pharmacokinetics of gemcitabine combined with platinum drugs such as cisplatin is dependent upon the order in which they are given.

Clinical evidence, mechanism, importance and management

(a) Carboplatin

Gemcitabine 1000 mg/m² on days 1, 8, and 15 has been given with carboplatin (maximum tolerated dose, giving an AUC of 5.2 mg/mL per minute) on day 1, in a monthly cycle. No difference was detected in toxicity or tolerated dose when the gemcitabine was given before or after the carboplatin. However, subsequent authors reported that this same drug schedule, with carboplatin given immediately after the gemcitabine, caused unexpected and severe thrombocytopenia, and could not be recommended.

(b) Cisplatin

When gemcitabine was given 4 hours before or after cisplatin there were no major differences in the plasma pharmacokinetics of gemcitabine, deaminated gemcitabine and platinum. Similarly, cisplatin given 24 hours before gemcitabine did not significantly change gemcitabine and deaminated metabolite and platinum. Similarly, cisplatin given 24 hours before gemcitabine did not significantly change gemcitabine and deaminated metabolite and platinum. Similarly, cisplatin given 24 hours before gemcitabine did not significantly change gemcitabine and deaminated metabolite and platinum.

(c) Oxaliplatin

The pharmacokinetics of gemcitabine 800 to 1500 mg/m² and its main metabolite did not appear to be affected by oxaliplatin 70 to 100 mg/m² when oxaliplatin was given immediately after gemcitabine once every two weeks.

Gemcitabine + Taxanes

One study found that giving paclitaxel before gemcitabine increased the gemcitabine levels by 25%, but other studies did not find a pharmacokinetic interaction. Gemcitabine distribution may be affected by docetaxel, but docetaxel pharmacokinetics are not affected. The clinical response to the combination of gemcitabine and a taxane may depend on the sequence of administration.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

In a study of gemcitabine and docetaxel, given on days 1 and 8 of a 21-day cycle, drug toxicity and pharmacokinetics were unaffected by the relative order of their administration. However, in another study, it appeared that while docetaxel pharmacokinetics were unaffected, the distribution of gemcitabine was altered by docetaxel, although there was no clear relationship between this and toxicity.

A response rate of 43% was reported in a study in which 35 patients with sarcomas were given gemcitabine 675 mg/m² over 90 minutes on day 1 and 8, followed by docetaxel 100 mg/m², given over 60 minutes, on day 8. The possible synergistic antitumour effect may have been secondary to both the prolonged gemcitabine infusion and the sequence of drug administration. More study is needed.

(b) Paclitaxel

A study in 18 patients with non-small-cell lung cancer found that when they were given gemcitabine 1000 mg/m² on days 1 and 8 and paclitaxel 150 to 200 mg/m² on day one as a 3-hour infusion immediately before the gemcitabine, the plasma levels of gemcitabine and the AUC of its deaminated metabolite were unchanged, as was the AUC of paclitaxel. However, paclitaxel increased gemcitabine triphosphate levels, potentially improving efficacy. In a study in 14 patients with non-small cell lung cancer, gemcitabine 800 mg/m² was administered on day 1 and 8 of a 21 day cycle and paclitaxel 110 mg/m² was given 3 hours before the second dose of gemcitabine on day 8. When paclitaxel was given first the clearance, volume of distribution and interpatient pharmacokinetic variability of gemcitabine were decreased. Plasma levels of gemcitabine were increased by 25%, but there was no correlation between these changes and toxicity, and the clinical significance of the interaction is uncertain. In another study, no pharmacokinetic interactions were detected between gemcitabine and paclitaxel given once weekly, although gemcitabine showed saturation kinetics at higher doses. Another study in patients with advanced breast cancer given gemcitabine, epirubicin and paclitaxel also found no pharmacokinetic interaction between gemcitabine and paclitaxel.

The high overall response rate of 71% in a phase II study in patients with advanced breast cancer treated with gemcitabine and paclitaxel, prompted an in vitro study which found that administration of paclitaxel followed by gemcitabine resulted in synergistic cytotoxic activity, whereas gemcitabine followed by paclitaxel had antagonistic activity. Phase III studies are being carried out to establish the order of administration of these drugs in patients with metastatic breast cancer.
**Imatinib + CYP3A4 inducers**

Rifampicin (rifampin) and St John’s wort (Hypericum perforatum) lower serum imatinib levels; other CYP3A4 inducers (such as carbamazepine, phenobarbital and phenytoin) are predicted to do the same.

**Clinical evidence**

(a) Rifampicin (Rifampin)

A study reported that pretreatment with rifampicin 600 mg daily for 11 days decreased the maximum serum levels and AUC of a 400 mg dose of imatinib by 54% and 74%, respectively.1

(b) St John’s wort (Hypericum perforatum)

In a study in 12 healthy subjects, the pharmacokinetics of a single dose of imatinib was determined before and on day 12 of two weeks of treatment with St John’s wort (Hypericum perforatum) extract (Kira [LI 160], Lichtwer Pharma) 300 mg three times daily. The AUC and maximum plasma level of imatinib was decreased by 30% and 15%, respectively. Imatinib clearance was increased by 43% and its half-life was decreased from 12.8 to 9 hours.2 Similar results were found in another study.3

**Mechanism**

Rifampicin is a known potent inducer of many cytochrome P450 isoenzymes, including CYP3A4, by which imatinib is metabolised. Therefore rifampicin increases imatinib metabolism and decreases its levels. St John’s wort induces intestinal CYP3A4 and it therefore also reduces imatinib levels.

**Importance and management**

Subtherapeutic levels of imatinib may occur if rifampicin is given. The manufacturers therefore reasonably recommend caution, and suggest that concurrent use with potent enzyme-inducing drugs should be avoided.4,5 St John’s wort has smaller effects, but they may be sufficient to impair the effects of imatinib, and it has therefore been suggested that concurrent use should also be avoided.4

No specific studies have been carried out with imatinib and other CYP3A4-inducing drugs, but the manufacturers suggest that carbamazepine, dexamethasone, phenobarbital, and phenytoin, may also reduce imatinib serum levels, and they have a possible case on file with phenytoin.6 The manufacturers therefore reasonably recommend caution, and suggest that concurrent use with these drugs should be avoided.4,5 However, if this is not possible it would be prudent to monitor the outcome of concurrent use, and increase the imatinib dose as necessary.

---

**Imatinib + Miscellaneous**

**Imatinib + CYP3A4 inhibitors**

Ketoconazole raises serum imatinib levels; other cytochrome P450 isoenzyme CYP3A4 inhibitors (such as other azoles and macrolides) are predicted to do the same.

**Clinical evidence**

(a) Ketoconazole

An open-label, randomised, crossover study in 14 healthy subjects found that the maximum serum levels and AUC of imatinib rose by 26% and 40%, respectively, when they were given a single 400-mg dose of ketoconazole with a single 200-mg dose of imatinib.6

(b) Voriconazole

A patient with chronic myeloid leukaemia developed a pustular eruption while taking imatinib 400 mg daily, increased to 800 mg daily 12 weeks after starting to take voriconazole for pulmonary aspergillosis. His imatinib plasma levels were approximately twice the predicted levels while taking both drugs. His condition improved within 3 weeks of stopping both voriconazole and imatinib, and did not recur with voriconazole treatment alone.5

**Mechanism**

Ketoconazole is a potent inhibitor of the cytochrome P450 iso-enzyme CYP3A4, which is involved in the metabolism of imatinib. Therefore ketoconazole reduces the metabolism and clearance of imatinib and its serum levels rise accordingly. Adverse skin reactions occur frequently with imatinib and may be associated with high doses of imatinib and/or increased levels due to an interaction with CYP3A4 inhibitors, such as voriconazole.2

**Importance and management**

The manufacturers therefore advise caution with ketoconazole and with other CYP3A4 inhibitors (examples listed are clarithromycin, erythromycin and itraconazole),3,4 but it is not entirely clear what action should be taken because information about excessive serum levels is very limited. The authors of one report suggest monitoring plasma levels of imatinib to identify patients at risk of severe toxicity.2

---

---

appeared and she developed Stevens-Johnson syndrome. Both drugs were again stopped and she recovered after treatment with methylprednisolone and desloratadine for one month. Two months later, she took a single dose of lansoprazole on the day before treatment with imatinib 300 mg daily (with prednisone and desloratadine) was started. One day later she developed eyelid and labial oedema and a generalised rash. She recovered after imatinib was stopped. Although the adverse effects could be attributed to either imatinib or lansoprazole alone, it was possible that the effects may have been the result of an interaction in which levels of imatinib were increased by lansoprazole, which is a weak inhibitor of CYP3A4. This needs confirmation.

(d) Oestrogens
A patient taking a low-dose oestrogen contraceptive developed nausea and abdominal pain after taking imatinib 400 mg daily for 4 months. Ultra-sound showed multiple gallstones and increased gallbladder wall thickness. Imatinib was reported to increase plasma oestrogen levels by inhibiting its metabolism by the cytochrome P450 isozyme CYP3A4, possibly leading to increased cholesterol excretion, reduced bile salt excretion and gallstone development. This needs confirmation.

(e) Paracetamol (Acetaminophen)
During clinical studies one patient regularly taking paracetamol for fever, died of acute liver failure 11 days after starting to take imatinib. The manufacturers report that imatinib inhibits paracetamol O-glucuronidation in vitro. Although this potential interaction has not been studied in humans, the manufacturers recommend caution during concurrent use, especially with high doses of paracetamol.1,2

(f) Warfarin
The manufacturers say that because warfarin is metabolised by CYP2C9, patients needing anticoagulation should be given low-molecular-weight or standard heparin instead. This recommendation is based on an observation in one patient1 and in vitro studies2,3 that show that imatinib can inhibit CYP2C9. There seems to be no other evidence that a clinically relevant interaction is likely to occur.

(g) Other drugs
The manufacturers of imatinib predict that it may raise the levels of pimozide with potentially serious consequences [arrhythmias] because of CYP3A4 inhibition. They also suggest that imatinib may raise the levels of the triazolo-benzodiazepines (e.g. triazolam, midazolam).1,2 This could lead to increased and prolonged sedation.

**Irinotecan + Antiepileptics**

In patients with malignant gliomas, enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin) and, to a lesser extent, non-enzyme-inducing antiepileptics (gabapentin, valproate) increased the clearance of irinotecan. The clearance of the active metabolite of irinotecan was also increased by phenytoin. A number of case reports support these suggestions.

**Clinical evidence, mechanism, importance and management**

(a) Carbamazepine
In a preliminary report of studies in patients with malignant glioma, the clearance of irinotecan was increased almost twofold in the presence of carbamazepine. Peak plasma levels and AUC of irinotecan and SN-38 were significantly decreased.1

(b) Phenobarbital
Preclinical data from rats2 indicate that phenobarbital may lead to a reduction in the AUC of both irinotecan and its active metabolite SN-38. This is thought to be because phenobarbital induces the enzymes responsible for glucuronidation of SN-38. In a preliminary report of studies in patients with malignant glioma, clearance of irinotecan was increased by about 1.7-fold in the presence of phenobarbital. The AUC and peak plasma levels of irinotecan and SN-38 were significantly decreased. In a Phase I study in patients given ciclosporin and irinotecan, giving phenobarbital 90 mg daily for 2 weeks before irinotecan allowed a dose escalation of irinotecan from 75 mg/m2 to 144 mg/m2. Phenobarbital increased irinotecan clearance by 27% and reduced the AUC of SN-38 by 75%, when compared to irinotecan pharmacokinetics in patients given irinotecan with ciclosporin. Further clinical studies are needed to assess the effects of phenobarbital (with ciclosporin; see also, ‘Irinotecan + Ciclosporin’, p.639) on the antitumour response and toxicity of irinotecan.

(c) Phenytoin
A 14-year-old girl with glioblastoma was given irinotecan 20 to 60 mg/m2 daily for 5 days on 2 consecutive weeks every 21 days for 2 cycles. During the first cycle she also received phenytoin 300 mg and dexamethasone 6 mg daily. Irinotecan clearance was increased 2.5-fold compared with that in other patients receiving irinotecan alone, and there was decreased exposure to the active metabolite of irinotecan, SN-38. The effect on clearance decreased slowly over 8 days after stopping phenytoin.4 Another patient taking phenytoin and irinotecan was found to have much lower AUCs for irinotecan and SN-38 compared with data from patients not taking phenytoin.5 Similarly, a third patient had a threefold increase in irinotecan clearance and about a 60% reduction in the AUCs of irinotecan and SN-38 after starting phenytoin.6 In a comparative study, the AUC of the lactone forms of irinotecan and SN-38 were 27% and 51% lower, respectively, in 10 children taking enzyme-inducing antiepileptics (7 receiving phenytoin) than in 21 children not taking these antiepileptics.1 A preliminary report of studies in patients with malignant glioma, clearance of irinotecan was increased by about twofold in the presence of phenytoin. Peak plasma levels and AUC of irinotecan and SN-38 were significantly decreased.1 It is thought that phenytoin increases the metabolism of irinotecan to an inactive metabolite by inducing the cytochrome P450 isozyme CYP3A, leading to decreased exposure to the active metabolite.5

The information is limited but serves to emphasise the need for caution and monitoring if irinotecan is given with phenytoin, which may reduce the availability of its active metabolite. Note that phenytoin has also been shown to increase the clearance of a related topoisomerase inhibitor, topotecan (see ‘Topotecan + Phenytoin’, p.667) and 9-aminocamptothecin (see ‘9-Aminocamptothecin + Antiepileptics’, p.610).

(d) Non-enzyme-inducing antiepileptics
Preclinical data from rats2 suggests that sodium valproate increases the AUC of the active metabolite of irinotecan, SN-38. This is because valproate inhibits its subsequent glucuronidation. The clinical relevance of this remains to be determined. A preliminary report of studies in patients with malignant gliomas found that in patients also taking non-enzyme-inducing antiepileptics (gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, valproate, or zonisamide) there was a small but statistically significant increase (about 1.4-fold) in irinotecan clearance.1

The pharmacokinetics of irinotecan are not altered by a herbal tea containing cannabis.

Clinical evidence, mechanism, importance and management

In a crossover study 24 patients were given intravenous irinotecan 600 mg before and 12 days after starting a 15-day course of 200 mL daily of a herbal tea containing cannabis 1 g/L. This was prepared from medicinal-grade cannabis (Cannabis sativa L. Flos, variety Bedrocan®) containing the cannabinoid Δ9-tetrahydrocannabinol 18% and cannabidiol 0.8%. The clearance and the AUC of irinotecan and its metabolites, SN-38 and SN-38G, were not significantly altered by the presence of cannabis. No dosage adjustments are likely to be needed if irinotecan is given with cannabis.1

Ciclosporin reduces the clearance of irinotecan and increases exposure to its active metabolite, SN-38.

Clinical evidence, mechanism, importance and management

In a phase 1 study in patients with refractory solid tumours or lymphomas, ciclosporin 5 to 10 mg/kg was given as a 6-hour infusion beginning 3 hours before administration of irinotecan (initial dose 25 mg/m² increased to 72 mg/m² weekly). Ciclosporin increased the AUC of SN-38 (the active metabolite of irinotecan) by 23 to 630% and reduced irinotecan clearance by 39 to 64%, when compared with historical controls. The effects of ciclosporin on irinotecan may be due to inhibition of irinotecan- and SN-38-related biliary transporters,1 and this suggestion is supported by a study in rats.2 Further clinical studies are needed to assess the effects of ciclosporin on the antitumour response and toxicity of irinotecan.

While some studies suggest that giving fluorouracil after irinotecan can reduce the conversion of irinotecan to its active metabolite, others do not.

Clinical evidence, mechanism, importance and management

A study in 33 patients with metastatic colorectal cancer found that the toxicity and pharmacokinetics of irinotecan given with fluorouracil depended upon the order of administration of the two drugs.1 When irinotecan was given before fluorouracil, the AUC of the major active metabolite of irinotecan, SN-38, was about 40% lower, and toxicity was lower. In this study, patients were randomised to receive a 60-minute infusion of irinotecan (150 mg/m² starting dose, escalated by 50 mg/m² increments) immediately before or after a 48-hour infusion of fluorouracil 3500 mg/m² modulated by folinic acid in cycle 1, then given in the reverse sequence in cycle 2. Similarly, in a study using historical controls, the AUC of SN-38 was about 28% lower and the AUC of irinotecan about 35% higher when irinotecan was given over 90 minutes immediately before a 7-day fluorouracil infusion, compared with irinotecan alone.2 Similar findings were reported in a study in rats.3 In contrast, another study found that fluorouracil did not substantially affect the metabolism of irinotecan to SN-38. The AUC of irinotecan and SN-38 did not differ between irinotecan alone, irinotecan immediately followed by folinic acid and fluorouracil, and irinotecan immediately after folinic acid and fluorouracil. In this study, irinotecan 100 to 150 mg/m² was given as a 90-minute infusion, and fluorouracil 210 to 500 mg/m² by rapid intravenous injection.4 Similarly, preliminary reports from another research group found that the clearance of irinotecan did not differ when it was given one day before or one day after 5 daily bolus doses of fluorouracil.3,5

Ketoconazole, and therefore probably irtraconazole, decreases irinotecan levels and increases the levels of its active metabolite.

Clinical evidence, mechanism, importance and management

A study found that ketoconazole decreased the AUC of irinotecan by 87% and increased the AUC of the active metabolite, SN-38, by 109%. This probably occurred because ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which irinotecan is metabolised. The manufacturers of irinotecan recommend that the concurrent use of ketoconazole should be avoided.1,2 The US manufacturers recommend stopping ketoconazole at least one week before starting irinotecan and continuing the concurrent use.3 It is likely that other azoles that are strong inhibitors of CYP3A4, such as itraconazole, may also affect the metabolism of irinotecan.

Milk thistle does not affect the pharmacokinetics of irinotecan.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study was undertaken in 6 patients who were being treated with intravenous irinotecan 125 mg/m² once weekly for 4 weeks, followed by a 2 week rest period. Four days before the second dose of irinotecan, a 14-day course of 200 mg milk thistle seed extract (containing silymarin 80%) three times daily was started. The pharmacokinetics of irinotecan and its metabolites did not differ between week 1 (no milk thistle), week 2 (4 days of milk thistle) or week 3 (12 days of milk thistle).1 No dosage alterations would therefore be expected to be needed if milk thistle (standardised with silymarin 80%) is given with irinotecan.

Irinotecan + Miscellaneous

Preclinical data suggest that vinorelbine and physostigmine may decrease the formation of the active metabolite of irinotecan, SN-38.

Clinical evidence, mechanism, importance and management

In studies in human liver microsomes, nifedipine, clonazepam, methylprednisolone, omeprazole, and vinorelbine had significant effects on the metabolism of irinotecan. However, only the effect of vinorelbine occurred at a concentration considered clinically relevant.1 Similarly, of various potential carboxylesterase inhibitors, only physostigmine was considered sufficiently potent to possibly inhibit irinotecan activation.2 Further study is needed to assess the clinical relevance of these findings.

Irinotecan + Oxaliplatin

An isolated report suggests that the cholinergic toxicity associated with irinotecan may be enhanced by oxaliplatin.

Clinical evidence, mechanism, importance and management

One of 15 patients given a 1-hour infusion of irinotecan 80 mg/m² following an 2-hour infusion of oxaliplatin 85 mg/m² experienced hypersalivation and abdominal pain, which was treated successfully with atropine. In this patient, symptoms did not recur during subsequent treatment with irinotecan alone, nor when drugs were separated by one day, but rechallenge with the original combined regimen produced cholinergic toxicity.1 The combination of irinotecan with oxaliplatin did not alter the pharmacokinetics of either drug in one study2 therefore it was suggested that the observed effects in the patient may have been due to a pharmacodynamic interaction.3 It has been suggested that the cholinergic effects of irinotecan, which is a potent inhibitor of acetylcholinesterase,4 may be enhanced by oxaliplatin, which may like other alkylating drugs also inhibit acetylcholinesterase.5 The clinical relevance of this report is unknown. The combination of irinotecan and oxaliplatin has been extensively evaluated in clinical studies, and this appears to be the only report of this problem. However, it has been noted that the prophylactic use of atropine with irinotecan could mask any increased cholinergic toxicity.3,5 Further study is needed.

Irinotecan + Rifampicin (Rifampin)

A single case report found that rifampicin reduced the formation of the two active metabolites of irinotecan. The clinical significance of this finding is unclear.

Clinical evidence, mechanism, importance and management

A case report describes a 54-year-old man with small cell lung cancer and Mycobacterium infection who was uneventfully treated with rifampicin 450 mg daily, isotiazid, streptomycin and pyrazaminide. After 2 weeks of antmycobacterial treatment he was given irinotecan, 75 mg/m² on days 1 and 8, and cisplatin 60 mg/m² on day 1 for 4 cycles, for one of which rifampicin treatment was interrupted for a 4-day period. There was no difference in the pharmacokinetic profile of irinotecan with or without concurrent rifampicin, but the AUC of two active metabolites of irinotecan were reduced by 20% and 58%,1

Further study is required to assess the significance of this finding. Also note that the effects of rifampicin can persist for some time after it is stopped and therefore a 4-day period may not have been sufficient for any effect to become apparent.

Irinotecan + Selenium

Selenium at a dose of 2.2 mg daily does not appear to alter the pharmacokinetics of irinotecan, nor does it attenuate the toxicity of irinotecan.

Clinical evidence, mechanism, importance and management

In a study in 13 patients with metastatic or unresectable solid tumours selenomethionine, at a dose of elemental selenium 2.2 mg daily, was given with irinotecan weekly, in escalating doses from 125 mg/m² to 160 mg/m² for 4 weeks of a 6-week cycle. Irinotecan doses above the previously recommended maximum tolerated dose were still considered intolerable, with 3 of 4 patients receiving a dose of 160 mg/m² developing dose-limiting diarrhoea. There were no significant alterations in the pharmacokinetics of irinotecan or its metabolites, SN-38 and SN-38G. It was suggested that higher doses of selenomethionine should be investigated to see if they protect against irinotecan toxicity.1

Irinotecan + Sorafenib

Sorafenib might increase levels of irinotecan and its major metabolite.

Clinical evidence, mechanism, importance and management

A study in 3 groups of 6 patients given sorafenib in doses of 200 mg, 400 mg or 800 mg daily, and irinotecan 125 mg/m² as an intravenous infusion found that the pharmacokinetics of irinotecan and its major active metabolite, SN-38, were not affected by sorafenib. In addition, sorafenib pharmacokinetics were not affected by irinotecan.1

In contrast, the manufacturers note that when sorafenib was given with irinotecan there was a 26 to 42% increase in the AUC of irinotecan, and a 67 to 120% increase in the AUC of SN-38. They suggest that this occurs because sorafenib inhibits glucuronidation of SN-38. The clinical significance of this finding is unknown, but they recommend caution on concurrent use.2,3

Irinotecan + St John’s wort (Hypericum perforatum)

St John’s wort increases the metabolism of irinotecan, which may decrease its activity.

Clinical evidence

In a randomised, crossover study St John’s wort decreased the plasma levels of the active metabolite of irinotecan, SN-38, by 42%. Myelosuppression was also reduced; with irinotecan alone the leucocyte and neutrophil counts decreased by 56% and 63%, respectively, but in the presence of St...
John’s wort the decreases were only 8.6% and 4.3%, respectively. In this study, irinotecan was given as a single 350-mg/m² intravenous dose every 3 weeks, and during one cycle a St John’s wort preparation was given three times daily, beginning 14 days before and stopping 4 days after the irinotecan.

**Mechanism**

St John’s wort induces the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein, which are both involved in the metabolism of irinotecan. The evidence suggests that St John’s wort increases the metabolism of irinotecan to an unknown inactive metabolite, rather than the active SN-38, thereby reducing its effects.

**Importance and management**

The evidence appears to be limited to this study. Irinotecan has a narrow therapeutic range, and the lower levels of SN-38 suggest that its activity will be reduced in the presence of St John’s wort. It would therefore seem sensible to warn patients who are about to receive irinotecan to avoid St John’s wort. It seems likely that topotecan, a related drug that is also a substrate for CYP3A4, will be similarly affected, but evidence for this is currently lacking.

**Irinotecan + Thalidomide**

Thalidomide slightly increases irinotecan levels, but the clinical significance of this is uncertain.

**Clinical evidence, mechanism, importance and management**

Patients with solid tumours treated with irinotecan 350 mg/m² on day 1 of a 3-week cycle were also given thalidomide 400 mg daily from days 1 to 14 of the first cycle. Thalidomide slightly increased the AUC of irinotecan by 21% (not significant) and its SN-38-glucuronide metabolite by 28%, but decreased the AUC of the SN-38 metabolite by 26%. There was no difference in the toxicities seen when irinotecan was given with or without thalidomide.

Further study is required in larger groups of patients to establish if these changes in irinotecan pharmacokinetics are clinically relevant.

**Irinotecan + Tobacco**

Retrospective data suggests that tobacco smoking might increase the clearance of irinotecan and reduce its toxicity, and presumably therefore, its efficacy.

**Clinical evidence**

In a retrospective analysis, the pharmacokinetics of irinotecan were compared between 49 patients who were smokers and 141 who were non-smokers, and who had received intravenous irinotecan 175 to 350 mg/m² (or a fixed dose of 600 mg) once every 3 weeks. Clearance of irinotecan was 18% faster in the group of patients who smoked, and these patients were also shown to have more extensive conversion of the active metabolite SN-38 to the inactive glucuronide (SN-38G). Smokers experienced significantly less haematological toxicity than non-smokers (grade 3 to 4 neutropenia 6% versus 38%), possibly as a result of the increased rate of clearance.

**Mechanism**

Irinotecan is metabolised by the cytochrome P450 CYP3A isoenzymes, which, although not the most commonly implicated isoenzyme in interactions involving tobacco smoke, may be induced by some of the components of tobacco smoke, resulting in increased clearance of irinotecan. In addition, smoking might induce glucuronyltransferases (which are responsible for glucuronidation).

**Letrozole + Cimetidine**

The pharmacokinetics of a single 2.5-mg dose of letrozole were unchanged by cimetidine 400 mg every 12 hours in 17 healthy subjects.

**Letrozole + Miscellaneous**

The UK manufacturers report that in interaction clinical studies there was no evidence of clinically relevant interactions between letrozole and other commonly prescribed drugs, namely benzodiazepines such as diazepam, barbiturates, di clofenac, furosemide, ibuprofen, omeprazole, and paracetamol (acetaminophen).

**Melphalan + Cimetidine**

Cimetidine modestly reduces the bioavailability of melphalan.

**Clinical evidence, mechanism, importance and management**

A study in 8 patients with multiple myeloma or monoclonal gammopathy showed that pretreatment with cimetidine 1 g daily for 6 days reduced the bioavailability of a 10-mg oral dose of melphalan by 30%. The melphalan half-life was reduced from 1.94 to 1.57 hours. The interindividual variation in melphalan pharmacokinetics was high. Note that, because of the variability in melphalan absorption, the dose of oral melphalan is usually cautiously increased until myelosuppression is seen, to ensure therapeutic levels. Therefore, this modest interaction with cimetidine is unlikely to have many clinical consequences.

**Melphalan + Food**

The absorption of oral melphalan can be reduced by food.

**Clinical evidence, mechanism, importance and management**

A study in 10 patients with multiple myeloma showed that the half-life of oral melphalan 5 mg/m² was unaffected when it was taken with a standardised breakfast, but the AUC was reduced by 39%. In one patient, no melphalan was detectable in the plasma when it was given with food. In 8 of the patients who had also been given intravenous melphalan at the same dose, the bioavailability of oral melphalan was calculated to be 85% (range 26% to 96%) when fasting and 58% (7% to 99%) when given with food. The authors recommend that melphalan should not be taken with food.

Melphalan + Interferon alfa

Interferon alfa modestly decreases the AUC of melphalan, but melphalan cytotoxicity is possibly increased because of the interferon-induced fever.

Clinical evidence, mechanism, importance and management

In 10 myeloma patients the AUC of melphalan 250 microgram/kg was reduced by 13% when it was given 5 hours after the administration of human interferon alfa (7 x 10⁶ units/m²), possibly due to the fever caused by the interferon.¹ The clinical importance of this is uncertain but the authors of the report suggest that despite this small reduction in the AUC, the cytotoxicity of the melphalan is increased by the fever. The use of interferon alfa with melphalan and prednisone in multiple myeloma has been associated with more adverse effects.²⁻⁴

Methotrexate + Amiodarone

An isolated case report tentatively attributes the development of methotrexate toxicity with the concurrent use of amiodarone.

Clinical evidence, mechanism, importance and management

An elderly woman, whose psoriasis was effectively controlled for 2 years with methotrexate, developed ulceration of the psoriatic plaques within 2 weeks of starting treatment with amiodarone. The reason is not understood. A modest increase in her dosage of furosemide is a suggested contributory factor because it might have interfered with the excretion of the methotrexate.¹

Methotrexate + Amphotericin B

Amphotericin B may delay the clearance of methotrexate.

Clinical evidence, mechanism, importance and management

Two children had delayed clearance of pulse methotrexate (1 g/m² over 24 hours) while they were receiving amphotericin B. Methotrexate levels were about 300 to 500% higher 48 hours after methotrexate when they were receiving amphotericin B, compared with methotrexate alone.¹ In a study, methotrexate clearance in 18 children given high-dose methotrexate (1 g/m² intravenously) was significantly correlated with the glomerular filtration rate (GFR).² Concurrent amphotericin B in 6 of the children significantly decreased the GFR.² A history of heavy amphotericin B treatment (greater than 30 mg/kg) correlated with decreased methotrexate clearance in 24 children with relapsed leukaemia.³ Amphotericin B may cause renal impairment, which can result in delayed methotrexate clearance. The adverse effects of methotrexate should be carefully monitored (e.g. patient reported symptoms, LFTs, blood counts) in patients taking amphotericin B or those previously extensively treated with the drug. In patients taking large doses of methotrexate (e.g. not the weekly doses given for conditions such as rheumatoid arthritis) the monitoring of methotrexate levels is recommended.

Methotrexate + Antibacterials; Aminoglycosides, oral

There is evidence that the gastrointestinal absorption of methotrexate can be reduced by paromomycin, neomycin and possibly other oral aminoglycosides, but increased by kanamycin.

Clinical evidence

A study in 10 patients with small cell bronchogenic carcinoma taking methotrexate found that when they were also given a range of oral anti-infectives (paromomycin, vancomycin, polymyxin B, nystatin) the urinary recovery of methotrexate was reduced by over one-third (from 69% to 4%)¹. The paromomycin was believed to have been responsible. In another study the concurrent use of neomycin 500 mg four times a day for 3 days reduced the methotrexate AUC and the 72-hour cumulative excretion by 50%.² In contrast, the same report suggests that kanamycin can increase the absorption of methotrexate, but no details are given.

Mechanism

Oral aminoglycosides reduce the activity of the gut flora, which metabolise methotrexate so that more is available for absorption. However, paromomycin³ and neomycin, in common with other oral aminoglycosides, can cause a malabsorption syndrome, which reduces drug absorption and presumably negates any effect altering the gut flora has. Kanamycin may possibly be different because it causes less malabsorption.

Importance and management

The documentation of these interactions is sparse, but it would seem prudent to be on the alert for a reduction in the response to methotrexate if patients are given oral aminoglycosides such as paromomycin or neomycin. An increased response may possibly occur with kanamycin. No interaction would be expected if aminoglycosides are given parenterally.

Methotrexate + Antibacterials; Cefotiam

Pancytopenia and pseudomembranous colitis occurred when a patient treated with low-dose methotrexate and loxoprofen was given cefotiam.

Clinical evidence, mechanism, importance and management

An elderly woman who had been treated with low-dose methotrexate 5 mg weekly and loxoprofen for one month developed acute pyelonephritis. Infection with Clostridium difficile was established and on day 7 she developed severe watery diarrhoea. Analysis showed pancytopenia and Clostridium difficile infection. Methotrexate and cefotiam were stopped, and vancomycin started, and the patient recovered.¹ It was suggested that the combination of the antineoplastic drug and antibacterial increased the risk of Clostridium difficile diarrhoea. In addition, the NSAID (see ‘Methotrexate + NSAIDs’, p.649) and renal impairment from the pyelonephritis could have contributed to the methotrexate toxicity.¹ This appears to be an isolated case, and any interaction with cefotiam is not established.

Methotrexate + Antibacterials; Ciprofloxacin

A report describes two patients who developed methotrexate toxicity when they were given ciprofloxacin.

Clinical evidence

When 2 patients with osteosarcoma, treated with high-dose methotrexate 12 g/m² over 2 weeks, were given ciprofloxacin 500 mg twice daily, either during or 2 days before the start of the methotrexate course, methotrexate elimination was delayed, resulting in raised serum levels, severe cutaneous toxicity and renal impairment. The first patient also had hepatic injury and haematological toxicity. Following increased folic acid rescue, methotrexate levels normalised after several days. In earlier courses without ciprofloxacin in the first patient and subsequent courses without ciprofloxacin in the second patient, methotrexate elimination was normal.1 This preliminary report1 has subsequently been published in full.2,3

Mechanism

Not fully understood. Ciprofloxacin may displace methotrexate from its plasma-protein binding sites resulting in a rise in levels of unbound methotrexate. Ciprofloxacin may also cause a decrease in renal clearance of methotrexate.

Importance and management

Information appears to be limited to one report, but it would seem prudent to monitor for raised methotrexate levels if concurrent use is necessary. More study is needed.

Methotrexate + Antibacterials; Co-trimoxazole or Trimethoprim

Eleven cases of severe bone marrow depression have been reported, three of them fatal, caused by the concurrent use of low-dose methotrexate and treatment doses of trimethoprim or co-trimoxazole (sulfamethoxazole and trimethoprim). Pancytopenia has also been reported in a few patients given treatment doses of co-trimoxazole shortly after stopping methotrexate.

Clinical evidence

A 61-year-old patient with rheumatoid arthritis, taking methotrexate 7.5 mg weekly, developed generalised bone marrow hypoplasia over 2 months after a 10-day course of treatment with co-trimoxazole for a urinary tract infection. She had taken a total of 775 mg of methotrexate when the hypoplasia appeared.1 Eleven other cases of severe bone marrow depression, three of them fatal, have been described in patients taking low-dose weekly methotrexate with given co-trimoxazole3-6,10 Life-threatening complications (no details given) are said to have occurred in two other patients taking low-dose methotrexate with unnamed sulfonamides.12 A 10-year (1981 to 1991) regional survey in Ottawa identified co-trimoxazole as one of four factors associated with serious pancytopenia in patients taking low-dose methotrexate. The other factors were elevated BUN or creatinine levels, increased mean corpuscular volumes and increasing age.13 Three cases of severe pancytopenia, one of them fatal, have been reported in patients given treatment doses of co-trimoxazole for pneumocystis pneumonia shortly after stopping low-dose methotrexate therapy.13,14 A fatal case of severe agranulocytosis and toxic epidermal necrolysis occurred in a patient receiving co-trimoxazole for prophylaxis of pneumocystis pneumonia after high-dose methotrexate therapy.15

Mechanism

Not fully understood. Both drugs can suppress the activity of dihydrofolate reductase and it seems possible that they can act additively to produce folate deficiency, which could lead to some of the bone marrow changes seen. There may also be a pharmacokinetic mechanism. An earlier study found that the concurrent use of co-trimoxazole had no effect on the pharmacokinetics of methotrexate in children;17 however, another study reported that co-trimoxazole caused an increase in ‘free’ methotrexate from about 37% to 52% while the renal clearance was more than halved.18 This was calculated to increase the exposure to methotrexate by 66%.18 Another sulfonamide, sulfafurazol (sulfisoxazole),19 has been found to cause a small reduction in the clearance of methotrexate by the kidneys.

Importance and management

Information seems to be limited to the reports cited but the interactions between methotrexate and co-trimoxazole or trimethoprim are established. Low-dose co-trimoxazole is commonly given to patients taking methotrexate as prophylaxis of pneumocystis pneumonia without problem. This type of patient should be having regular blood monitoring as a matter of course. However, the situation with higher doses of either drug is potentially more hazardous. Some have recommended avoiding the combination. If both drugs must be used, the haematological picture should be very closely monitored because the outcome can be life-threatening.

Methotrexate + Antibacterials; Penicillins

Reduced clearance and acute methotrexate toxicity has been attributed to the concurrent use of various penicillins (amoxicillin, benzylpenicillin, carbenicillin, dioclocillin, fluococillin, mezlocillin, oxacillin, penicillin, pheoxymethylpenicillin, piperacillin, ticarcillin) in a small number of case reports.

Clinical evidence

Reduced methotrexate clearance and acute methotrexate toxicity has been attributed to the concurrent use of various penicillins in a number of patients. See ‘Table 17.2,’ (p.644) for details. A survey of the Wyeth/Lederle safety database in 1996 identified two additional unpublished cases of methotrexate toxicity (aplastic anaemia, thrombocytopenia, pneumonitis) in patients who had recently started penicillins.1

### Table 17.2 Reports of reduced methotrexate clearance during penicillin use (continued)

### Mechanism

It is thought that weak acids such as the penicillins can possibly successfully compete with methotrexate in the kidney tubules for excretion so that the methotrexate is retained, thereby increasing its effects and its toxicity.2 However, this was not demonstrated in a study with fluclucoxacin,3 and the mechanism has been disputed.4

### Importance and management

Information seems to be limited to the reports given here, which would seem to indicate that serious interactions between methotrexate and penicillins are uncommon. It is not known why only a few patients have been affected and what other factors may have contributed, but the problem does not seem to be confined to patients receiving high-dose methotrexate. There is not enough evidence to forbid concurrent use (although some do advise against it)5, but close monitoring is obviously advisable. One published recommendation is to carry out twice-weekly platelet and white cell counts for 2 weeks initially, with the measurement of methotrexate levels if toxicity is suspected. Folinic acid (leucovorin) rescue should be available.6 For the general guidelines given by the CSM in the UK on the use of methotrexate see *Importance and management* in ‘Methotrexate + NSAIDs’, p.649.

### Methotrexate + Antibacterials; Tetracyclines

#### An isolated report describes severe methotrexate toxicity when a patient was also given pristinamycin.

#### Clinical evidence

A 13-year-old boy with acute lymphoblastic leukaemia had a relapse and began a series of regimens with high-dose methotrexate in combination with other drugs, including dexamethasone, mercaptourine, vincristine, cytarabine and asparaginase, tioguanine and ifosfamide. During a late cycle when he was also taking pristinamycin 2 g daily for a staphylococcal infection, the clearance of methotrexate was markedly decreased (half-life prolonged from 6 to 203 hours). He developed severe methotrexate toxicity (oral mucositis, anisuria, balanitis, neutropenia and thrombocytopenia) and was given folic acid rescue and haemodialysis.1

#### Mechanism

Not understood, but on the basis of experimental evidence the authors of the report excluded the possibilities of kidney impairment or reduction by the pristinamycin of liver metabolism.1

#### Methotrexate + Antibacterials; Vancomycin

#### Clinical evidence, mechanism, importance and management

Two patients treated with a chemotherapy regimen containing high-dose methotrexate, cisplatin, doxorubicin and ifosfamide had delayed methotrexate excretion and methotrexate toxicity during a cycle soon after they had received vancomycin. Methotrexate levels took 170 to 231 hours to fall to 200 micromol/mL, and toxicity (mucositis) occurred. Subclinical...
renal impairment was found, which subsequently improved. In previous
and subsequent cycles, where vancomycin was not given, serum meth-
отрексат levels in both patients fell to 200 micromol/mL within 48 to
96 hours. It was suggested that vancomycin caused subclinical nephro-
toxicity, which resulted in delayed excretion of methotrexate, which is pri-
marily renally excreted.

However, in another report of 8 patients who had received high-dose methotrexate following the use of vancomycin (all but one within 10 days)
for previous neutropenia, there was no significant interaction in the ab-
sence of overt renal impairment. It was suggested that the difference in
outcome may be due to slightly lower methotrexate doses and the fact
that the drug regimen in the 8 patients did not include ifosfamide, which par-
ticularly in combination with cisplatin may cause cumulative renal tubular
damage.

Vancomycin is commonly used in oncology patients with febrile neutro-
penia, and this appears to be the first report of this interaction. The authors
of this report suggest that it would be prudent to measure glomerular
filtration rate with an EDTA renal scan before giving high-dose methotrex-
ate to patients recently treated with vancomycin, to allow modification of
the methotrexate dose if necessary. However, the authors of the second report
disagree and suggest such monitoring cannot be supported by their
findings. Further study is needed.

following vancomycin administration in the absence of overt renal impairment. Ann Oncol
2. Shamash J, Joel S, Lundholm L, Millard L, Oliver T. High-dose methotrexate clearance fol-
lowing prior vancomycin administration: no significant interaction in the absence of overt renal

Methotrexate + Antiepileptics

Enzyme-inducing antiepileptics appear to increase the clearance of
methotrexate given as a 24-hour infusion, and their use is asso-
ciated with lower efficacy of combination therapy for B-lineage
leukemia.

Clinical evidence, mechanism, importance and management

In a retrospective survey, long-term antiepileptic use (phenytoin, pheno-
barbital, carbamazepine, or a combination) was associated with worse
event-free survival, and greater haematological relapse and CNS relapse
in children receiving chemotherapy for B-lineage acute lymphoblastic leu-
kaemia. Faster clearance of high-dose methotrexate given as a 24-hour in-
fusion was found in those receiving these enzyme-inducing antiepileptics,
but clearance of short 4 to 6-hour methotrexate infusions did not appear to
be affected, neither was weekly low-dose methotrexate. Further study is
needed.

Note that reduced phenytoin and carbamazepine levels, but unaltered
phenobarbital levels, have been reported in various case reports of patients
receiving chemotherapy including methotrexate, see ‘Table 14.1’, (p.519).

Methotrexate + Ascorbic acid (Vitamin C)

A study in a single patient showed that the urinary excretion of
methotrexate was not significantly changed by the concurrent use
of large amounts of vitamin C.

Clinical evidence, mechanism, importance and management

Vitamin C 1 g three times daily was found to have no effect on the urinary excretion of methotrexate 45 mg given intravenously to a woman with breast cancer, despite the urine becoming more acidic at pH 5.9 (compare ‘Methotrexate + Urinary alkalinisers’, p.654). She was also receiving oral cyclophosphamide, propranolol, amitriptyline, perphenazine and prochlo-
prperazine. No special precautions appear to be necessary.

Methotrexate + Caffeine

Although caffeine may theoretically reduce the efficacy of meth-
отрексат, the clinical significance of a high caffeine intake is
unclear.

Clinical evidence

A study in 39 patients who had recently started treatment with methotrex-
ate 7.5 mg weekly found that patients with a self reported high caffeine in-
take (more than 180 mg caffeine per day, 13 patients) had less relief in
their symptoms of rheumatoid arthritis, such as swollen joints and joint
pain, and smaller reductions from baseline in their erythrocyte sedimenta-
tion rate (ESR), a marker for inflammation, than patients with a low caf-
feine intake (less than 120 mg caffeine per day, 13 patients). A survey of
91 patients taking methotrexate 5 to 15 mg weekly for rheumatoid arthritis
found that those who were regular coffee drinkers (more than 7 cups a
week) had a higher rate of methotrexate discontinuation (due to treatment
failure in 80% of cases).2

In contrast, an analysis of data in 264 patients taking long-term meth-
отрексат for rheumatoid arthritis found that the consumption of caffeinated
beverages did not appear to affect the efficacy of methotrexate for rheu-
matoid arthritis in either low, moderate or high consumers of caffeinated
drinks. The average dose of methotrexate was 16 mg weekly and the av-
average intake of caffeine from caffeinated drinks was 212 mg daily. No dif-
fERENCE in inflammatory markers or worsening of rheumatoid arthritis was
found between the low-caffeine intake group and the high-caffeine intake
Group. A survey in 64 patients taking methotrexate (mean dose of 13 mg
weekly) for psoriasis and psoriatic arthritis found no effect on the efficacy
or dosage requirements of methotrexate between low caffeine intake (less
than 120 mg daily) and high caffeine intake (more than 180 mg daily).3

Mechanism

It is not known exactly how methotrexate produces its effects in rheuma-
toid arthritis, but one theory is that it possibly increases levels of adenosine
by blocking a step in purine biosynthesis, leading to accumulation of ade-
nosine, which results in anti-inflammatory effects.1 It also inhibits the
enzyme 5-aminimidazole-4-carboxamide ribonucleotide (AICAR) trans-
formylase, raising levels of AICAR, which in turn increases adenosine
levels. It may also contribute to the phosphorylation of adenosine nucleo-
tides creating an accumulation of adenosine in tissues.1,3 Caffeine is an
adenosine receptor antagonist and therefore could reverse the effects
of methotrexate.

Importance and management

There is limited information available regarding a potential interaction be-
tween caffeine consumption and methotrexate. The data collection results
and patient survey seem to indicate that caffeine intake is not an issue,
even with a high intake, although one study and another survey did find a
reduced efficacy in those with a higher caffeine intake. However, these re-
sults, particularly the surveys, were limited by a number of factors, includ-
ing subjective reporting of caffeine consumption, lack of caffeine blood
levels, and uncontrolled ingestion of both drugs. One UK manufacturer of
intravenous methotrexate (licenced for rheumatoid arthritis) recommends
avoiding the excessive consumption of caffeine and theophylline-contain-
ing drinks.2 There do not appear to be any case reports or studies indicat-
ing treatment failure with a high caffeine intake in patients receiving
chemotherapy with high-dose methotrexate. More study is needed but
bear in mind that a high caffeine intake may be a factor in a reduced ben-
efit from methotrexate given for psoriasis or rheumatoid arthritis.

Methotrexate + Chloroquine or Hydroxychloroquine

Chloroquine caused a moderate reduction in the AUC of methotrexate in one study. Conversely, hydroxychloroquine caused a minor increase in the AUC of methotrexate in another study.

**Clinical evidence, mechanism, importance and management**

Eleven patients with rheumatoid arthritis taking methotrexate 15 mg weekly were studied after they took a single dose of methotrexate alone and after they took methotrexate with chloroquine 250 mg. The chloroquine reduced the maximum plasma levels of methotrexate by 20% and its AUC by 28%. It is suggested that this occurs because the absorption of the methotrexate from the gut is reduced in some way.1 These reductions are only modest, but they may reduce both the toxicity and the efficacy of the methotrexate: the clinical importance of this interaction awaits assessment.

In contrast, in a randomised crossover study in 10 healthy subjects, hydroxychloroquine 200 mg increased the AUC of methotrexate 15 mg by 52%, while still slightly decreasing the maximum methotrexate level (by 17%).2 The authors considered that the increased AUC could explain the increased efficacy of the combination in rheumatoid arthritis, while the decreased maximum level could explain the reduction in acute liver toxicity.2 Further study is needed.

**Methotrexate + Cisplatin**

The risk of methotrexate toxicity appears to be markedly increased by the previous use of cisplatin. Methotrexate may inhibit the clearance of cisplatin.

**Clinical evidence, mechanism, importance and management**

Six out of 106 patients developed clinical signs of methotrexate toxicity and died 6 to 13 days after receiving standard doses of methotrexate (20 to 50 mg/m²) in the absence of signs of renal impairment, and despite having previously been given methotrexate without serious toxicity. On this occasion all had previously been given cisplatin. Four of the patients were regarded as good-risk (i.e. methotrexate toxicity was not considered likely as they did not have renal or hepatic impairment, and their general condition was good).1 A study in children and adolescents suggested that those who had received a cumulative dose of cisplatin greater than 160 mg/m² had delayed methotrexate clearance and a greater risk of methotrexate toxicity.2 Similarly, a further report by the same authors, in 14 patients receiving high-dose methotrexate,2 indicated that prior treatment with one course of cisplatin sharply increased the serum levels of methotrexate, particularly if the cumulative cisplatin dose exceeded 400 mg/m².

The picture is not totally clear but it seems possible that the previous use of cisplatin causes kidney damage that may not necessarily be detectable with the usual creatinine clearance tests. The effect is to cause a marked reduction in the clearance of the methotrexate. The serum methotrexate levels of such patients should be closely monitored so that any delay in its clearance is detected early and folic acid rescue therapy can be given.2 This appears to prevent serious toxicity.1,3

There is also a report that suggests that methotrexate inhibits the renal clearance of cisplatin. The renal clearance of platinum in 4 of 5 patients with non-small-cell lung cancer given cisplatin 50 mg/m² and methotrexate 40 mg/m² was reduced in the first 6 hours after administration (50% lower in the first 3 hours). Apart from a transient increase in serum urea nitrogen and creatinine in one patient, there was no sign of nephrotoxicity with concurrent use.2

**Methotrexate + Colestyramine**

The serum methotrexate levels of three patients given methotrexate by infusion were markedly reduced bycolestyramine.

**Clinical evidence**

An 11-year-old girl with osteosarcoma who developed colitis when treated with high-dose intravenous methotrexate, was subsequently given colestyramine 2 g every 6 hours from 6 to 48 hours after the methotrexate. Serum methotrexate levels at 24 hours were approximately halved. A marked fall in serum methotrexate levels was seen in another patient similarly treated.1 Colestyramine similarly reduced methotrexate levels in cases of toxicity in another two patients.2,3

**Mechanism**

Methotrexate undergoes enterohepatic recirculation, that is to say it is excreted into the gut in the bile and reabsorbed further along the gut. If colestyramine is given orally, it can bind strongly to the methotrexate in the gut, thereby preventing its reabsorption and, as a result, the serum levels fall.1,4

**Importance and management**

The documentation seems to be limited. In the cases cited1-3 the colestyramine was deliberately used to reduce serum methotrexate levels. However, in some circumstances it might represent an unwanted interaction. Since methotrexate is excreted into the gut in the bile, separating the oral dosages of the colestyramine and methotrexate may not necessarily prevent their coming into contact and interacting together. Monitor concurrent use.

**Methotrexate + Corticosteroids**

Methotrexate clearance may be modestly reduced by the long-term use of prednisolone, but methotrexate does not alter prednisolone pharmacokinetics. Limited evidence suggests methotrexate may alter prednisone levels. Dexamethasone may increase the acute hepatotoxicity of high-dose methotrexate.

**Clinical evidence, mechanism, importance and management**

There is some evidence that prednisolone may reduce the clearance of methotrexate: patients taking long-term prednisolone 15 mg daily had a 20% lower clearance of intramuscular methotrexate 10 mg and a 30% higher AUC than patients given prednisolone 15 mg daily for just 4 days before the methotrexate, or those not given corticosteroids.1 In another study, methotrexate had no effect on prednisolone pharmacokinetics in 7 patients, or methylprednisolone pharmacokinetics in one patient.2 Preliminary findings of another study suggested that methotrexate may increase plasma methylprednisolone levels in response to a dose of prednisone; in 2 of 4 patients given methotrexate, plasma methylprednisolone levels remained stable despite a decrease in the prednisone dose.3 These findings require confirmation. Their clinical relevance is uncertain.

Dexamethasone may increase the acute hepatotoxicity of high-dose methotrexate. A retrospective comparison in children with brain tumours given methotrexate alone (24 patients), or with dexamethasone (33 patients), found that no serious brain oedema occurred in either of the groups 1. 2. 3.
and there were no differences in bone marrow toxicity or mucositis, but liver enzymes were significantly higher in the dexamethasone group indicating liver toxicity. AST levels were 76 units/L, and ALT levels were 140 units/L compared with 39 units/L. This effect was not due to differences in serum methotrexate levels. The authors recommend that dexamethasone should not be included in high-dose methotrexate protocols for children with brain tumours when they are not glucocorticoid dependent.

Methotrexate + Diuretics

Some very limited evidence suggests that triamterene may possibly increase the bone marrow suppressive effects of methotrexate. It seems doubtful if thiazides interact adversely.

Clinical evidence, mechanism, importance and management

A 57 year-old woman who had been treated for several years with daily doses of diclofenac 150 mg, atenolol 50 mg and triamterene with hydrochlorothiazide 50/25 mg, for rheumatoid arthritis and hypertension, additionally started treatment with methotrexate 5 mg weekly. After 2 months she was admitted to hospital with pancycapenia, extensive mucosal ulceration and renal impairment. The authors point out that triamterene is structurally similar to folate and has anti-folate activity, which may therefore have been additive with the effects of methotrexate. But the diclofenac may also have contributed (see ‘Methotrexate + NSAIDs’, p.649). In 1998, the manufacturer noted there were two other reports of pancycapenia in patients taking methotrexate and triamterene, but again the patients were also taking NSAIDs.

A study in 9 patients found that neither furosemide nor hydrochlorothiazide had any effect on the clearance of methotrexate in the urine. However, a study in women with breast cancer, treated with methotrexate, cyclophosphamide and fluorouracil found that the concurrent use of a thiazide diuretic appeared to increase the myelosuppressant effects, but it is not clear which of the antinociceptives might have been affected.

Methotrexate + Folinates

Folic acid or folinic acid are sometimes added to low-dose methotrexate treatment for rheumatoid arthritis or psoriasis to reduce adverse effects. Folic acid is frequently used as an antidote to high-dose methotrexate in cancer therapy. Patients taking methotrexate should avoid the inadvertent use of folates in multivitamin preparations.

Clinical evidence, mechanism, importance and management

Methotrexate acts as a folic acid antagonist by reversibly binding to the enzyme dihydrofolate reductase so blocking the conversion of folic acid to tetrahydrofolate. Therefore folic acid and folinic acid (a derivative of tetrahydrofolate) would be expected to interfere with both the toxic and therapeutic effects of methotrexate.

Folic acid or folinic acid are commonly used to reduce the adverse effects of low-dose methotrexate used for rheumatoid arthritis and psoriasis, although the optimum doses and schedules to maximise tolerability and efficacy remain to be determined.

Similarly, folic acid is used in conjunction with high-dose methotrexate for various cancers to minimise toxicity, when it is typically started 24 hours after methotrexate administration (folic acid or ‘leucovorin’ rescue). In this setting, the antidote effect is clearly influenced by the dose of folicin in relation to the dose of methotrexate, and the timing of folicin administration in relation to methotrexate administration.

Patients taking methotrexate for any indication should avoid the inadvertent or unsupervised use of folates, which are commonly found in multivitamin preparations.

Methotrexate + Fluorouracil

The absorption of low-dose oral methotrexate appears not to be significantly affected by food.

Clinical evidence, mechanism, importance and management

In 10 children with lymphoblastic leukaemia the peak serum levels of a 15-mg/m² oral dose of methotrexate (measured at 1.5 hours) were reduced by about 40% when the methotrexate was taken with a milky meal (milk, cornflakes, sugar, white bread and butter). The AUCₘₕ was reduced by about 25%. A smaller reduction in methotrexate absorption was seen when it was taken after a citrus meal (orange juice, fresh orange, white bread, butter and jam). However, a 4-hour study is too short to assess the extent of the total absorption. Another study in 16 other children given methotrexate 8 to 22.7 mg/m² found that the peak levels and AUC were not significantly affected if methotrexate was given before a meal. Yet another study in 12 healthy subjects found that a high fat-content breakfast delayed the absorption of methotrexate 7.5 mg orally by about 30 minutes.

Structural similarities and pharmacological interactions

Methotrexate acts as a folic acid antagonist by reversibly binding to the enzyme dihydrofolate reductase so blocking the conversion of folic acid to tetrahydrofolate. Therefore folic acid and folinic acid (a derivative of tetrahydrofolate) would be expected to interfere with both the toxic and therapeutic effects of methotrexate.

Folic acid or folinic acid are commonly used to reduce the adverse effects of low-dose methotrexate used for rheumatoid arthritis and psoriasis, although the optimum doses and schedules to maximise tolerability and efficacy remain to be determined.

Similarly, folic acid is used in conjunction with high-dose methotrexate for various cancers to minimise toxicity, when it is typically started 24 hours after methotrexate administration (folic acid or ‘leucovorin’ rescue). In this setting, the antidote effect is clearly influenced by the dose of folinic in relation to the dose of methotrexate, and the timing of folinic administration in relation to methotrexate administration.

Patients taking methotrexate for any indication should avoid the inadvertent or unsupervised use of folates, which are commonly found in multivitamin preparations.
but the extent of the absorption was unchanged.\textsuperscript{3} It would therefore appear that methotrexate may be taken without regard to meals.

\section*{Methotrexate + Miscellaneous}

\textbf{Animal studies} suggested that the toxicity of methotrexate might be increased by the use of chloramphenicol, aminosalicylic acid, sodium salicylate, sulfamethoxypyridazine, tetracycline or tolbutamide, but confirmation of this in man has only been seen with the salicylates, sulphonamides and possibly tetracycline.

\textbf{Clinical evidence, mechanism, importance and management}

Some lists, reviews and books on interactions say that chloramphenicol, aminosalicylic acid, sodium salicylate, sulfamethoxypyridazine, tetracycline or tolbutamide interact with methotrexate, apparently based largely on the preliminary findings of a study in which male mice were treated for 5 days with each of 4 doses of methotrexate (1.53 to 12.25 mg/kg intravenously) and immediately afterwards with non-toxic intraperitoneal doses of the drugs listed. These drugs were said to decrease the lethal dose and/or decrease the survival time of the mice.\textsuperscript{1} That is to say, the toxicity of the methotrexate was increased. The reasons are not understood, but it is suggested that displacement of the methotrexate from its plasma protein binding sites could result in a rise in the levels of unbound and active methotrexate, and in the case of sodium salicylate to a decrease in renal clearance.

These \textit{animal} studies were done in 1968. Since then the clinical importance of the interaction with salicylates has been confirmed (see ‘Methotrexate + NSAIDs’, p.649); there are a few cases involving ‘sulphonamides’, (p.643); and there are two isolated case reports of an interaction with ‘tetracyclines’, (p.645), but there appears to be no direct clinical evidence of interactions between methotrexate and chloramphenicol or tolbutamide. The results of \textit{animal} experiments cannot be applied directly and uncritically to man and it now seems probable that some of these suggested or alleged interactions are more theoretical than real.

\section*{Methotrexate + Nitrous oxide}

\textbf{Clinical evidence, mechanism, importance and management}

A study in which intravenous methotrexate, cyclophosphamide and fluorouracil (CMF) were used within 36 hours of mastectomy suggested that stomatitis may be caused by a toxic interaction between methotrexate and nitrous oxide used during anaesthesia. Stomatitis was much more common in those receiving CMF within 6 hours of surgery.\textsuperscript{1-3} A possible reason is that the effects of methotrexate on tetrahydrofolate metabolism are increased by nitrous oxide, and this has been confirmed in \textit{animals}.\textsuperscript{4} It was found that the incidence of stomatitis, severe leucopenia, thrombocytopenia, and of severe systemic and local infections could be reduced by giving calcium folinate (leucovorin) and intravenous hydration.\textsuperscript{3,5} Alternatively, the use of nitrous oxide shortly before methotrexate administration should be avoided.\textsuperscript{4}

\section*{Methotrexate + NSAIDs}

\textbf{Increased methotrexate toxicity, sometimes life-threatening, has been seen in a few patients also taking NSAIDs whereas other patients have been treated uneventfully. The pharmacokinetics of methotrexate can also be changed by some NSAIDs (aspirin, choline magnesium trisalicylate, etodolac, etoricoxib, ibuprofen, metamizole sodium, naproxen, rofecoxib, sodium salicylate, tolmetin). The development of toxicity may be dose related and the risk appears to be lowest in those taking low-dose methotrexate for psoriasis or rheumatoid arthritis who have normal renal function.}

\textbf{Clinical evidence}

\textbf{(a) Aminophenazone}

Megaloblastic pancytopenia occurred in a woman with rheumatoid arthritis who took methotrexate 15 mg weekly with aminophenazone 1 to 1.5 g daily.\textsuperscript{1}

\textbf{(b) Aspirin and other salicylates}

A study in 15 patients with rheumatoid arthritis given a single 10-mg bolus dose of methotrexate, either with or without aspirin 975 mg four times daily, found that the methotrexate clearance was reduced by aspirin (systemic clearance about 16%, renal clearance of unbound methotrexate about 30%). Also the unbound fraction of methotrexate was higher during aspirin use. Despite these changes no acute toxicity was seen.\textsuperscript{2} Another study found that aspirin did not affect the pharmacokinetics of methotrexate.\textsuperscript{3} Yet another study found that, although aspirin did not alter the pharmacokinetics of methotrexate, it did increase the AUC of the metabolite 7-hydroxymethotrexate.\textsuperscript{4}

A study in 4 patients found that the renal clearance of methotrexate was reduced by 35% by an infusion of sodium salicylate (2 g initially, then 33 mg/minute).\textsuperscript{5} A further study found that choline magnesium trisalicylate reduced methotrexate clearance by 24 to 41%, and increased the unbound fraction by 28%, when compared with paracetamol (acetaminophen).\textsuperscript{6}

Lethal pancytopenia in 2 patients given methotrexate and aspirin prompted a retrospective survey of the records of other patients given intra-arterial infusions of methotrexate 50 mg daily for 10 days, for epidermoid carcinoma of the oral cavity. Six out of 7 who developed rapid and serious pancytopenia were found to have taken aspirin or other salicylates.\textsuperscript{7} There are other case reports\textsuperscript{8,9} of methotrexate toxicity in patients taking salicylates but whether a causal relationship exists is uncertain. It has been suggested that pneumonitis in patients receiving low-dose methotrexate may have resulted from the concurrent use of aspirin 4 to 5 g daily.\textsuperscript{10}

See also the report about the comparative use of aspirin and other NSAIDs in section (w), below, on NSAIDs in general.

\textbf{(c) Azapropazone}

A woman who had been taking methotrexate 25 mg weekly for 4 years for psoriasis had acute toxicity (oral and genital ulceration, bone marrow failure) shortly after starting to take azapropazone (reducing from a dose of 2.4 g on the first day, 1.8 g on the second day to 1.2 g daily for a week). She was also taking aspirin 300 mg daily.\textsuperscript{11,12}

\textbf{(d) Bromfenac}

In a short-term study, 10 patients taking methotrexate weekly were given bromfenac 50 mg three times daily for 6 days. No significant changes were seen in either the pharmacokinetics of bromfenac or methotrexate. However, the AUC of the major metabolite of methotrexate, 7-hydroxymethotrexate, was increased by 30% and its renal clearance was reduced by 16%. Eight of the patients had mild to moderate adverse effects and one patient had to withdraw because of moderate hypertension. No patient had any clinically important abnormal laboratory test results.\textsuperscript{13} Note that systemic bromfenac has been withdrawn from the market because of reports of hepatic failure.

\textbf{(e) Celecoxib}

Fourteen female patients with rheumatoid arthritis taking methotrexate 5 to 20 mg weekly for at least 3 months were also given celecoxib 200 mg or a placebo twice daily for a week. It was found that the maximum serum levels of the methotrexate, its AUC, renal clearance, and other pharmacok-
inet parameters were unchanged by the celecoxib.\textsuperscript{14} The authors note that, in clinical studies, celecoxib was taken in combination with low-dose methotrexate for up to 12 weeks by over 450 patients, and the incidence of adverse effects was similar to that in patients taking methotrexate with placebo.\textsuperscript{14}

\textit{(f) Diclofenac}\n
A study found that diclofenac 100 mg daily did not affect the pharmacokinetics of methotrexate;\textsuperscript{25} however, 5 patients taking low-dose methotrexate 7.5 to 12.5 mg weekly for psoriasis or rheumatoid arthritis developed serious/fatal neutropenias. These cases probably involved other drug interactions, but diclofenac may have been an additional factor in two of them.\textsuperscript{25} Other cases involving diclofenac are mentioned in the sections on indometacin (k) and ketoprofen (l).

\textit{(g) Etodolac}\n
A pharmacokinetic study in patients with rheumatoid arthritis found that etodolac 600 mg daily did not affect the AUC of methotrexate, but the duration of exposure was lengthened (mean residence time increased from 8.5 to 11.4 hours). No clinical toxicity was seen.\textsuperscript{16}

\textit{(h) Etoricoxib}\n
A study in patients taking methotrexate 7.5 to 20 mg weekly for rheumatoid arthritis found that the addition of etoricoxib 60, 90 or 120 mg daily had no effect on the methotrexate AUC or on its renal clearance. However, another similar study found that etoricoxib 120 mg daily increased the methotrexate AUC by 28\% and reduced its clearance by 13\%.\textsuperscript{17}

\textit{(i) Flurbiprofen}\n
A study in 6 patients taking low doses of methotrexate 10 to 25 mg weekly found no important changes in methotrexate levels when they were given flurbiprofen 100 mg three times daily.\textsuperscript{18} In another study of 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly and flurbiprofen 3 mg/kg daily, methotrexate oral and renal clearance were similarly unaffected by flurbiprofen.\textsuperscript{19}

In contrast to these pharmacokinetic studies, a case report describes an elderly woman who had been taking methotrexate 2.5 mg three times a week for 3 years for rheumatoid arthritis, who developed haematemesis, neutropenia and thrombocytopenia (diagnosed as methotrexate toxicity) within 1 to 2 weeks of starting to take flurbiprofen 100 mg daily.\textsuperscript{20}

\textit{(j) Ibuprofen}\n
A study in 7 patients found that the clearance of oral methotrexate 7.5 to 15 mg was halved by ibuprofen 40 mg/kg per day, when compared with paracetamol (acetaminophen).\textsuperscript{21} In a related study the clearance of methotrexate was reduced by 40\% by ibuprofen.\textsuperscript{6} Another study in 6 patients with rheumatoid arthritis taking methotrexate 10 to 25 mg weekly found that ibuprofen 800 mg three times daily had no effect on the pharmacokinetics of methotrexate.\textsuperscript{9,22} Similar findings have been reported by other workers.\textsuperscript{23}

A patient taking methotrexate who was given ibuprofen required prolonged folic acid rescue because the clearance of methotrexate had fallen by two-thirds.\textsuperscript{22} Another patient receiving high-dose methotrexate (7.5 g/m\textsuperscript{2}) had severe methotrexate-induced nephrotoxicity and delayed excretion of methotrexate while taking ibuprofen 400 mg every 4 hours.\textsuperscript{22} A report attributes pancytopenia and resulting pneumonia to a 16-year-old patient taking methotrexate 5 to 10 mg weekly to the concurrent use of ibuprofen 600 mg twice daily (and also 1 mg prednisolone daily).\textsuperscript{24}

\textit{(k) Indometacin}\n
The AUC of child taking methotrexate 7.5 mg/m\textsuperscript{2} weekly for 9 months was increased by 140\% when indometacin and aspirin were also given.\textsuperscript{25} Another study found that indometacin did not affect the pharmacokinetics of methotrexate.\textsuperscript{3}

Two patients given sequential intermediate-dose methotrexate and fluorouracil who were also taking indometacin 75 to 100 mg daily died from acute drug toxicity, which the authors of the report attributed to indometacin-associated renal failure.\textsuperscript{26} Another case of acute renal failure has been described,\textsuperscript{27} but there were no cases of toxicity in 4 other patients taking methotrexate with either paracetamol (acetaminophen) or indometacin.\textsuperscript{26} An elderly woman taking indometacin 50 mg daily rectally and diclofenac 100 mg daily intravenously died after being given single 10-mg intramuscular dose of methotrexate.\textsuperscript{28}

\textit{(l) Ketoprofen}\n
In a study in 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly and ketoprofen 3 mg/kg daily, the methotrexate oral and renal clearance and the fraction of methotrexate unbound were unaffected by ketoprofen.\textsuperscript{19} Similarly, in another study in 18 patients with rheumatoid arthritis who were given intravenous methotrexate 15 mg weekly, ketoprofen had no significant effect on the AUC, half-life, or clearance of methotrexate and its major metabolite, 7-hydroxymethotrexate.\textsuperscript{20} However, a retrospective study of 118 cycles of high-dose methotrexate treatment (800 to 8300 mg/m\textsuperscript{2}; mean 3200 mg/m\textsuperscript{2}) in 56 patients found that 4 out of the 9 patients who developed severe methotrexate toxicity had also taken ketoprofen 150 to 200 mg daily for 2 to 15 days. Three of them died. A marked and prolonged rise in serum methotrexate levels was observed. Another patient who had methotrexate toxicity had also been given diclofenac 150 mg (in one day).\textsuperscript{30} The authors of this report state that ketoprofen should not be given at the same time as high-dose methotrexate, but it may be safe to give it 12 to 24 hours after the methotrexate because 50\% of the methotrexate is excreted by the kidneys within 6 to 12 hours. This was tried in two patients without adverse effects.\textsuperscript{30}

\textit{(m) Lumiracoxib}\n
In a double-blind, placebo-controlled study in patients with rheumatoid arthritis given low-dose methotrexate 7.5 to 15 mg weekly, lumiracoxib 400 mg daily for 7 days had no significant effects on the pharmacokinetics of methotrexate.\textsuperscript{31}

\textit{(n) Meloxicam}\n
Thirteen patients with rheumatoid arthritis were given intravenous methotrexate 15 mg before and after taking meloxicam 15 mg daily for a week. The pharmacokinetics of the methotrexate were unaffected by the meloxicam and no increase in toxicity was seen.\textsuperscript{32}

\textit{(o) Metamizole sodium (Dipyrone)}\n
A study in a patient with osteosarcoma found that metamizole sodium 4 g daily more than doubled the methotrexate AUC during the first cycle of high-dose methotrexate treatment.\textsuperscript{33}

\textit{(p) Naproxen}\n
Naproxen had no significant effect on the AUC, half-life, or clearance of methotrexate and its major metabolite 7-hydroxymethotrexate in 18 patients with rheumatoid arthritis given intravenous methotrexate 15 mg weekly.\textsuperscript{29} Other studies have found that naproxen did not affect the pharmacokinetics of methotrexate.\textsuperscript{3} In a study in 27 patients with rheumatoid arthritis who had taken oral methotrexate 7.5 to 15 mg weekly for at least 3 months, the concurrent use of naproxen 600 mg twice daily with lanosoprazole did not affect the pharmacokinetics of methotrexate or 7-hydroxymethotrexate.\textsuperscript{34} Another study in patients with rheumatoid arthritis with normal renal function found that no toxicity was caused when naproxen 500 mg twice daily was given with methotrexate 15 mg given orally or intravenously, nor was the methotrexate clearance altered.\textsuperscript{35}

In contrast, a study found that the clearance of methotrexate was decreased by 22\% by naproxen.\textsuperscript{6,21} In addition, two children taking methotrexate for 1 and 2 years had increases in the AUC of methotrexate of 22\% and 71\% when given naproxen with aspirin or indometacin, respectively.\textsuperscript{25} Another study in 9 children taking methotrexate 0.22 to 1.02 mg/kg per week found that the clearance was increased in 4 children by more than 30\% when they were given naproxen 14.6 to 18.8 mg/kg daily. There was also a 30\% or more change in the pharmacokinetics of naproxen in 6 of the patients, but as both increases and decreases in clearance occurred, the significance of these findings are uncertain.\textsuperscript{26} A woman died of gross methotrexate toxicity apparently exacerbated by the concurrent use of naproxen,\textsuperscript{37} and a report attributes pneumonia in a patient taking methotrexate 7.5 to 10 mg weekly to the concurrent use of naproxen (initially 1 g then 500 mg daily).\textsuperscript{38}

\textit{(q) Parecoxib}\n
Studies in patients with rheumatoid arthritis found that oral valdecoxib 40 mg twice daily had no clinically significant effect on the plasma levels of methotrexate given weekly by the intramuscular route [dose not stated].\textsuperscript{39} Even so the manufacturers suggest that careful monitoring should be considered, probably because of the problems seen with other NSAIDs. Note that valdecoxib is the main metabolite of parecoxib.

\textit{(p) Phenylbutazone}\n
Two patients taking methotrexate for psoriasis developed methotrexate toxicity and skin ulceration shortly after starting to take phenylbutazone 200 to 600 mg daily. One of them died from sepsicaemia following bone marrow depression.\textsuperscript{40}
No effect on the pharmacokinetics of either free or bound methotrexate was seen in 20 patients with rheumatoid arthritis taking methotrexate 10 mg weekly when they were given piroxicam 20 mg daily for at least 15 days.\textsuperscript{41} In another study in 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly, methotrexate oral and renal clearance were similarly unaffected by piroxicam 20 mg daily.\textsuperscript{19}

\section*{Rofecoxib}

Rofecoxib 12.5 to 50 mg once daily had no effect on the AUC and renal clearance of methotrexate or 7-hydroxymethotrexate in 19 patients taking methotrexate 7.5 to 20 mg once weekly.\textsuperscript{42} However, the authors note that in previous evaluations (data on file), higher than therapeutic doses of rofecoxib (75 mg and 250 mg) were associated with a 23% and 40% increase in the AUC of methotrexate, and an 11% and 40% decrease in its renal clearance, respectively.\textsuperscript{52}

\section*{Sulindac}

Sulindac (mean dose 400 mg daily) had no effect on the pharmacokinetics of a single 10- mg/m\textsuperscript{2} intravenous dose of methotrexate, but it slightly increased the AUC of the 7-hydroxymethotrexate metabolite.\textsuperscript{4}

\section*{Tolmetin}

Three children taking methotrexate for between 6 months and 1 year had increases in the AUC of methotrexate of 42% when given tolmetin, and of 18% and 25% when given tolmetin with aspirin.\textsuperscript{25}

\section*{NSAIDs in general}

In a study of 34 patients with rheumatoid arthritis taking methotrexate 5 or 10 mg/m\textsuperscript{2} (to nearest 2.5 mg) weekly, 12 patients also took aspirin (average 4.5 g daily) and 22 took other NSAIDs. Twenty-one of the 34 also took prednisone. Toxicity, sometimes serious (5 patients withdrawn), was common, but no clinical differences between aspirin or other NSAIDs with respect to this toxicity was seen during 12 months of current use.\textsuperscript{43}

A preliminary report of a study in 87 patients receiving long-term treatment with methotrexate (mean weekly dose 8.19 mg), most of whom were also taking unspecified NSAIDs, found that the majority (72%) experienced no untoward effects and in the rest adverse effects were only relatively mild.\textsuperscript{44} The concurrent use of methotrexate and NSAIDs in more than 450 patients with psoriatic arthritis or rheumatoid arthritis was said to be without clinical interaction problems.\textsuperscript{45}

A literature review of interactions between methotrexate and NSAIDs found that low-dose methotrexate pharmacokinetics were unaltered by NSAIDs, with the exception of salicylates.\textsuperscript{46}

In a review of the results of 315 patients with rheumatoid arthritis taking low-dose methotrexate, 13 patients had low platelet counts. The thrombocytopenia was believed to have resulted from an interaction with an NSAID or in some patients a multiple drug interaction. If multiple drug interactions were not involved, the authors found that if the NSAID was given on a separate day, or dosages spaced according to the NSAID half-life, therapy could be re-introduced avoiding the problems of thrombocytopenia.\textsuperscript{47}

\section*{Mechanism}

Methotrexate is largely cleared unchanged from the body by renal excretion. The NSAIDs as a group inhibit the synthesis of the prostaglandins (PGE\textsubscript{2}) resulting in a fall in renal perfusion, which could lead to a rise in serum methotrexate levels, accompanied by increased toxicity. In addition, salicylates competitively inhibit the tubular secretion of methotrexate, which would further reduce its clearance.\textsuperscript{3} NSAIDs can also cause renal impairment, which would allow the methotrexate to accumulate. The pyrazolone derivatives and related drugs (e.g. aspirin, metamizole sodium, phenylbutazone, aminophenazone), in particular, can cause bone marrow depression, which could be additive with that of methotrexate. Protein binding, displacement of methotrexate or its metabolite (7-hydroxymethotrexate) have also been suggested as possible additional mechanisms.\textsuperscript{48,49} There is also some evidence that 7-hydroxymethotrexate is cleared more slowly in the presence of NSAIDs.\textsuperscript{4}

\section*{Importance and management}

The evidence presented here clearly shows that a few patients taking methotrexate have developed very serious toxicity, apparently due to the concurrent use of NSAIDs whereas many other patients have experienced no problems at all. There is also other evidence that the pharmacokinetics of the methotrexate are changed (in particular reduced clearance) by some NSAIDs (aspirin, choline magnesium trisalicylate, etodolac, ibuprofen, metamizole sodium, rofecoxib (at higher than therapeutic doses), sodium salicylate, tolmetin), which might be expected to increase its toxicity. The consensus of opinion seems to be that the risks are greatest with high-dose methotrexate (150 mg or more daily to treat neoplastic diseases) and in patients with impaired renal function, but less in those given low doses (5 to 25 mg weekly) for psoriasis or rheumatoid arthritis and with normal kidney function. The manufacturers of methotrexate and the CSM do not advise the avoidance of NSAIDs (except azapropazone and non-prescription aspirin and ibuprofen), even though their use is a recognised additional risk factor for toxicity. Instead their advice is that the methotrexate dosage should be well monitored, which implies that the precautions for methotrexate use should be stepped up. The advice of the CSM in the UK is that any patient given methotrexate alone should have a full blood count, renal and liver function tests before starting treatment. These should be repeated weekly until therapy is stabilised, and thereafter every 2 to 3 months. Patients should be told to report any sign or symptom suggestive of infection, particularly sore throat (which might possibly indicate that white cell counts have fallen) or dyspnoea or cough (suggestive of pulmonary toxicity).\textsuperscript{50} Aminophenazone or metamizole sodium can cause agranulocytosis on their own (and they consequently have limited use) so their use with methotrexate should also be avoided.

Some of the NSAIDs cited here have not been reported to interact (celecoxib, lumiracoxib, meloxicam, piroxicam), and information about some other NSAIDs seems to be lacking, but the same general precautions indicated above should be followed with all NSAIDs just to be on the safe side.

Methotrexate + Paracetamol (Acetaminophen)

Paracetamol appears not to interact with methotrexate.

Clinical evidence, mechanism, importance and management

A study in patients with psoriasis taking methotrexate in doses up to 25 mg weekly, no cases of toxicity occurred in 4 patients also taking paracetamol or indomethacin. In one study, methotrexate clearance was reduced by NSAIDs but not by paracetamol, which was included in the study as a control.

Methotrexate + Proton pump inhibitors

The excration of methotrexate is reported to have been reduced in twelve patients given omeprazole and three patients given lansoprazole. However, similar elevations in methotrexate levels in another patient were independent of omeprazole use. One patient had myalgia and elevated 7-hydroxymethotrexate levels when given methotrexate with pantoprazole.

Clinical evidence

(a) Lansoprazole

In a study in 76 patients with solid tumours treated with high-dose methotrexate infusions (300 mg/m² to 12 g/m² over 1 to 24 hours), the clearance of methotrexate and its metabolite 7-hydroxymethotrexate was significantly decreased and plasma levels significantly increased in the 3 patients who were also given lansoprazole 30 mg daily.

(b) Omeprazole

In a study in 76 patients with solid tumours treated with high-dose methotrexate infusions (300 mg/m² to 12 g/m² over 1 to 24 hours), the clearance of methotrexate and its metabolite 7-hydroxymethotrexate was significantly decreased and the plasma levels significantly increased in the 10 patients who had also been given omeprazole 20 to 40 mg daily. A patient with Hodgkin’s disease developed osteosarcoma and was treated with cyclophosphamide, bleomycin, dacarbazine and methotrexate, following a complete response to 5-day methotrexate, meloxicam, acetylsalicylic acid, salicylic acid and sodium. Methotrexate elimination was delayed and so further folic acid was given. When later cycles of methotrexate were given, with ranitidine instead of omeprazole, the
elimination of methotrexate was normal. The elimination half-life of the initial phase after the first dose given with omeprazole was 65% longer, when compared with that of the second dose without omeprazole.3

In contrast to these findings, a case is reported in which a man with chondroblastic osteosarcoma, who had been taking omeprazole, was treated with high-dose methotrexate 20 g over 6 hours with hydration, urinary alkalisation and, after 24 hours, folic acid rescue. The folic acid dose was adjusted in response to elevated methotrexate levels and omeprazole was stopped. A second dose of methotrexate 2 weeks later, this time without omeprazole, resulted in similar elevated methotrexate levels. Thus the elevated methotrexate levels in this patient could not be attributed to co-administered omeprazole.4

(c) Pantoprazole

Severe generalised myalgia occurred in a man taking pantoprazole 20 mg daily after he received intramuscular methotrexate 15 mg weekly. The symptoms subsided and eventually disappeared when the pantoprazole was replaced with ranitidine. The symptoms reappeared in response to rechallenge with pantoprazole, and the AUC of 7-hydroxymethotrexate was found to be increased by about 70%, although the AUC of methotrexate was unchanged.5

Mechanism

Proton pump inhibitors may affect renal, and possibly hepatic, clearance of methotrexate by inhibition of methotrexate transporter proteins.1,6 It has been suggested that omeprazole may inhibit the activity of a hydrogen-ion dependent mechanism in the kidney, on which methotrexate depends for its excretion, so that its loss is diminished. It has also been suggested that the situation with lansoprazole may be similar, but that pantoprazole may differ since at about the pH found in the renal tubules (pH 5), pantoprazole is more slowly activated than omeprazole.1 However, a case of an interaction with pantoprazole has also been reported.5

Importance and management

Information seems to be limited to these few reports and with the exception of one case report, they all found that proton pump inhibitors reduced the clearance of methotrexate. Any changes in methotrexate kinetics are important in terms of the potential for increased toxicity. Further study is required. The authors of one study in which the levels of methotrexate and its active metabolite were increased during the concurrent use of omeprazole or lansoprazole advise against concurrent use.1 Further, the authors of one report recommend that if omeprazole is necessary for a patient about to receive methotrexate, then omeprazole should be discontinued 4 to 5 days before methotrexate administration.7 The situation with other proton pump inhibitors may be similar. Ranitidine was found to be a suitable alternative in two of the cases.3,8 Note that the risks would appear to be most significant with high-dose methotrexate, but the case report involving a 15 mg weekly dose of methotrexate introduces a note of caution in all patients.9

Methotrexate + Sulfasalazine

The pharmacokinetics of methotrexate are unaffected by sulfasalazine. Clinical studies in patients with rheumatoid arthritis suggest that the combination of methotrexate and sulfasalazine may not improve therapeutic efficacy and may result in folate-deficiency anaemias.

Clinical evidence, mechanism, importance and management

A study in 15 patients with rheumatoid arthritis found that when sulfasalazine 2 g was given with methotrexate 7.5 mg weekly, the pharmacokinetics of the methotrexate remained unchanged. Similarly, methotrexate did not alter the trough levels of sulfasalazine.1 Although this study suggests there is no reason to avoid the concurrent use of sulfasalazine and methotrexate, clinical studies in patients with rheumatoid arthritis have found that concurrent use does not significantly increase therapeutic efficacy and seems to increase the development of folate-deficiency anaemias.2 The results of an in vitro study suggest this may be because sulfasalazine is a potent inhibitor of the reduced folate carrier- (RFC-) mediated cellular uptake of methotrexate and folinate.3 An alternative explanation is that both sulfasalazine and methotrexate promote enhanced adenosine release which may suppress inflammation and the combination of two drugs with the same mechanism of action may not improve the therapeutic response of either.4

Although the concurrent use of methotrexate with etretinate can be successful, the incidence of severe liver toxicity appears to be considerably increased. The serum levels of methotrexate may be increased by etretinate.

Clinical evidence

A man was given a 48-hour infusion of methotrexate 10 mg every week, for chronic discoid psoriasis but when he was also given etretinate 30 mg daily his serum methotrexate levels almost doubled. Concentrations at 12 and 24 hours during the infusion were 0.11 mmol/L, compared with 0.07 and 0.05 mmol/L before the etretinate.1 A later study2 in psoriatic patients found that those receiving etretinate had 38% higher maximum plasma levels of methotrexate, but no difference in clearance or elimination half-life (i.e. no methotrexate accumulation).

Severe toxic hepatitis has been reported in a number of cases when both etretinate and methotrexate were given.3,5 It may take several months to develop.5 In one clinic, signs of liver toxicity were seen in 2 out of 10 patients given both drugs, but there was no evidence of liver toxicity in 531 patients given methotrexate alone or in 110 patients given etretinate alone.5

Mechanism

Not understood. The increased incidence of toxic hepatitis may possibly be related to the increased maximum methotrexate plasma levels.

Importance and management

Although methotrexate and etretinate have been used together with success for psoriasis,6,8 the risk of severe drug-induced hepatitis seems to be very considerably increased. One author says that he has decided not to use this combination in future.3 Concurrent use should clearly be undertaken with great care. Etretinate has been largely superseded by acitretin (a metabolite of etretinate, which has a shorter half-life) but some consider that the combination of methotrexate and acitretin should also be avoided.9

No adverse interaction appears to occur between methotrexate and tacrolimus.

Clinical evidence, mechanism, importance and management

A study in 3 bone marrow transplant patients taking tacrolimus 30 micrograms/kg per day found that low-dose methotrexate (15 mg/m² on day 1, and 10 mg/m² on days 3, 6, and 11) did not significantly affect clinical care and no interaction of clinical significance was seen. A further study in 40 patients given methotrexate (15 mg/m² on day 1 followed by 10 mg/m² on days 3, 6 and 11 after a transplant) with 30 micrograms/kg of intravenous tacrolimus daily, similarly found no evidence of an adverse interaction.

Methotrexate + Theophylline

Methotrexate causes a modest reduction in the theophylline clearance. Theophylline may reduce methotrexate-induced neurotoxicity, but there is the possibility that it may also reduce methotrexate efficacy.

Clinical evidence

(a) Effects on theophylline

The apparent clearance of theophylline (given as oral aminophylline, choline theophyllinate or theophylline) was reduced by 19% in 8 patients with severe, steroid-dependent asthma after 6 weeks of treatment with intramuscular methotrexate 15 mg weekly. Three patients complained of nausea and the theophylline dosage was reduced in one of them as the theophylline level was more than 20 micrograms/mL.

(b) Effects on methotrexate

Four of 6 patients aged 3 to 16 years with acute lymphoblastic leukaemia and high-dose methotrexate-induced neurotoxicity had a complete resolution of their symptoms when they were given a 2.5-mg/kg aminophylline infusion over 1 hour. The other 2 had some improvement in symptoms. One patient also had symptom relief with rapid-release theophylline. Similar results were reported for another child who developed neurotoxicity after receiving high-dose methotrexate. In this case, aminophylline was reported not to alter methotrexate levels. A patient with methotrexate-induced leukoencephalopathy recovered after being given a combination of intravenous folic acid with intravenous aminophylline 145 mg daily for 7 days.

Mechanism

It is not known why theophylline clearance is altered. Methotrexate neurotoxicity may be linked with increased levels of adenosine. Theophylline is a competitive antagonist for adenosine receptors at serum concentrations within the therapeutic range used in respiratory disease.

Importance and management

The clinical importance of the small reduction in theophylline clearance is uncertain, although it may be worth bearing this in mind in patients maintained at the higher end of the therapeutic levels for theophylline, as they may be more likely to develop toxicity. Aminophylline may reduce methotrexate-induced neurotoxicity, and, although there is some evidence that theophylline does not alter the cytotoxic effects of methotrexate, this requires confirmation.

One UK manufacturer of methotrexate (licenced for rheumatoid arthritis) recommends avoiding excessive consumption of caffeine and theophylline-containing drinks, however this recommendation appears to be based on studies and surveys which looked at the effects of caffeine intake in patients taking low-dose, weekly methotrexate for rheumatoid arthritis or psoriasis,5,6 see ‘Methotrexate + Caffeine’, p.646.

Methotrexate + Urinary alkalinisers

Alkalinisation increases the solubility of methotrexate in the urine and also increases its excretion.

Clinical evidence, mechanism, importance and management

Methotrexate is much more soluble in alkaline than in acid fluids, therefore urinary alkalinisers such as sodium bicarbonate and acetazolamide (and ample fluids) are often given to patients receiving high-dose methotrexate to prevent the precipitation of methotrexate in the renal tubules, which would cause damage. However alkalinisation also increases the loss of methotrexate in the urine because at high pH values more of the drug exists in the ionised form, which is not readily reabsorbed by the tubules. This increased loss was clearly shown in about 70 patients in whom alkalinisation of the urine (to pH greater than 7) with sodium bicarbonate and hydration reduced the methotrexate serum levels at 48 hours by 73% and at 72 hours by 76%. In this instance the interaction was being exploited therapeutically to avoid toxicity. This interaction has also been shown by others. The possible consequences should be recognised if concurrent use is undertaken.

For the effects of acidic urine on methotrexate excretion see ‘Methotrexate + Ascorbic acid (Vitamin C)’, p.646.

Mitomycin + Doxorubicin

An increased incidence of cardiotoxicity has been seen in patients treated with mitomycin who were previously or simultaneously given doxorubicin.

Clinical evidence, mechanism, importance and management

Fourteen out of 91 (15.3%) patients with advanced breast cancer who had previously failed to respond to doxorubicin developed congestive heart failure when later treated with a combination of intravenous mitomycin 20 mg/m² every 4 to 6 weeks and megestrol acetate 160 mg daily. None of them had any pre-existing heart disease. This compares with only 3 out of 89 (3.5%) of another group of patients who had received doxorubicin but no mitomycin. The maximum cumulative dose of doxorubicin was 450 mg/m² and all of the patients had also been given cyclophosphamide. Some of them also received other drugs during the doxorubicin phase of treatment. These included fluorouracil, methotrexate, tegafur and vincristine. The heart failure developed slowly (mean time of 8.5 months) compared with those in the control group (1.5 months).

Other studies have also suggested that the combination of mitomycin and doxorubicin may increase cardiotoxicity. In a randomised study, 2 of 39 patients treated with doxorubicin 45 mg/m² once every 3 weeks and mitomycin 10 mg/m² once every 6 weeks developed cardiomyopathy, compared with none of 42 patients treated with doxorubicin 75 mg/m² once every 3 weeks alone.

The reasons for this apparent synergistic cardiotoxicity are not understood, but it may be related to free radical generation. This interaction is not established with certainty. The authors of one report suggest that its in-
Serious and potentially life-threatening intravascular haemolysis and renal failure may develop rarely after the long-term use of mitomycin and fluorouracil.

Clinical evidence, mechanism, importance and management

Two patients developed chronic haemolysis and progressive renal impairment after long-term treatment with mitomycin and fluorouracil following partial or total gastrectomy for gastric cancer. The haemolysis was exacerbated by blood transfusions. The authors of the report suggest that these two cases are “...the extreme of a syndrome we are finding increasingly in our posttransfusional patients, after 6 months or more of maintenance therapy.” A similar syndrome occurred in 2 other patients, one with gastric carcinoma and one without, when treated with these two drugs.2,3 This severe and potentially fatal syndrome has also been seen with mitomycin alone.4,5 Its incidence is not known, but note that a regimen of fluorouracil, doxorubicin and mitomycin (FAM) has been widely used in gastric cancer and there are only a few reports of this syndrome. The authors of one report suggest that the drugs should be stopped at the first sign of intravascular haemolysis, persistent proteinuria and rising urea levels (two consecutive values above 8 mmol/L).1 The syndrome has also occurred when tamoxifen was given to patients who had been treated with mitomycin, see ‘Mitomycin + Tamoxifen’, below.

Importance and management

Information appears to be limited to the reports cited, but it seems to be an established relation. Patients given both drugs should be closely monitored for changes in blood cell counts. Because of its immunomodulatory effects, cisimidine has been used as an adjunct to carmustine in the treatment of malignant melanoma, but this did not improve outcomes.5

Cancer Treat Rep (1985) 69, 733.
5. Morton RF, Creagan ET, Schaid DJ, Kardinal CG, McCormack GW, McHale MS, Wiesenfeld M. Phase II trial of recombinant leukocyte A interferon (IFN-a2A) plus 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) and the combination cimetidine with BCNU in patients with disseminated malignant melanoma. 

Nitrosoureas; Lomustine + Theophylline

A single case report describes thrombocytopenia and bleeding attributed to the concurrent use of lomustine and theophylline.

Clinical evidence, mechanism, importance and management

An asthmatic woman taking theophylline and treated for medulloblastoma with lomustine, prednisone and vincristine, developed severe nose bleeds and thrombocytopenia 3 weeks after the third cycle of chemotherapy.1 This was attributed to the concurrent use of lomustine and theophylline. The suggested explanation for this effect is that theophylline inhibited the activity of phosphodiesterase within the platelets, thereby increasing cyclic AMP levels and disrupting normal platelet function, which seems to be supported by an experimental study.2 While lomustine causes thrombocytopenia. What is known is far too limited to act as more than a warning of the possibility of increased thrombocytopenia during the concurrent use of theophylline and lomustine.

2. DeWys WD, Bathina S. Synergistic anti-tumour effect of cyclic AMP elevation (induced by theophylline) and cytotoxic drug treatment. 

Pemetrexed + Miscellaneous

Aspirin and ibuprofen had little effect on pemetrexed clearance in patients with normal renal function, but they, and other short-acting NSAIDs, should be withheld in patients with mild to moderate renal function. NSAIDs with longer half-lives such as piroxicam should be withheld in all patients. Caution is recommended if pemetrexed is given with nephrotoxic drugs such as the aminoglycosides, loop diuretics, and ciclesporin, and drugs that are secreted by the renal tubules, such as probenecid and penicillin.

Clinical evidence, mechanism, importance and management

(a) Cisplatin

The US manufacturers state that there is no pharmacokinetic interaction between pemetrexed and cisplatin, but there is the possibility that cisplatin-induced nephrotoxicity could decrease pemetrexed clearance and increase its toxicity. However, it should be noted that the use of pemetrexed with cisplatin is indicated for mesothelioma.1,2

(b) Folic acid and vitamin B12

Oral folic acid and intramuscular vitamin B12 has been reported to not alter the pharmacokinetics of pemetrexed1 and because these vitamins were found to decrease pemetrexed toxicity, it is recommended that all patients receiving pemetrexed should receive folic acid and B12 supplements.1,2

(c) Nephrotoxic drugs

The manufacturers consider that the concurrent use of nephrotoxic drugs could potentially decrease the clearance of pemetrexed and therefore increase its toxicity. In the UK, the manufacturer specifically mentions aminoglycosides, loop diuretics, platinum compounds (see also (a) cisplatin above) and ciclosporin, and recommends caution with combined use, and, if necessary, close monitoring of creatinine clearance.

(d) NSAIDs and Aspirin

In a study in 27 patients with advanced cancer, aspirin 325 mg every 6 hours for 9 doses, starting 2 days before and with the last dose 1 hour before an infusion of pemetrexed 500 mg/m², did not alter the pharmacokinetics of pemetrexed.3 In a similar study ibuprofen 400 mg four times daily caused a slight 16% decrease in the clearance of pemetrexed, and increased its AUC by 20%.3 The effects of higher doses of aspirin or ibuprofen are not known, but they could be greater. Because of this, in patients with normal renal function, the manufacturer recommends caution when pemetrexed is used with high doses of NSAIDs (e.g. ibuprofen greater than 1.6 g daily) or high-dose aspirin (greater than 1.3 g daily).2 Moreover, in patients with mild to moderate renal impairment, the manufacturer recommends that NSAIDs and higher dose aspirin be avoided for 2 days before, the day of, and for 2 days after pemetrexed use.1,2

Because of the lack of data on pemetrexed clearance with NSAIDs with longer half-lives (e.g. piroxicam), the manufacturer recommends that all patients taking these NSAIDs stop them for 5 days before pemetrexed, on the day, and for at least 2 days afterwards.1,2

(e) Probenecid and other drugs secreted by the renal tubules

It is possible that drugs that are secreted by the renal tubules (e.g. probenecid, penicillin) could decrease the clearance of pemetrexed, which is also secreted by this mechanism. For this reason, the manufacturer recommends caution with combined use, and, if necessary, close monitoring of creatinine clearance.

Procarbazine + Antiepileptics

The use of enzyme-inducing antiepileptics seems to increase the risk of procarbazine hypersensitivity reactions.

Clinical evidence, mechanism, importance and management

A study of the records of 83 patients with primary brain tumours who were treated with procarbazine between 1981 and 1996 showed that 20 of them had procarbazine hypersensitivity reactions. Of these 20, 95% had taken antiepileptics compared with 71% of those not developing hypersensitivity. In addition, there was a significant dose-response association between the development of hypersensitivity reactions and the serum levels of the antiepileptics used (phenytoin, phenobarbital, or carbamazepine, with or without valproate).1 It was suggested that the enzyme-inducing antiepileptics may increase the metabolism of procarbazine to metabolites causing hypersensitivity. This may also explain why the incidence of procarbazine-induced hypersensitivity is higher in patients with brain tumours, who commonly receive seizure-prophylaxis therapy.1

Procarbazine + Chlormethine (Mechlorethamine)

A report on two patients suggests that the use of high doses of procarbazine with chlormethine may result in neurological toxicity.
Clinical evidence, mechanism, importance and management

Two patients with acute myelogenous leukaemia admitted to hospital for narrow transplantation and who were given high doses of procarbazine 12.5 and 15 mg/kg and chloromethine 0.75 and 1 mg/kg on the same day became lethargic, somnolent and disoriented for about a week. Two other patients who received the same drugs on different days had no neurological complications. In addition, only one of 45 patients treated with high-dose procarbazine alone had similar persistent lethargy. Although no interaction has been proved, the authors suggest that the chloromethine may have enhanced the neurotoxic effects of the procarbazine, and advise that it would be prudent to avoid high-doses of these drugs on the same day. 1

Note that lower doses of the combination have been widely used in the MOPP regimen (mechlorethamine, vincristine, procarbazine, and prednisone) without problems.1

Procarbazine + Miscellaneous

The effects of drugs that can cause CNS depression or lower blood pressure may possibly be increased by the presence of procarbazine.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

In one early clinical study, 4 of 48 patients developed postural hypotension when treated with procarbazine. In addition, another patient with hypertension (180/110 mmHg) had a progressive fall in blood pressure (to 110/80 mmHg) while being treated with procarbazine. 1 Additive hypotensive effects may therefore be expected if procarbazine is given to patients taking antihypertensives.

(b) CNS depressants

Procarbazine can cause CNS depression ranging from mild drowsiness to profound stupor. In early clinical studies, the incidence was variably reported as 8%, 14%, and 31% (when combined with prochlorperazine, see also (c) below). 1,2 Additive CNS depression may therefore be expected if other drugs possessing CNS-depressant activity are given with procarbazine.

(c) Prochlorperazine

An isolated report describes an acute dystonic reaction (difficulty in speaking or moving, intermittent contractions of muscles on the left side of the neck) in a patient taking procarbazine with prochlorperazine. 4 Prochlorperazine was thought to have contributed to the sedative effects of procarbazine in one early clinical study. 3

Procarbazine + Symptomimetics

Despite warnings, it seems doubtful that the weak MAO-inhibitory properties of procarbazine can under normal circumstances cause a hypertensive reaction with tyramine or other sympathomimetics.

Clinical evidence, mechanism, importance and management

The manufacturers say that procarbazine is a weak inhibitor of MAO and therefore predict that interactions with certain foods and drugs may occur in rare cases.1 This is apparently based on the results of animal experiments, which show that the monoamine oxidase inhibitory properties of procarbazine are weaker than pheniprazine.2 There seem to be no formal reports of hypertensive reactions in patients taking procarbazine who have eaten tyramine-containing foods (e.g. cheese) or after using indirectly-acting sympathomimetic amines (e.g. phenylpropanolamine, amphetamine, etc.). The only account traced is purely anecdotal and unconfirmed: “...I recall one patient who described vividly reactions to wine and chicken livers which had occurred while he was taking MOPP chemotherapy (mechlorethamine, vincristine, procarbazine, and prednisone) several years earlier. Since he had not been forewarned, the reactions had been a frightening experience.”3 A practical way to deal with this interaction problem has been suggested by a practitioner in an Oncology unit:3 patients taking procarbazine should ideally be given a list of the potentially interacting foodstuffs (see ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153), with a warning about the nature of the possible reaction but also with the advice that it very rarely occurs. The foods may continue to be eaten, but patients should start with small quantities to ensure that they still agree with them. Those taking MOPP should also be told that any interaction is most likely to occur during the second week of a 14-day course of treatment with procarbazine, and during the week after it has been stopped.

Raltitrexed + Miscellaneous

On theoretical grounds the manufacturers say that folic acid and folic acid may possibly interfere with the action of raltitrexed. Warfarin and NSAIDs do not appear to interact with raltitrexed.

Clinical evidence, mechanism, importance and management

(a) Folinates

The antimitabolite, raltitrexed, is a folate analogue and is a potent and specific inhibitor of the enzyme thymidylate synthase. Inhibition of this enzyme ultimately interferes with the synthesis of deoxyribonucleic acid (DNA) leading to cell death. The intracellular polyglutamation of raltitrexed leads to the formation within cells of even more potent inhibitors of thymidylate synthase. Folate (methylene tetrahydrofolate) is a co-factor required by thymidylate synthase and therefore theoretically folic acid or folic acid may interfere with the action of raltitrexed. Clinical interaction studies have not yet been undertaken to confirm these predicted interactions.1

(b) Warfarin, NSAIDs

The manufacturers say that no specific clinical interaction studies have been conducted but a review of the clinical study database did not reveal any evidence of interactions between raltitrexed and warfarin, NSAIDs or other drugs.1

Sorafenib + Miscellaneous

Sorafenib levels may be reduced by inhibitors of CYP3A4. Antacids may reduce the absorption of sorafenib. Sorafenib may increase doxetaxel and doxorubicin levels. Isolated cases of raised INRs and bleeding have been reported in patients taking warfarin with sorafenib.

Clinical evidence, mechanism, importance and management

(a) Cytochrome P450 inducers

A 5 day course of rifampicin (rifampin) reduced the AUC of a single dose of sorafenib by an average of 37%. Other inducers of the cytochrome P450 isozyme CYP3A4, such as St John’s Wort, carbamazepine, phenytoin, phenobarbital and dexamethasone, may also reduce sorafenib levels.1

(b) Docetaxel

Sorafenib 200 mg or 400 mg twice daily on days 2 to 19 of a 21-day cycle increased the AUC and maximum concentration of docetaxel 75 or
100 mg/m² every 21 days were increased by 36 to 80%, and 16 to 32%, respectively. The manufacturer therefore recommends caution with concurrent use of these drugs.1

(c) Doxorubicin

A 21% increase in the AUC of doxorubicin occurred when it was given with sorafenib. The manufacturers therefore recommend caution with concurrent use of these drugs.1,2

(d) Drugs that affect gastrointestinal pH

Drugs, such as antacids, H₂-receptor antagonists or proton pump inhibitors, that raise the pH of the gastrointestinal tract may reduce the solubility of sorafenib, although this has not been specifically studied. The manufacturers therefore recommend avoiding chronic treatment with these drugs during treatment with sorafenib as they cannot exclude the possibility that these drugs will reduce sorafenib efficacy.1

(e) Warfarin

A study in patients given sorafenib and taking warfarin found that the INR did not differ between those patients taking sorafenib and those not taking sorafenib, despite previous in vitro evidence that sorafenib inhibits the cytochrome P450 isoenzyme CYP2C9, the main isoenzyme involved in the metabolism of warfarin. However, raised INRs and infrequent bleeding have been reported in patients taking warfarin with sorafenib. The manufacturers therefore advise close monitoring of the INR patients taking these drugs together.1,2 A study in patients given sorafenib and taking warfarin found that the INR did not differ between those patients taking sorafenib and those not taking sorafenib, despite previous in vitro evidence that sorafenib inhibits the cytochrome P450 isoenzyme CYP2C9, the main isoenzyme involved in the metabolism of warfarin. However, raised INRs and infrequent bleeding have been reported in patients taking warfarin with sorafenib. The manufacturers therefore advise close monitoring of the INR patients taking these drugs together.1,2

A single case report indicates that phenytoin can reduce or abolish the effects of streptozocin.

Clinical evidence, mechanism, importance and management

A patient with an organic hypoglycaemic syndrome, due to a metastatic apud cell carcinoma of the pancreas, who was taking streptozocin 2 g daily with phenytoin 400 mg daily for 4 days, failed to show the expected response until the phenytoin was withdrawn.2 It would seem that the phenytoin inhibited the effects of the streptozocin by some mechanism as yet unknown. Although this is an isolated case report its authors recommend that concurrent use should be avoided.

Aminoglutethimide, but not anastrozole, exemestane, or letrozole, markedly increases tamoxifen clearance and reduces its serum levels. Tamoxifen modestly reduces anastrozole and letrozole levels, but it does not alter aminoglutethimide levels, or exemestane levels and effects.

Clinical evidence

(a) Effect on tamoxifen

In 6 menopausal women with breast cancer aminoglutethimide 250 mg four times daily for 6 weeks markedly reduced the serum levels of tamoxifen 20 to 80 mg daily and most of its metabolites. The clearance of the tamoxifen was increased by 3.2-fold and the tamoxifen AUC was reduced by 73% (range 56 to 80%).1 Conversely, the concurrent use of anastrozole 1 mg daily for 28 days did not affect the pharmacokinetics of tamoxifen in a double-blind, placebo-controlled study in 34 women with breast cancer who had been taking tamoxifen 20 mg daily for at least 10 weeks.2 Similarly, letrozole 2.5 mg daily had no effect on the pharmacokinetics of tamoxifen in 18 women taking tamoxifen 20 mg daily.2 Further, a study in 32 women clinically disease-free following primary treatment for breast cancer and who had been taking tamoxifen 20 mg daily for at least 4 months found that exemestane 25 mg daily for 8 weeks had no effect on the pharmacokinetics of tamoxifen or the formation of tamoxifen metabolites and the combination was well-tolerated.4

(b) Effect on aromatase inhibitors

Tamoxifen 20 to 80 mg daily did not alter the pharmacokinetics of aminoglutethimide 250 mg four times daily.1 In a pilot study, 18 post-menopausal women with breast cancer were given exemestane 25 mg daily for 14 days, then exemestane and tamoxifen 20 mg daily for 4 weeks. Tamoxifen did not affect the pharmacokinetics (plasma levels) or pharmacodynamics (estrone, estrone sulfate and estradiol suppression) of exemestane and the combination was well-tolerated.5 In 12 women letrozole levels were reduced by 38% (range 0 to 70%) 6 weeks after tamoxifen 20 mg daily was added to letrozole 2.5 mg daily. This reduction persisted after 4 to 8 months; however, the estradiol suppressant effects of letrozole did not appear to be affected.6 Similarly, although the estradiol suppressant effects of anastrozole 1 mg daily did not appear to be affected by tamoxifen 20 mg daily in two studies,7,8 in one of these studies, anastrozole levels were decreased by 27% by tamoxifen.7

Mechanism

It is likely that aminoglutethimide, an enzyme inducer, increases the metabolism of the tamoxifen by the liver, thereby increasing its loss from the body. It is not known how tamoxifen reduces anastrozole and letrozole levels, although it may also be via enzyme induction.6

Importance and mechanism

Theoretically, the combination of an oestrogen antagonist such as tamoxifen and an aromatase inhibitor should provide additional benefit in the treatment of hormone-dependent cancers, however, no clinical studies have yet found this to be so. The pharmacokinetic interactions described above may partly explain this. It may be preferable to use these drugs sequentially rather than concomitantly.6

Tamoxifen and other anti-oestrogens + Herbal medicines

Indirect evidence hints at the possibility that some herbal medicines that possess oestrogenic activity may oppose the actions of anti-oestrogens, such as tamoxifen, used in the treatment of breast cancer.

Clinical evidence, mechanism, importance and management

A letter in the Medical Journal of Australia1 draws attention to the fact that some women with breast cancer receiving chemotherapy or hormone antagonists who develop menopausal symptoms have found relief from hot flushes by taking a Chinese herb ‘dong quai’ (or ‘danggui’ root), which has been identified as Angelica sinensis. A possible explanation is that this and some other herbs (vitex berry (Agnus castus), hops flower (lupulus), ginseng root, black cohosh (cimicifuga)) have significant oestrogen-binding activity and physiological oestrogenic actions.2 The concern expressed in the letter is that the oestrogenic activity of these herbs might directly stimulate breast cancer growth and oppose the actions of competitive oestrogen receptor antagonists such as tamoxifen. Consider also, ‘Tamoxifen and other anti-oestrogens + HRT’, p.659.
Although this is largely speculative at the moment, the writer of the letter suggests that such herbal medicines are undesirable in patients with breast cancer. In addition to tamoxifen, there are now a number of other drugs used for breast cancer that in one way or another reduce the stimulation of oestrogen receptors (anastrozole, exemestane, letrozole, toremifene). More study is needed.

### Tamoxifen and other anti-oestrogens + HRT

Contrary to expectations HRT may not increase the risk of recurrent breast cancer in women taking tamoxifen. HRT is reported to oppose the lipid-lowering effects of tamoxifen.

**Clinical evidence, mechanism, importance and management**

(a) Antioestrogenic effects

In a cohort study of the use of HRT in the management of menopausal symptoms in women treated for breast cancer, the use of continuous combined HRT (an oestrogen plus a progesterone) was not associated with an increased risk of breast cancer recurrence in women taking tamoxifen. This is of interest since HRT might be expected to oppose the effects of anti-oestrogens such as tamoxifen in the treatment and prevention of breast cancer. For this reason, HRT and other oestrogens are often considered to be contraindicated in women taking anti-oestrogens such as anastrozole, exemestane, letrozole, tamoxifen and toremifene (see also ‘Tamoxifen and other anti-oestrogens + Herbal medicines’, p.658). The cohort study described suggests that there need not be a complete restriction on their concurrent use, but ideally randomised prospective studies are required to confirm this.

(b) Cardiovascular effects

A large-scale comparative study was undertaken over a 12-month period in groups of women taking tamoxifen alone, HRT alone, or tamoxifen with transdermal HRT to see whether the cardiovascular risk factors (low-density lipoprotein cholesterol, high-density lipoprotein-cholesterol levels, platelet counts) were changed by concurrent use. It was found that the decrease in total and LDL-cholesterol levels due to the tamoxifen was unchanged in current HRT users, but reduced by two-thirds in women taking tamoxifen who then started HRT. It would therefore seem important to check the outcome of concurrent use. More study is needed.

### Tamoxifen + Medroxyprogesterone acetate

Medroxyprogesterone affects the metabolism of tamoxifen but the clinical importance of this is uncertain.

**Clinical evidence, mechanism, importance and management**

In 20 women with breast cancer taking tamoxifen 20 mg twice daily, the addition of medroxyprogesterone acetate 500 mg twice daily only slightly reduced the tamoxifen serum levels over a 6-month period, but considerably reduced the levels of the desmethyl metabolite of tamoxifen, presumably because of some effect on the metabolism of the tamoxifen by the liver. The clinical importance of this interaction awaits assessment.

### Tamoxifen + Rifampicin (Rifampin)

Rifampicin increased the metabolism of tamoxifen.

**Clinical evidence, mechanism, importance and management**

In 10 healthy men rifampicin 600 mg daily for 5 days reduced the AUC of a single 80-mg dose of tamoxifen by 86%, reduced the peak plasma levels by 55%, and reduced the half-life by 44%. Similarly, the AUC of N-demethyltamoxifen was reduced by 62%.1 It is likely that rifampicin induces the metabolism of tamoxifen by the cytochrome P450 isozyme CYP3A4, thereby reducing its levels. These findings suggest that the efficacy of tamoxifen may be reduced by rifampicin. However, there is some in vitro evidence that suggests that tamoxifen and rifampicin have additive antineoplastic effects in pancreatic carcinoma cell lines.2 Also, tamoxifen induces its own metabolism on long-term use.3 Thus, further study is needed to assess the clinical impact of the long-term combined use of these drugs.

### Tamoxifen + SSRIs

Paroxetine reduces the metabolism of tamoxifen to one of its active metabolites. The clinical relevance of this is unknown, although one small case-control study found that inhibitors of CYP2D6 such as the SSRIs did not increase the recurrence of breast cancer in tamoxifen users.

**Clinical evidence**

Twelve women taking tamoxifen 20 mg daily were also given paroxetine 10 mg daily for 4 weeks, and plasma levels of tamoxifen and its metabolites were measured.1 Before paroxetine, the plasma levels of the 4-hydroxy-N-desmethyl-tamoxifen metabolite (endoxifen) were about 12 times higher than those of the 4-hydroxy-tamoxifen metabolite. Paroxetine reduced endoxifen levels by 56%, but those of N-desmethyl-tamoxifen, and 4-hydroxy-tamoxifen were unchanged. The reduction in endoxifen levels was greatest in those who were extensive metabolisers of the cytochrome P450 isozyme CYP2D6 (see ‘Genetic factors’, (p.4)). In a further study by the same research group, 80 women starting tamoxifen 20 mg daily had plasma levels of tamoxifen measured after 1 and 4 months of therapy.2 These were then correlated with CYP2D6 metaboliser phenotype and the concurrent use of CYP2D6 inhibitors (taken by 24 women). In women who were CYP2D6 extensive metabolisers, use of CYP2D6 inhibitors was associated with a 58% lower endoxifen level, which was substantially lower in those taking paroxetine, but only slightly reduced by venlafaxine, and intermediate in those taking sertraline.2 However, a case-control study of 28 women taking tamoxifen with recurrences of oestrogen receptor positive breast cancer found that there was no difference in the number of women taking CYP2D6 inhibitors (fluoxetine, paroxetine, sertraline) between cases and controls (women taking tamoxifen with no recurrence). Similarly, there was no differences for CYP2C9 inhibitors (including paroxetine and sertraline).3

**Mechanism**

Endoxifen and 4-hydroxy-tamoxifen are more active anti-oestrogens than tamoxifen.1 Tamoxifen is metabolised to 4-hydroxy-tamoxifen and N-desmethyl-tamoxifen principally by CYP3A,2 although others have found that other isoenzymes are involved,4 and to endoxifen by CYP2D6.1 Of the SSRIs, paroxetine is the most potent inhibitor of CYP2D6. However, tamoxifen resistance may be more to do with altered oestrogen receptor sensitivity than reduced levels of tamoxifen metabolites.5 Further it has been suggested that the plasma levels of tamoxifen and metabolites found in one study6 would be sufficient to block oestrogen binding to oestrogen receptors so that a decrease in endoxifen levels would not substantially affect anti-oestrogen activity.7
Importance and management

Although information is limited, it is established that potent inhibitors of CYP2D6 such as paroxetine can alter the metabolism of tamoxifen to its active metabolites. However, this effect has on the clinical efficacy of tamoxifen remains to be established. The one small case-control study suggests the effect is not great. At present, there is insufficient evidence to recommend caution when giving SSRIs with tamoxifen, but further study is clearly needed. Any interaction would apply equally to other CYP2D6 inhibitors, see ‘Table 13’, (p.6) for a list.

**Taxanes + Amifostine**

Amifostine had no effect on docetaxel and paclitaxel pharmacokinetics, except in one study which found that amifostine extended paclitaxel plasma circulation time. Amifostine appears not to reduce the toxicity of these taxanes.

**Clinical evidence, mechanism, importance and management**

In a randomised study, amifostine did not alter the response to, or the pharmacokinetics of, *paclitaxel*, neither did it protect against *paclitaxel*-related neurotoxicity or myelotoxicity.1 Another study in 8 patients has confirmed that amifostine (750 mg/m² as a 15-minute infusion 30 minutes beforehand) had no effect on the pharmacokinetics of *paclitaxel* 135 to 200 mg/m². Six of the patients were also taking epirubicin and cisplatin.2 Although the preliminary findings of an earlier study had suggested that pre-treatment with amifostine reduced the AUC of *paclitaxel* by 29%,3 the full report of this study concluded that amifostine had no clinically relevant effect on *paclitaxel* pharmacokinetics.4 In a study in which patients were given amifostine 500 mg as an infusion over 15 minutes just before low-dose *paclitaxel* 80 mg/m² as a one-hour infusion, amifostine reduced maximum plasma levels by about 20%. However, the AUC of paclitaxel was not affected, but the paclitaxel plasma circulation time was prolonged.5 Amifostine had no effect on the pharmacokinetics of *docetaxel*, nor did it reduce *docetaxel*-induced myelotoxicity.6 7 The finding in two of these studies1,5 that the toxicity of taxanes was not reduced by amifostine does not support earlier in vitro data where amifostine protected normal tissue from *paclitaxel* toxicity.6 Most studies show no beneficial or adverse consequences from giving amifostine with the taxanes. Further study is needed to evaluate the possible effects of amifostine on taxane plasma circulation time.

**Taxanes + Ciclosporin**

Ciclosporin increases the levels of docetaxel and paclitaxel after oral administration.

**(a) Docetaxel**

One study has demonstrated that the bioavailability of oral docetaxel may be increased from 8% to 90% by ciclosporin due to inhibition of both P-glycoprotein transport and the metabolism of docetaxel by the cytochrome P450 isozyme CYP3A4.1 In another study, the AUC of ciclosporin was increased by about 1.5-fold when it was given with oral docetaxel, probably because of competitive inhibition of CYP3A4-mediated ciclosporin metabolism.2

**(b) Paclitaxel**

Oral paclitaxel has poor bioavailability because of a high affinity for P-glycoprotein in the gastrointestinal tract. Studies in mice have shown that the combination of ciclosporin with oral paclitaxel produced a tenfold increase in systemic exposure to paclitaxel. Plasma levels of paclitaxel were below therapeutic concentrations in 5 patients when they were given an oral dose (inhaled formulation) of paclitaxel 60 mg/m² followed by intravenous doses of 175 mg/m² for subsequent courses. However, therapeutic levels above 100 micromol/mL (a ninefold increase) were achieved in 9 patients who received the same regimen with ciclosporin 15 mg/kg. The combination was well-tolerated, but further study is required to determine whether paclitaxel treatment via the oral route is as active as that by the intravenous route.3

**Taxanes + Cisplatin or Carboplatin**

The toxicity of paclitaxel given with cisplatin appears to be dependent on the order of administration, with more severe myelo-suppression occurring if cisplatin is given first. There does not appear to be any sequence dependent interaction for the combination of docetaxel with carboplatin or docetaxel with cisplatin. Paclitaxel may reduce the thrombocytopenia associated with carboplatin. The combination of carboplatin with paclitaxel appears to be more neurotoxic than carboplatin with docetaxel.

**(a) Carboplatin**

Several clinical studies have found that the severity of thrombocytopenia with the combination of *paclitaxel* and carboplatin was less than that expected with carboplatin alone.4–5 This does not appear to be due to any changes in carboplatin pharmacokinetics. In one study, patients were given carboplatin as a 30-minute infusion, either alone or immediately following *paclitaxel* 175 mg/m² as a 3-hour infusion, and it was found that the pharmacokinetics of carboplatin were not significantly affected by *paclitaxel*.4 Similarly, a pharmacokinetic interaction was not noted when *paclitaxel* and carboplatin were given in either order in another study.4 Other studies found the AUC of carboplatin to be similar to that predicted, despite the presence of paclitaxel.5 Although one study found the AUC of carboplatin to be about 12% lower in the presence of *paclitaxel*, the same researchers also found that the AUC associated with a 50% decrease in platelet count increased by 68% (i.e. more carboplatin is needed to cause the same degree of thrombocytopenia, which suggests a pharmacodynamic basis for the attenuated toxicity of the combination). Other researchers also noted that the AUC of carboplatin causing a 50% reduction in platelets was about 6.3 mg/mL per minute when given with *paclitaxel* compared with historical data of 4 mg/mL per minute when given alone.6 Although thrombocytopenia may be lower than expected, myelosuppression (in the form of neutropenia) is a dose-limiting toxicity.
of the combination of carboplatin and paclitaxel. In one study, patients given paclitaxel with carboplatin experienced significantly greater neurotoxicity than those given docetaxel with carboplatin, but the regimens were similar in efficacy. Further, there appear to be no pharmacokinetic interactions between carboplatin and docetaxel.

(b) Cisplatin

Early studies of the combination of cisplatin and paclitaxel showed that the degree of myelosuppression was sequence dependent. When cisplatin was given first, a greater degree of myelosuppression was seen. Pharmacokinetic studies suggest that sequence-dependent differences in myelosuppression may be due to a 25% reduction in paclitaxel clearance when cisplatin is given first. For this reason, the manufacturers recommend that cisplatin is given first.

Cokinetic studies suggest that sequence-dependent differences in myelosuppression are greater for the combination when paclitaxel is given over 24 hours as opposed to 3 hours. When paclitaxel is given with cisplatin, neurotoxicity (peripheral neuropathy) is common, and there is some evidence that this is more severe if the paclitaxel is given over 3 hours as opposed to 24 hours. In one study, neurotoxicity was unexpectedly severe when paclitaxel alone was used in patients who had relapsed after treatment with cisplatin; however, this was not the case in another similar study.

In contrast to paclitaxel, early studies did not reveal any obvious sequence dependence for the combination of docetaxel and cisplatin. In addition, cisplatin did not cause any significant changes in pharmacokinetics.

**Taxanes + Cyclophosphamide**

There is some evidence to suggest that the toxicity associated with combinations of paclitaxel and cyclophosphamide is dependent on the order of administration. Results from one study indicate that docetaxel pharmacokinetics are unaltered by cyclophosphamide.

**Clinical evidence, mechanism, importance and management**

(a) Docetaxel

The pharmacokinetics of docetaxel were not altered by pretreatment with an intravenous bolus dose of cyclophosphamide in a phase I study. For a report that the pharmacokinetics of docetaxel are not affected by ifosfamide, see ‘Cyclophosphamide or Ifosfamide + Taxanes’, p.628.

(b) Paclitaxel

A study in patients given paclitaxel as a 24-hour infusion and cyclophosphamide as an infusion over 1 hour that neutropenia and thrombocytopenia were more severe when paclitaxel preceded cyclophosphamide. Similarly, in another study, concurrent use of a continuous 72-hour infusion of paclitaxel and a daily bolus of cyclophosphamide had acceptable toxicity. However, when the cyclophosphamide was given as a single intravenous dose after the end of the 72-hour paclitaxel infusion, severe hematological and gastrointestinal toxicity occurred. Whether the clinical efficacy of this combination is also altered by the schedule and sequence has not been determined. See also ‘Cyclophosphamide or Ifosfamide + Taxanes’, p.628.

**Taxanes + Protease inhibitors**

Life-threatening haematological toxicities have been reported in a few patients taking protease inhibitors when given paclitaxel or docetaxel. Nelfinavir and ritonavir appear to inhibit the clearance of paclitaxel and are predicted to inhibit the metabolism of docetaxel by CYP3A4.

**Clinical evidence**

(a) Docetaxel

A HIV-positive 64-year-old woman taking nelfinavir was given trastuzumab and docetaxel 36 mg/m² for breast cancer. Three days later she was hospitalised with early, severe myelosuppression, which was attributed to an interaction between the nelfinavir and docetaxel, and she died from sepsis.

(b) Paclitaxel

A 39-year-old woman taking lopinavir was given carboplatin and paclitaxel 175 mg/m² for adenocarcinoma. Five days later she was hospitalised with early, severe myelosuppression, which was attributed to an interaction between lopinavir and paclitaxel, and she later died. In another report, an HIV-positive patient who was taking lopinavir/ritonavir, delavirdine and didanosine was also given paclitaxel 100 mg/m² to treat Kapoor’s sarcoma. Within 3 days he developed myalgia and arthralgia, and 8 days after treatment developed fever, tachycardia and a productive cough. He was treated with antibacterials and G-CSF, but later died. Findings at post mortem included severe oesophageal mucositis, Streptococcus viridans pneumonia and a massive saddle embolism (an embolism that sits across two vessels). A second patient taking indinavir, ritonavir, lami-vudine and stavudine developed severe leucopenia and thrombocytopenia.
within 7 days of being given paclitaxel 100 mg/m² for Kaposi’s sarcoma, and again after a second course of paclitaxel. Further courses of paclitaxel were tolerated by giving a reduced dose of 60 mg/m² together with G-CSF.²

The UK manufacturer of paclitaxel briefly mentions that studies in patients with Kaposi’s sarcoma, who were taking multiple concomitant medications, suggest that the systemic clearance of paclitaxel was significantly lower in the presence of nelfinavir and ritonavir, but not with indinavir.³

Mechanism

Paclitaxel is metabolised by the cytochrome P450 enzymes CYP2C8 and CYP3A4. Docetaxel is metabolised by CYP3A4. Pro tease inhibitors such as ritonavir and indinavir are known to inhibit CYP3A4, which might result in increased taxane levels and toxicity.

Importance and management

Evidence is limited, nevertheless the UK manufacturers advise that paclitaxel should be given to patients also receiving protease inhibitors with caution.³ The manufacturers of docetaxel also advise that it should be used with caution with drugs that inhibit CYP3A4, see ‘Taxanes; Docetaxel + Miscellaneous’, below, which would include the protease inhibitors.

Evidence is limited, nevertheless the UK manufacturers advise that paclitaxel should be given to patients also receiving protease inhibitors with caution.³ The manufacturers of docetaxel also advise that it should be used with caution with drugs that inhibit CYP3A4, see ‘Taxanes; Docetaxel + Miscellaneous’, below, which would include the protease inhibitors.

Taxanes; Docetaxel + Cannabis

The pharmacokinetics of docetaxel are not altered by a herbal tea containing cannabis.

Clinical evidence, mechanism, importance and management

In a crossover study 24 patients were given docetaxel 180 mg before and on day 12 of a 15-day course of 200 mL daily of a cannabis tea containing cannabis 1 g/L. This was prepared from medicinal-grade cannabis (Cannabis sativa L. Flos, variety Bedrocan®) containing the cannabinoids Δ9-tetrahydrocannabinol 18% and cannabidiol 0.8%. The clearance and the AUC of docetaxel were not significantly altered by the cannabis. No dosage adjustments are likely to be needed if docetaxel is given with cannabis.¹

Taxanes; Docetaxel + Antiepileptics

Enzyme-inducing antiepileptics (phenytoin, carbamazepine, and phenobarbital) increase the clearance of paclitaxel and increase its maximum tolerated dose.

Clinical evidence, mechanism, importance and management

In a study in patients with glioblastoma multiforme the maximum tolerated dose (MTD) of paclitaxel was 43% higher in patients receiving antiepileptics (phenytoin, carbamazepine, and phenobarbital) than in those not receiving them.¹ Another study in patients with recurrent malignant gliomas reported the same finding: a 50% increase in MTD coupled with a 104% increase in plasma clearance of paclitaxel in those taking antiepileptics. In addition, this study reported that the dose-limiting toxicity differed: central neurotoxicity in those taking antiepileptics and myelosuppression and/or gastrointestinal toxicity in those not.² It is probable that enzyme-inducing antiepileptics increase the metabolism of paclitaxel and therefore it is likely that patients taking these antiepileptics will require an increase in paclitaxel dose. Further study is needed. Note that barbiturates are predicted to increase the metabolism of docetaxel, see ‘Taxanes; Docetaxel + Miscellaneous’, above.

Taxanes; Paclitaxel + Ketoconazole

Ketoconazole does not appear to affect the pharmacokinetics of paclitaxel.

Clinical evidence, mechanism, importance and management

Women with ovarian cancer were treated with 3-hour infusions of paclitaxel 175 mg/m² once every 21 days. It was found that when single oral doses of ketoconazole were given 3 hours before or 3 hours after the paclitaxel, the serum levels of the paclitaxel and its principal metabolite (6-alpha-hydroxypaclitaxel) remained unchanged. These findings confirmed those of in vitro studies. The conclusion was reached that these two drugs can therefore be given together safely without any dosage adjustments.²

**Taxanes; Paclitaxel + Miscellaneous**

**In vitro** studies with human liver tissue suggest that no metabolic interactions are likely to occur between paclitaxel and cimetidine, dexamethasone or diphenhydramine. **Cremophor** may inhibit the intracellular uptake and metabolism of paclitaxel.

**Clinical evidence, mechanism, importance and management**

(a) **Cimetidine, Dexamethasone, Diphenhydramine**

On the basis of an in vitro study using human liver slices and human liver microsomes it has been concluded that the metabolism of paclitaxel is unlikely to be altered by cimetidine, dexamethasone or diphenhydramine, all of which are frequently given to prevent the hypersensitivity reactions associated with paclitaxel or its vehicle, Cremophor (see b, below). The UK manufacturers say that paclitaxel clearance in patients is not affected by cimetidine premedication, although some authors have advised caution when using cimetidine with docetaxel or paclitaxel since cimetidine is known to affect the cytochrome P450 isoenzyme CYP3A4, which is responsible, in part, for the metabolism of these taxanes.

(b) **Cremophor**

In vitro, Cremophor was found to inhibit the metabolism of paclitaxel in human liver microsomes, which might be expected to increase its toxicity. The concentration used in the in vitro study may be achieved clinically in patients given paclitaxel with Cremophor as the vehicle. This may be worth bearing in mind if other drugs formulated with Cremophor are given with paclitaxel.

(c) **Methotrexate**

An in vitro study in human bladder cancer cells found that the antineoplastic effect of paclitaxel in combination with methotrexate was dependent on the order of exposure to the two drugs.

**Teniposide + Antiepileptics**

Carbamazepine, phenytoin and phenobarbital markedly increase the clearance of teniposide. A reduction in its effects has been noted in B-lineage leukaemia.

**Clinical evidence, mechanism, importance and management**

The clearance of teniposide was increased two to threefold (from 13 to 32 mL/minute per kg) in 6 children with acute lymphocytic leukaemia when they also took phenytoin or phenobarbital. Another patient had a twofold increase in teniposide clearance when carbamazepine was given. In a retrospective survey, long-term antiepileptic use (phenytoin, phenobarbital, carbamazepine, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. In this study, faster clearance of teniposide was found in those receiving antiepileptics. These effects probably occur because these antiepileptics are potent liver enzyme inducers, which may increase the metabolism of teniposide by the liver and thereby reduce its levels. The authors of these reports therefore conclude that an increased dosage of teniposide will be needed in the presence of antiepileptics to achieve therapeutic systemic exposure to the drug comparable to that achievable in their absence. It may be preferable to use alternative antiepileptics (that are not enzyme inducers) in patients requiring teniposide.

**Temodol + Miscellaneous**

Valproic acid may reduce the clearance of temozolomide. Carbamazepine, H₂-receptor antagonists, dexamethasone, phenobarbital, phenytoin, prochlorperazine and ondansetron did not affect the clearance. Food, but not ranitidine slightly reduced extent of absorption of temozolomide.

**Clinical evidence, mechanism, importance and management**

The manufacturer notes that concurrent use of carbamazepine, dexamethasone, H₂-receptor antagonists, ondansetron, phenobarbital, phenytoin or prochlorperazine did not affect the clearance of temozolomide, based on an analysis of population pharmacokinetics from phase II studies. However, valproic acid modestly reduced the clearance of temozolomide. Ranitidine 150 mg twice daily had no effect on the absorption or plasma pharmacokinetics of temozolomide, or that of its active metabolite in a study in 12 patients given temozolomide 150 mg/m² daily. The manufacturer notes that food slightly reduces the temozolomide AUC by 9% and maximum plasma concentration by 33%. They recommend that it should be given without food.

**Thalidomide + Doxorubicin**

The concurrent use of thalidomide and doxorubicin is associated with an increased risk of deep-vein thrombosis in patients with multiple myeloma.

**Clinical evidence, mechanism, importance and management**

In a study in 100 patients with newly diagnosed multiple myeloma given induction chemotherapy (dexamethasone, vincristine, doxorubicin, cyclophosphamide, etoposide and cisplatin) with or without thalidomide, deep vein thrombosis developed in 14 of the 50 patients (28%) given thalidomide compared with 2 of 50 patients (4%) not given thalidomide. Deep vein thrombosis has been reported to occur in 10% of patients treated for multiple myeloma but is reported to occur in about 2% in patients with multiple myeloma treated with thalidomide alone.

In a further study by the same authors, 232 patients with multiple myeloma were treated with DT-PACE (dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, etoposide) if they had preceding standard dose therapy but no prior autotransplantation, or with DCEP-T (dexamethasone, cyclophosphamide, etoposide, cisplatin, thalidomide) for relapse after transplantation. Deep-vein thrombosis developed in 31 of 192 patients (16%) treated with the doxorubicin-containing regimen (DT-PACE) and only 1 of 40 (2.5%) treated with DCEP-T (no doxorubicin). In patients with multiple myeloma, the risk of deep-vein thrombosis appears to be increased when thalidomide is given with combination chemotherapy containing doxorubicin. It has been suggested that, until more information is available, the concurrent use of thalidomide and doxorubicin should probably be limited to patients in monitored investigational studies. 

Thalidomide + Epoetins

A higher than expected incidence of thromboembolic events occurred in patients with myelodysplastic syndrome treated with thalidomide and darbepoetin-alfa, but not in patients with multiple myeloma given thalidomide with epoetin.

Clinical evidence, mechanism, importance and management

A Phase II study to investigate the efficacy and tolerability of the concurrent use of thalidomide 100 mg daily and darbepoetin-alfa 2.25 micrograms/kg per week subcutaneously in patients with myelodysplastic syndrome was discontinued because of an unexpectedly high incidence of thromboembolic events. Of the first 7 patients enrolled in the study, two developed deep-vein thrombosis and one died of pulmonary embolism. The authors recommended careful monitoring and possibly thromboprophylaxis (heparin or warfarin) in patients with myelodysplastic syndrome given both thalidomide and epoetin.1

In contrast to these findings, in a study in patients with multiple myeloma treated with thalidomide, thromboses were reported in 4 of 49 patients (8.1%) also treated with epoetin and in 14 of 150 patients not treated with epoetin (9.3%). These results suggest that epoetin does not increase the risk of thrombosis in patients with multiple myeloma receiving thalidomide.2

The differences in findings have not been explained, but may be due to differences in both the disease states and the actions of darbepoetin alfa and epoetin in different regimens.

Thalidomide + Interferons

Severe bone marrow depression is reported in a patient given thalidomide with peginterferon alfa.

Clinical evidence, mechanism, importance and management

A patient with multiple myeloma in remission after an autologous stem cell transplantation was given thalidomide 200 mg daily. Five weeks after also being given peginterferon alfa-2b severe reversible bone marrow hypoplasia developed. Peginterferon was probably responsible for the bone marrow depression. However, thalidomide may also cause bone marrow depression and it was suggested that the severe suppression in this patient may have been due to the combined effects of the peginterferon and thalidomide.1

Thalidomide + Miscellaneous

Rifampicin and phenobarbital did not appear to alter thalidomide clearance in one study. Thalidomide increases the effect of other CNS depressants, and its CNS depressant activity is reduced by CNS stimulants. Thalidomide does not alter the pharmacokinetics of oral contraceptive steroids.

Clinical evidence, mechanism, importance and management

(a) CNS depressants

Animal studies have shown an increase in CNS depressant activity when thalidomide was given with alcohol, barbiturates, chlorpromazine and reserpine.1

(b) CNS stimulants

The depressant effect of thalidomide is reduced by the concurrent use of CNS stimulants such as metamfetamine and methylphenidate.1

(c) Cytochrome P450 isoenzyme inducers

There was no clear relationship between thalidomide clearance and the concurrent use of enzyme inducers such as rifampicin (rifampin), or phenobarbital in a study in patients with glioma.2 For the possible additive CNS depressant effect with barbiturates, see CNS depressants, above.

(d) Hormonal contraceptives

Thalidomide 200 mg daily for 3 weeks did not alter the pharmacokinetics of single doses of ethinylestradiol/norethisterone in two studies in healthy women.3,4 Thalidomide is not therefore expected to alter the clinical efficacy of oral contraceptives. Note that, because thalidomide is an established human teratogen, it is very important that women taking it do not become pregnant. In the USA, it is standard practice to recommend that two forms of contraception should be used, of which hormonal contraceptives can be one.5 This is because, even though hormonal methods of contraception are highly effective, they do, on rare occasions, fail.

Thalidomide + Zoledronic acid

The pharmacokinetics of zoledronic acid are not affected by thalidomide.

Clinical evidence, mechanism, importance and management

In a study intravenous zoledronic acid 4 mg every 4 weeks with alternate day prednisolone was given with or without thalidomide 200 mg daily for up to 1 year. The zoledronic acid pharmacokinetics were not affected by thalidomide and based on renal function no clinically adverse interaction occurred during concurrent use. The subjects in this study were patients with multiple myeloma with no disease progression 6 weeks after autologous stem-cell transplantation and conditioning with melphalan.1

Thiopurines + Allopurinol

The haematological effects of azathioprine and mercaptopurine are markedly increased by allopurinol.

Clinical evidence

(a) Azathioprine

A patient taking allopurinol 300 mg daily for gout was also given azathioprine 100 mg daily to treat autoimmune haemolytic anaemia. Within 10 weeks his platelet count fell from 236 to 45 x 10^9/L, his white cell count fell from 9.4 to 0.8 x 10^9/L and his haemoglobin concentration fell from 11.5 to 5.3 g/dL.1

A number of other reports similarly describe reversible bone marrow toxicity associated with anaemia, pancytopenia, leucocytopenia and thrombocytopenia in patients given azathioprine with allopurinol,1,10 and in one case a fatality occurred as a result of neutropenia and septicemia.8 In a retrospective analysis of 24 patients who had received both azathioprine and allopurinol, 11 developed leucopenia, 7 developed moderate anaemia, and 5 developed thrombocytopenia. Only 14 of the patients had received a greater than two-thirds reduction in their azathioprine dose when allopurinol was started, but despite this, some of these patients still developed haematological toxicity.10

(b) Mercaptopurine

In early studies, allopurinol 200 to 300 mg reduced the effective dose of mercaptopurine by approximately fourfold in 7 patients with chronic granulocytic leukaemia or variants.11
Thiopurines + 5-Aminosalicylates

The haematological toxicity of azathioprine and mercaptopurine may be increased by mesalazine, olsalazine or sulfasalazine. Balsalazide may be less likely to interact but this requires confirmation.

Clinical evidence

(a) Balsalazide

The frequency of clinically important neutropenia did not significantly increase in 10 patients with Crohn’s disease receiving azathioprine or mercaptopurine when they were given balsalazide 6.75 g daily for 8 weeks, but significant increases in whole blood 6-thioguanine nucleotide concentrations were seen.

(b) Mesalazine

A 13-year-old boy with severe ulcerative pancolitis and cholangitis was treated with prednisone 60 mg daily, ursodeoxycholic acid 15 mg/kg daily and mesalazine 25 mg/kg daily. When azathioprine 2 mg/kg daily was added in an attempt to reduce the prednisone dosage, he developed marked and prolonged azathioprine toxicity (severe pancytopenia), which was attributed to an interaction resulting from abnormally high, persistent levels of an azathioprine metabolite. In another study, there was a trend towards an increased rate of clinically important neutropenia in 10 patients with Crohn’s disease receiving azathioprine or mercaptopurine when they were given mesalazine 4 g daily for 8 weeks. One patient was withdrawn from the study after 6 weeks because of leucopenia. Significant increases in whole blood 6-thioguanine nucleotide concentrations were also seen.

(c) Olsalazine

A case report describes a patient with Crohn’s disease who had two separate episodes of bone marrow suppression while receiving mercaptopurine 50 to 75 mg daily and olsalazine 1 to 1.75 g daily. It was found necessary to reduce the mercaptopurine dosage on the first occasion and to withdraw both drugs on the second.

(d) Sulfasalazine

A decrease in leukocyte counts was seen in 4 patients taking azathioprine (2.1 to 3.3 mg/kg daily) after the addition of sulfasalazine. This lasted several months in one patient, and was transitory in two. The fourth patient developed agranulocytosis after 4 days, which required treatment discontinuation. When the drugs were later resumed at a lower dose, no reduction in leukocyte counts occurred. Another report describes 38 patients taking azathioprine (mean dose 92.8 mg) and sulfasalazine (mean dose 2.1 g) for rheumatoid or psoriatic arthritis. Some patients did well, but in general the combination was poorly tolerated, and only 45% continued treatment after 6 months. Reasons for withdrawal included rash (3 patients), gastrointestinal upset (7), leucopenia (1) and nephrotic syndrome (1). In another study, there was a trend towards an increased rate of clinically important neutropenia in 12 patients with Crohn’s disease receiving azathioprine or mercaptopurine when they were given sulfasalazine 4 g daily for 8 weeks. One patient withdrew from the study after 6 weeks because of leucopenia. Significant increases in whole blood 6-thioguanine nucleotide concentrations were also found.

Mechanism

The metabolism of azathioprine and mercaptopurine depends on S-methylation by thiopurine methyltransferase (TPMT) and oxidation by xanthine oxidase. An in vitro study using recombinant TPMT found that both sulfasalazine and its metabolites inhibit the activity of TPMT. Therefore if these drugs are used together, the clearance of azathioprine and mercaptopurine may be reduced by the sulfasalazine, resulting in an increase in their toxicity (there is only a small margin between their therapeutic and toxic levels). About 11% of patients may be at particular risk because of genetic polymorphism whereby they have TPMT enzyme activity that is only half that of the rest of the population. An in vitro study confirmed that mesalazine, olsalazine and its metabolite olsalazine-O-sulfate and balsalazide are inhibitors of recombinant TPMT. In patients, increased levels of 6-thioguanine nucleotide are probably due to inhibition of TPMT. It is suggested that the reported in vitro concentration (IC_{50}) of balsalazide required to halve the TPMT activity is about 1000 times higher than peak plasma levels after therapeutic doses and therefore an interaction is unlikely. Mesalazine and olsalazine peak levels may also be less than the IC_{50} concentrations, but peak plasma levels of sulfasalazine are close to IC_{50} concentrations.

Importance and management

These reports underline the importance of taking particular care if azathioprine or mercaptopurine are used with balsalazide, mesalazine, olsalazine, or sulfasalazine. Balsalazide may be less likely to interact, but this requires confirmation. Some have postulated that the interaction may actually benefit patients, as increased whole blood 6-thioguanine nucleotide...
or mild leucopenia is associated with a greater chance of remission in those taking azathioprine or mercaptopurine.\textsuperscript{1,2} Extra monitoring of white blood cell counts is required when starting therapy with the combination.\textsuperscript{3} More study is needed.

### Thiopurines; Azathioprine + Co-trimoxazole or Trimethoprim

There is some evidence that the risk of haematological toxicity may be increased in renal transplant patients taking azathioprine if they are given co-trimoxazole or trimethoprim, particularly if they are given for extended periods. However, other evidence suggests that the drugs may be used together safely, and the combination is commonly used in practice.

**Clinical evidence**

The observation that haematological toxicity often seemed to occur in renal transplant patients given azathioprine and co-trimoxazole, prompted a retrospective survey of the records of 40 patients. It was found that there was no difference in the incidence of thrombocytopenia and neutropenia in those given azathioprine, either alone, or with co-trimoxazole, (trimethoprim 160 to 320 mg and sulfamethoxazole 800 mg to 1.6 g daily) for a short time (6 to 16 days), but a significant increase occurred in the incidence and duration of thrombocytopenia and neutropenia if both drugs were given together for 22 days or more.\textsuperscript{1}

Another report describes a marked fall in white cell counts in renal transplant recipients during concurrent treatment with either co-trimoxazole (described as frequent) or trimethoprim (3 cases).\textsuperscript{2} In one case the fall occurred within 5 days and was managed by temporarily withdrawing the azathioprine and reducing the trimethoprim dosage from 300 to 100 mg daily.\textsuperscript{2}

Conversely, in an early study, there was no difference in the incidence of leucopenia when renal transplant recipients were given co-trimoxazole or other antibacterials.\textsuperscript{3} Similarly, in 252 renal transplant patients given continuous prophylaxis with co-trimoxazole or sulphasalazine for 12 to 25 months, toxicity was minimal: leucopenia occurred only occasionally and was reversed by temporarily withholding azathioprine. This was needed in a similar number of patients with each antibiotic.\textsuperscript{4} In another placebo-controlled study in cardiac transplant recipients taking triple therapy including azathioprine, co-trimoxazole prophylaxis for 4 months did not alter total white blood cell counts: leucopenia did not occur and no change in azathioprine dose was required.\textsuperscript{5}

**Mechanism**

Not understood. It seems possible that the bone marrow depressant effects of all three drugs may be additive. In addition, in some patients impaired renal function may allow co-trimoxazole levels to become elevated, and haemodialysis may deplete folate levels, which could exacerbate the antileukemic effects of the co-trimoxazole. Trimethoprim has been shown to inhibit renal tubular creatinine secretion.\textsuperscript{6}

### Thiopurines; Mercaptopurine + Doxorubicin

One study postulated that the hepatotoxicity of \textit{intra-venous} mercaptopurine can be increased by doxorubicin.

**Clinical evidence, mechanism, importance and management**

One report describes 11 patients who developed liver damage after being given \textit{intra-venous} mercaptopurine 500 mg/m² daily for 5 days, with doxorubicin 50 mg/m² on the first day. The frequency and severity of liver damage was greater than the authors had previously seen with mercaptopurine alone. They postulated that doxorubicin potentiated the hepatotoxicity of mercaptopurine.\textsuperscript{1} Mercaptopurine is no longer commonly used \textit{intra-venously}, and the dose given in this study is much higher than that currently used \textit{orally}. The general applicability of this study is therefore unknown.

### Thiopurines; Mercaptopurine + Food

Food may reduce and delay the absorption of mercaptopurine.

**Clinical evidence**

A study in 17 children with acute lymphoblastic leukaemia showed that the absorption of mercaptopurine 5 mg/m² was reduced if it was given 15 minutes after a standard breakfast of 250 mL of milk and 50 g of biscuits, when compared with fasting. The AUC was reduced by 26%, the maximum plasma levels by 36%, and the time to maximum plasma levels delayed from 1.2 to 2.3 hours.\textsuperscript{1} Some individuals showed more marked effects than others; 11 subjects had a decrease in absorption, whereas 6 subjects had no change or a small increase.\textsuperscript{2} Similarly, in another study in 7 children, peak plasma mercaptopurine levels were lower and were delayed when it was given with a standard breakfast compared with those after an overnight fast.\textsuperscript{2} However, in a third study in 10 children, mercaptopurine levels varied widely between individuals and there was no clear effect of food. The peak plasma levels were increased only 11% (range 67% decrease to 81% increase), and the AUC was increased by a mean of 3% (range 53% decrease to 86% increase) when given in the fasting state compared with after food.\textsuperscript{7}

**Mechanism**

Not understood. Delayed gastric emptying is a suggested reason.\textsuperscript{1}
Importance and management

The documentation is limited, and the interaction is not established. Merca
topurine levels vary widely, and it is not established whether food is a
clear factor in this variation. Some have suggested that mercaptopurine
should be taken before food to optimise its absorption,3 whereas others do
not consider the evidence sufficient to make a recommendation.3

Thiopurines; Mercaptopurine + Methotrexate

Methotrexate can increase the bioavailability of mercaptopurine, but the
contribution this makes to their synergistic action in leu-
kaemia is unclear. One report suggests the combination may not
be synergistic.

Clinical evidence, mechanism, importance and management

In 14 children receiving maintenance therapy for leukaemia oral low-dose
methotrexate 20 mg/m² increased the AUC and peak plasma levels of
mercaptopurine 75 mg/m² by 31% and 26%, respectively.1 In another
study, 10 children with acute lymphoblastic leukaemia in remission were
treated with mercaptopurine 25 mg/m² daily and intravenous infusions of
high-dose methotrexate 2 or 5 g/m² once every other week for consolida-
tion therapy. It was found that methotrexate 2 or 5 g/m² increased the
AUC of mercaptopurine by 69% and 93%, respectively, and raised the
maximum serum levels of mercaptopurine by 108% and 121%, respecti-
vely.2 The reasons for this pharmacokinetic interaction are not under-
stood, although it is thought that methotrexate is a xanthine oxidase
inhibitor, which may therefore inhibit the metabolism of mercaptopu-
rine.1,2

The combination of methotrexate and mercaptopurine has an established
place in the therapy of leukaemia and has been found to be synergistic.
These pharmacokinetic findings may be part of the explanation for this, al-
thought biochemical mechanisms may be more important.3 The risk of re-
fractory leukaemia did not appear to be related to the pharmacokinetics of
methotrexate or mercaptopurine, which showed considerable inter and in-
trapatient variability, in one study in children.4

In contrast, one report suggests that, in certain circumstances at least, the
combination of mercaptopurine and methotrexate may not be synergistic.
In a study, children with newly diagnosed acute lymphoblastic leukaemia
were given intravenous mercaptopurine 1 g/m² over 6 hours, either alone,
or after low-dose oral methotrexate (6 doses of 30 mg/m²) or high-dose in-
travenous methotrexate (1 g/m² over 24 hours). Methotrexate increased the
plasma levels of mercaptopurine, but, unexpectedly, it was also found that
thioguanine nucleotide levels in bone marrow leukaemic lym-
phoblasts were 13-fold lower during methotrexate use. It is not known whether
methotrexate would reduce thiopurine metabolite levels in leukemic lymph-
phoblasts when mercaptopurine is given as continuation therapy where the
leukemic burden is less substantial than in newly diagnosed cases. In ad-
dition, the changes in leukocyte counts over 3 days suggested mercaptop-
urine alone had little effect, and although methotrexate caused a reduction in
intracellular thiopurine metabolite levels, it produced a greater decrease in
leukocytes than mercaptopurine alone. It was concluded that in this par-
ticular study, the antileukaemic effect was primarily due to methotrexate.5

Topotecan + Amifostine

In 10 women with ovarian cancer amifostine (given daily, before
topotecan, for 5 days) did not significantly affect the pharmacokinetics of topotecan.1

1. Zackrisson A-L, Malmström H, Peterson C. No evidence that amifostine influences the plasma
103–8.

Topotecan + Phenytin

Phenytin may possibly increase topotecan clearance.

Clinical evidence, mechanism, importance and management

A 5-year-old child with medulloblastoma received a course of topotecan,
firstly with phenytin and then without. Phenytin increased the total top-
totecan clearance by 47%.1 This suggests that an increased topotecan dos-
age may possibly be needed in the presence of phenytin in other patients.
For a similar effect of antiepileptics on related topoisomerase inhibitors,
see ‘Irinotecan + Antiepileptics’, p.638 and ‘9-Aminocamptothecin + An-
tiepileptics’, p.610.

Phenytin alters the disposition of topotecan and N-desmethyl topotecan in a patient with

Topotecan + Probencid

In mice, probenecid markedly inhibited the renal tubular secre-
tion of topotecan, which led to an increase in topotecan systemic exposure.1

1. Zamboni WC, Houghton PJ, Johnson RK, Hulstein JL, Crom WR, Cheshire PJ, Hanna SK,
Richmond LB, Luo X, Stewart CL. Probencid alters topotecan systemic and renal disposition

Topotecan + Ranitidine

Ranitidine does not alter the pharmacokinetics of topotecan.

Clinical evidence, mechanism, importance and management

In 18 patients with solid tumours, the pharmacokinetics of topotecan (giv-
en in initial doses of 2.3 mg/m² daily for 5 days and repeated every 3
weeks) and its active metabolite, topotecan lactone, were not affected by
the previous use of ranitidine 150 mg twice daily for 4 days.1 No special
precautions would seem necessary if ranitidine or other drugs that increase
gastroic pH are given with oral topotecan.

does not reduce the bioavailability of orally administered topotecan. Cancer Chemother Phar-

Toremifene + Antiepileptics

Carbamazepine, phenobarbital and possibly phenytin can re-
duce the serum levels of toremifene.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study of toremifene in two groups of 10 patients (a
control group and a group of patients taking antiepileptics) found that the
AUC of a single 120-mg dose of toremifene and its half-life was approxi-
mately halved in the antiepileptic group. The antiepileptics used were car-
bamazepine alone (3 patients) or with clonazepam (3 patients), or
phenobarbital alone (3 patients) or with phenytin (1 patient). This in-
teraction is thought to occur because these antiepileptics induce the liver
enzymes (almost certainly the cytochrome P450 isoenzyme CYP3A4) by
which toremifene is metabolised, resulting in increased toremifene clear-

1. Zackrisson A-L, Malmström H, Peterson C. No evidence that amifostine influences the plasma
103–8.
Toremifene + Miscellaneou

Based on theoretical considerations, the manufacturers advise care when toremifene is given with thiazides and with CYP3A inhibitors such as erythromycin, ketoconazole, and tromethamine - cin.

Clinical evidence, mechanism, importance and management

The manufacturers of toremifene note that it is mainly metabolised by the cytochrome P450 isoenzymes CYP3A4, CYP3A5, and CYP3A6 so it is suggested that drugs that can inhibit these enzymes (such as erythromycin, ketoconazole, and tromethamine - cin) may possibly increase its effects. Hypercalcemia is a recognised adverse effect of toremifene, and it is suggested that drugs such as the thiazides, which decrease renal calcium excretion, may increase the risk of hypercalcemia. These warnings are based on indirect evidence and theoretical considerations so that their clinical importance awaits confirmation.

Toremifene + Rifampicin (Rifampin)

Rifampicin increases the metabolism of toremifene, and might be expected to reduce its efficacy.

Clinical evidence, mechanism, importance and management

A study in 9 healthy men found that rifampicin 600 mg daily for 5 days reduced the AUC, peak plasma levels, and half-life of a single 120-mg dose of toremifene by 87%, 55%, and 44%, respectively. Similarly, the AUC of 1-demethyltoremifene was reduced by 80%. Rifampicin may therefore reduce the efficacy of toremifene.

Toremifene + Antifibrinolytics

In acute promyelocytic leukaemia the combination of tretinoin and antifibrinolytics such as tranexamic acid and aprotinin has been associated with fatal thrombotic complications.

Clinical evidence, mechanism, importance and management

In an analysis of 31 patients with acute promyelocytic leukaemia (APL) treated over a 7-year period, the use of the combination of tretinoin and tranexamic acid resulted in increased plasma levels of tretinoin. It was suggested that this resulted in increased plasma levels of tretinoin. Another study has also shown that tranexamic acid may inhibit the ADP-stimulated platelet aggregation of tretinoin, and it was suggested that this resulted in increased plasma levels of tretinoin. Ketekonazole may similarly affect the pharmacokinetics of tretinoin.

Tretinoin + Azoles

The metabolism of tretinoin can be inhibited by fluconazole, and a case report describes tretinoin toxicity as a result of this interaction. Ketekonazole may interact similarly.

Clinical evidence, mechanism, importance and management

A 4-year-old boy with acute promyelocytic leukaemia was given induction chemotherapy consisting of cytarabine, daunorubicin and tretinoin 45 mg/m² daily in two divided doses. Febrile neutropenia was treated with meropenem and amphotericin B for periods up to day 20. On day 20 he started antifungal prophylaxis with fluconazole 100 mg daily. The next day he complained of headache and a week later he had headache, vomiting and papilloedema. His CT scan was normal. Pseudotumor cerebri was diagnosed and symptoms of increased intracranial pressure resolved within a day of stopping tretinoin. Restarting tretinoin on day 30 at 75% of the previous dose resulted in headache and vomiting, and the treatment was continued from day 35 with an even lower dose (30%), which caused headache but only one episode of vomiting. Fluconazole was stopped on day 41 and within 24 hours the patient had improved clinically with the headache and vomiting fully resolved. He was then able to tolerate the full dose of tretinoin without adverse effects.

Vinca alkaloids + Azoles

Itraconazole can increase the toxicity of vincristine and vinblastine; posaconazole and voriconazole may interact similarly. There is a theoretical possibility that itraconazole and ketoconazole may increase the toxicity of vinorelbine.

Clinical evidence, mechanism, importance and management

Four out of 14 patients with ALL given induction chemotherapy with weekly injections of vincristine (with prednisone, daunorubicin and asparaginase) and antifungal prophylaxis with itraconazole 400 mg daily, developed severe and early vincristine-induced neurotoxicity (parasthesia and muscle weakness of the hands and feet, paralytic ileus, mild laryngeal nerve paralysis). The degree and early onset of these neurotoxic reactions were unusual, and were less reversible except for mild parasthesia in one patient. The complications were more serious than in a previous
series of 460 patients given vincristine without itraconazole (29% compared to 6%). Five children with ALL developed severe vincristine toxicity attributed to the concurrent use of itraconazole. They were also receiving *nifedipine*, (p.671), which is known to reduce the clearance of vincristine, and which may have made things worse. Severe vincristine neurotoxicity developed in four other children and two adults with ALL when they were given itraconazole. Another study similarly indicates that greater vincristine toxicity may occur in patients given itraconazole.

The reasons for this interaction are not understood, but among the suggestions are that the *itraconazole* inhibits the metabolism of vincristine by the cytochrome P450 enzyme system, so that it is cleared from the body less quickly. Another possible explanation is that *itraconazole* inhibits P-glycoprotein, and increased vincristine neurotoxicity may be the result of the inhibition of this pump in endothelial cells of the blood-brain barrier.

The authors of one report suggest that *itraconazole* should be avoided in patients taking vincristine, and the manufacturers of vincristine also issue a warning about the increased risks of concurrent use. Acute neurotoxicity and myelotoxicity occurred in a boy with Hodgkin's lymphoma treated with vinblastine, doxorubicin and methotrexate when he was also given itraconazole. The toxicity did not occur when he was given the same chemotherapy without itraconazole. Some UK and US manufacturers advise caution if vinorelbine, which is metabolised by CYP3A4, is given with inhibitors of this isoenzyme such as *itraconazole* and * ketoconazole* because of the theoretical risk of increased neurotoxicity. The manufacturers of *vindesine* note that concurrent administration with CYP3A inhibitors may result in early onset or increased severity of vincristine side-effects.

The manufacturers of *posaconazole* advise avoidance of concurrent use with vinca alkaloids (*vincristine* and *vinblastine* are named), but if they are given, then dose adjustments of the vinca alkaloids should be considered. The manufacturers of *voriconazole* advise caution if it is given to patients treated with the vinca alkaloids (*vincristine* and *vinblastine* are named) because of the risk of neurotoxicity. The US manufacturer recommends that dose adjustments of the vinca alkaloids should be considered.

Vinca alkaloids + Macrolides

**Clinical evidence**

Three patients with renal cell carcinoma given cisplatin 10 or 13 mg/kg daily and erythromycin 1 g daily for 3 days developed severe toxicity when given *vinblastine* 7 to 10 mg/m² on the third day. Cisplatin was used as a modifier of multidrug resistance and *erythromycin* was given to achieve higher cisplatin levels at a lower dose (see ‘Cisplatin + Anti-tubercillass: Macrolides’, p.1016). To rule out increased cisplasin toxicity, one patient was given *erythromycin* without cisplatin but he still developed *vinblastine* toxicity (severe neutropenia, constipation, myositis, severe myalgia) typical of much higher doses of *vinblastine*. Of the other 2 patients, only negligible toxicity developed in one when he was later given *vinblastine* alone, and the other had received cisplatin and *vinblastine* on two previous occasions without problems. Other authors report that they have used *clarithromycin* with standard doses of vinca alkaloids in at least 6 patients without any evidence of increased toxicity.

**Mechanism**

Uncertain, but *erythromycin* inhibits the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of *vinblastine*. This would be expected to reduce the metabolism of *vinblastine* resulting in an increase in its toxicity.

**Importance and management**

Information seems to be limited to this report. On the basis of their findings the authors suggest that *erythromycin should be avoided at the time of vinblastine infusion*. Use with *clarithromycin* may be safe. The UK manufacturers of *vincristine* and *vinblastine* have warned that caution should be exercised in patients taking any drugs known to inhibit the CYP3A subfamily because of the risk of an earlier onset and/or increased severity of adverse effects. One manufacturer of *vinblastine* states that *erythromycin may increase vinblastine toxicity*. Note that *itraconazole*, another CYP3A4 inhibitor, is known to increase the toxicity of vincristine, see ‘Vinca alkaloids + Azoles’, p.668.

**Vinca alkaloids + Mitomycin**

**A syndrome of acute pulmonary toxicity, characterised by severe shortness of breath, can occur when vinblastine, vindesine or vinorelbine is given with mitomycin. Fatalities have occurred.**

**Clinical evidence, mechanism, importance and management**

There are now numerous reports describing acute lung disease in patients given mitomycin with vinca alkaloids, which appears to be different to the chronic pulmonary fibrosis seen with mitomycin alone. Sudden onset of acute shortness of breath has been described shortly after administration of the vinca alkaloid as part of a vinca alkaloid and mitomycin-containing regimen. Chest radiographs have shown diffuse lung damage characterised by interstitial infiltrates and pulmonary oedema. The acute syndrome has usually improved over 24 hours, although some patients have chronic respiratory impairment (60% in one case series). Fatalities have occurred. The syndrome has been reported with mitomycin and *vinblastine*, *vindesine*, or *vinorelbine*. The incidence is reported to be about 3 to 6%.

The potential hazards of combining these drugs should be recognised, and in view of the unpredictability of the reaction, close observation of patients receiving this combination is recommended. If the reaction occurs, supportive measures such as supplemental oxygen and mechanical ventilation may be needed. Corticosteroids are also often used in an attempt to treat the acute symptoms, and to possibly decrease the risk of chronic respiratory impairment. In patients who have developed acute pulmonary toxicity, the use of both mitomycin and vinca alkaloids should subsequently be avoided.

Vinca alkaloids; Vinblastine + Bleomycin

The combination of vinblastine and bleomycin with or without cisplatin commonly causes Raynaud’s phenomenon. Rarely, it also appears to cause serious life-threatening cardiovascular toxicity.

Clinical evidence, mechanism, importance and management

Five patients (aged 23 to 58) treated for germ cell tumours died from unexpected acute life-threatening vascular events (myocardial infarction, rectal infarction, cerebrovascular accident) after treatment with VPB (vin-
blastine, bleomycin, cisplatin). A survey of the literature by the authors of this paper revealed 14 other cases of both acute and long-term cardiovascular problems (myocardial infarction, coronary heart disease, cerebrov-
ascular accident) in patients given VPB.1

Raynaud’s phenomenon is common, occurring in one-third to half of those treated with vinblastine and bleomycin or VPB.2,3 and there is evidence that blood vessels are pathologically altered.2 Cisplatin may con-
tribute to the effect.3 Analysis of late vascular toxicity after chemotherapy for testicular cancer revealed that the use of VPB carried a higher risk of Raynaud’s phenomenon than bleomycin with etoposide and cisplatin (BEP).4

The use of the VPB (PVB) regimen has largely been replaced by the BEP (PEB) regimen, because of its reduced toxicity.

Vinca alkaloids; Vinblastine + Protease inhibitors

Severe neutropenia has been seen in two patients given vinblast-
ine and antiretroviral regimens including lopinavir/ritonavir.

Clinical evidence, mechanism, importance and management

A 55-year-old HIV-positive man who was taking zidovudine, lamivudine, abacavir, nevirapine and ritonavir-boosted lopinavir experienced unexpected severe gastrointestinal and haematological toxicities and moderate renal failure after the second and third intravenous injections of vinblas-
tine 10 mg given to treat multicentric Castleman’s disease (MCD). Subse-
quently, the antiretrovirals were stopped and the patient did not experience these toxicities when vinblastine was given alone. When the MCD was un-
der control, the antiretrovirals were then restarted, and the vinblastine dose reduced to 3 mg every three weeks without problems.1 A second HIV-pos-
itive patient who was taking a lopinavir/ritonavir-based antiretroviral regimen developed life-threatening neutropenia when given ABVD chem-
otherapy, consisting of doxorubicin, bleomycin, vinblastine and dacar-
zabase for Hodgkin’s lymphoma. Further vinblastine treatment was successfully given by interrupting the protease inhibitors around the time the chemotherapy was given.2

It was suggested that the metabolism of vinblastine by the cytochrome P450 isoenzyme CYP3A was inhibited by ritonavir, resulting in increased toxicity.

These appear to be the only cases so far of a possible interaction. Never-
theless, it would now be prudent to carefully monitor any patient taking a ritonavir-based antiretroviral regimen who receives vinblastine. Further study is needed.

Vinca alkaloids; Vincristine + Antiepileptics

Carbamazepine and phenytoin appear to reduce the plasma levels of vincristine, and may reduce its efficacy. A number of case re-
ports have described reduced phenytoin levels in patients receiving chemotheraphy including vinca alkaloids.

Clinical evidence, mechanism, importance and management

The systemic clearance of vincristine 2 mg was 63% higher and the AUC was 43% lower in 9 patients receiving carbamazepine or phenytoin than in 6 patients not taking antiepileptics. In this study, patients were being treated with procarbazine, lomustine and vincristine for brain tumours.1 In a retrospective survey, long-term antiepileptic use (phenytoin, pheno-
barbital, carbamazepine, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leu-
kaemia. The authors considered that the increased clearance of vincristine induced by the antiepileptics was a likely factor in these findings.2

These enzyme-inducing antiepileptics increase the metabolism of vinc-
ristine by the cytochrome P450 isoenzyme CYP3A4. However, in vitro studies have shown that phenytoin may potentiate the antineoplastic (anti-
mitotic) effects of the vinca alkaloids.3,4 Thus, further study is required to determine the overall effect of phenytoin on the efficacy and toxicity of vincristine and other vinca alkaloids. Carbamazepine would be ex-
pected to reduce the efficacy of vincristine.

Note that a number of case reports have described reduced phenytoin levels in patients receiving chemotherapy including vinca alkaloids, see ‘Table 14.1’, (p.519).

tiiepileptic combination therapy.17 The UK manufacturer recommends that vincristine
should be given 12 to 24 hours before asparaginase.3 Regimens in-
cluding both drugs are commonly used in treating leukaemia.

Vinca alkaloids; Vincristine + Asparaginase

An isolated case report suggests that vincristine neurotoxicity may possibly have been increased by subsequent asparaginase ther-
apy.1,2 The UK manufacturer recommends that vincristine should be given 12 to 24 hours before asparaginase.3 Regimens in-
cluding both drugs are commonly used in treating leukaemia.

2. Hildebrand J, Kenis Y. Additive toxicity of vincristine and other drugs for the peripheral nerv-
Some limited evidence suggests that vincristine neurotoxicity may possibly be increased by isoniazid.

Clinical evidence, mechanism, importance and management

An 85-year-old woman with Hodgkin’s disease was given COPP/ABVD, alternating every 28 days. She started COPP (cyclophosphamide and 2 mg vincristine on day 1, with procarbazine and prednisone days 1 to 14) and was also given isoniazid 300 mg daily as prophylaxis of tuberculosis. Five days after the start of this treatment she experienced tingling in her fingers and weakness in her legs, which was interpreted by the authors of this report as being vincristine toxicity brought about by the concurrent use of isoniazid (paraesthesia of the feet and/or hands being a recognised early manifestation of vincristine toxicity). Their reasoning was that such a small dosage of vincristine dosage on its own was unlikely to cause severe neurotoxicity of this kind, but it is not clear why isoniazid should apparently interact like this. The authors suggest that the age of this patient and her diabetes (well controlled) may have contributed to this increase in vincristine neurotoxicity.

This report is consistent with another much earlier report of two patients who also developed peripheral neurotoxicity when they were given vincristine after starting to take isoniazid and pyridoxine, the cumulative doses of vincristine being 11 mg and 11.2 mg, respectively, and of a case of severe neurotoxicity with an overdose of isoniazid and high-dose vincristine.

Nifedipine reduces the clearance of vincristine.

Clinical evidence, mechanism, importance and management

In a study in 12 patients nifedipine reduced the clearance of a single 2-mg intravenous dose of vincristine by 68%, and increased the AUC threefold, when compared with 14 patients receiving vincristine alone. Nifedipine was given at a dose of 10 mg three times daily for 3 days before and 7 days after vincristine was given. However, no important adverse effects were noted in either group of patients, suggesting that these pharmacokinetic changes did not markedly increase vincristine toxicity.

Further study is needed. Note that increased vincristine-related neurotoxicity has been seen in a child taking nifedipine and itraconazole (see “Vinca alkaloids + Azoles”, p.668).

Antiparkinsonian and related drugs

The drugs in this section are considered together because their major therapeutic application is in the treatment of Parkinson’s disease, although some of the related antimuscarinic (anticholinergic) drugs included here are also used for other conditions. Parkinson’s disease is named after Dr James Parkinson who originally described the four main signs of the disease, namely rigidity, tremor, dystonias and dyskinesias (movement disorders). Similar symptoms may also be displayed as the unwanted adverse effects of therapy with certain drugs.

The basic cause of the disease lies in the basal ganglia of the brain, particularly the striatum and the substantia nigra, where the normal balance between dopaminergic nerve fibres (those that use dopamine as the chemical transmitter) and cholinergic nerve fibres (those that use acetylcholine as the transmitter) is lost, because the dopaminergic fibres degenerate. As a result the cholinergic fibres end up in relative excess. Much of the treatment of Parkinson’s disease is based on an attempt to redress the balance, and there are several groups of drugs that can be used to this end. These are listed in ‘Table 18.1’, (below), and discussed below.

**Levodopa**

Levodopa can pass the blood-brain barrier (unlike dopamine), where it is converted into dopamine, and thus acts by ‘topping up’ the CNS dopaminergic system. Levodopa is most usually given with carbidopa or benzerazide (dopa-decarboxylase inhibitors), which prevent the ‘wasteful’ peripheral metabolism of levodopa. This allows lower doses of levodopa to be given, which results in fewer adverse effects.

**Amantadine (and memantine)**

These drugs may augment dopaminergic activity in the brain.

**Dopamine agonists**

Bromocriptine, cabergoline, pergolide, ropinirole and similar drugs act as dopamine agonists and so also have the effect of increasing dopaminergic activity in the brain.

**Entacapone and tolcapone**

The catechol-O-methyltransferase (COMT) inhibitors work by inhibiting the peripheral metabolism of levodopa by COMT. Note that this enzyme is the major metabolising enzyme for levodopa when a decarboxylase inhibitor (e.g. benzerazide) is being used.

**Rasagiline and seleagine**

The selective irreversible MAO-B inhibitors enhance dopamine activity by preventing dopamine degradation. These drugs sometimes interact like older non-selective MAOIs, and the reader is cross-referred to the information under MAOIs when appropriate. Selegiline undergoes rapid first-pass metabolism to produce amfetamine metabolites. A buccal tablet has been developed, which markedly reduces this first-pass metabolism, and is consequently given as a smaller dose.

**Antimuscarinics**

Benzhexol, orphenadrine, procyclidine and other antimuscarinic (anticholinergic) drugs work by correcting the relative cholinergic excess.

The interactions that affect the antimuscarinic effects of these drugs are discussed in this section. However, the antimuscarinics also affect the actions of other drugs (such as the centrally-acting anticholinesterases) and these are therefore discussed elsewhere in the publication.

</table>
An interaction between amantadine and co-trimoxazole is thought to have caused acute confusion in an elderly man and amantadine toxicity in a patient with end-stage renal disease. However, in both cases other factors could have been responsible for the adverse reactions.

Clinical evidence, mechanism, importance and management

A 49-year-old woman was taking amantadine 200 mg daily, haloperidol 5 mg daily and flurazepam 30 mg at night was given phenelzine 15 mg twice daily for depression. Within 72 hours her blood pressure rose from 140/90 to 160/110 mmHg. The phenelzine was withdrawn, and 24 hours later, the amantadine and haloperidol were withdrawn. The blood pressure remained elevated for a further 72 hours. In contrast, a woman is reported to have been successfully and uneventfully treated with amantadine 200 mg daily for Parkinson’s disease and phenelzine 45 mg daily for depression.

The first case appears to be the only reported interaction with amantadine. Its general importance is uncertain, but bear it in mind in case of an unusual response to treatment.

One manufacturer of selegiline states that concurrent use of amantadine can increase the occurrence of adverse effects (e.g. dizziness, tremor, orthostatic hypotension).

Amantadine + Phenytoin

A 27-year-old woman was taking amantadine 100 mg twice daily and phenytoin 200 mg daily for epilepsy. Within 7 to 8 days of starting amantadine the patient became mentally confused, incoherent and combative. He also showed cogwheel rigidity and a resting tremor. Within 24 hours of stopping the amantadine and co-trimoxazole, the patient’s mental status returned to normal. The reasons for this reaction are not understood, but on the basis of animal studies, the authors suggest that the trimethoprim component of the co-trimoxazole may have competed with the amantadine for renal secretion. This resulted in an accumulation of amantadine and led to the adverse effects seen. This interaction is more likely in the elderly because ageing results in a decrease in the clearance of these and many other drugs. However, it should be noted that both drugs can cause some mental confusion, and also that mental confusion is not an uncommon symptom of infection in the elderly. Another case of amantadine toxicity has been reported in a 27-year-old woman with end-stage renal disease who was also taking co-trimoxazole. As in the other case the authors suggest that the trimethoprim component of the co-trimoxazole may have competed with the amantadine for renal secretion. However, they also note that amantadine toxicity occurred 5 days after the amantadine dose was increased, and during an episode of acute renal failure, which could both account for the toxicity. These seem to be the only reports of a possible interaction, so the general importance of this interaction remains uncertain.

Amantadine + Phenylpropanolamine

The use of amantadine in a patient also taking phenylpropanolamine resulted in psychosis, and concurrent use in another patient resulted in intense and recurrent déjà vu experiences.

Clinical evidence, mechanism, importance and management

A case report describes the development of severe psychosis in a woman within 7 to 8 days of taking amantadine 100 mg and phenylpropanolamine 80 mg daily. The reasons are not known, but both drugs alone, and in high doses sometimes cause psychosis, and concurrent use may enhance this effect. Another report describes intense and recurrent déjà vu experiences in a 39-year-old man taking amantadine 100 mg twice daily and phenylpropanolamine 25 mg twice daily during a viral infection. These experiences stopped the day he discontinued the drugs. He had previously taken phenylpropanolamine without this effect. The authors considered the déjà vu experiences to be related to increased dopamine activity caused by both drugs.

Concurrent use need not be avoided, but remain aware of the potential for this interaction.

Amantadine + Valproate

An isolated report describes a rise in blood pressure in a patient on amantadine within 72 hours of taking phenelzine. One manu-
Nevertheless, be aware that amantadine toxicity (e.g. headache, nausea, or dizziness) could possibly result from the concurrent use of quinidine or quinidine.

### Antimuscarinics + Tobacco

Amantadine clearance was not altered by tobacco smoking in one study.

### Clinical evidence, mechanism, importance and management

The elimination of a single 3-mg/kg dose of amantadine was compared between heavy smokers (20 or more cigarettes daily) and non-smokers. Although a higher apparent volume of distribution was noted in the heavy smokers, renal and plasma clearances were unchanged, suggesting that no interaction of note occurs.1

### Antimuscarinics + Antimuscarinics

Additive antimuscarinic effects, both peripheral and central, can develop if two or more drugs with antimuscarinic effects are used together. The outcome may be harmful.

### Clinical evidence, mechanism, importance and management

The antimuscarinic (sometimes called anticholinergic) effects of some drugs are exploited therapeutically. These include antimuscarinic bronchodilators, gastrointestinal antispasmodics, mydriatics, urological antimuscarinics, and drugs such as trihexyphenidyl and benzatropine (see ‘Table 18.1’, (p.672)), which are used for the control of parkinsonian symptoms. Other drugs, such as some antiemetics, sedating antihistamines, antipsychotics, and tricyclic antidepressants, (see ‘Table 18.2’, (below)), may also possess some antimuscarinic effects that are unwanted and troublesome, but usually not serious, unless they are worsened by the addition of another drug with similar properties.

The easily recognised and common peripheral antimuscarinic effects are blurred vision, dry mouth, constipation, difficulty in urination, reduced sweating and tachycardia. Central effects include confusion, disorientation, visual hallucinations, agitation, irritability, delirium, memory problems, belligerence and even aggressiveness. Problems are most likely to arise in patients with particular physical conditions such as glaucoma, prostatic hypertrophy or constipation, in whom antimuscarinic drugs should be used with caution, if at all. It has been pointed out that the antimuscarinic adverse effects can mimic the effects of normal ageing.

‘Table 18.1’, (p.672) and ‘Table 18.2’, (below) list many of the drugs with antimuscarinic effects, which may be expected to be additive if used together, but apart from some reports describing life-threatening reactions (see ‘Antipsychotics + Antimuscarinics’, p.708) there are very few reports describing this simple additive interaction, probably because the outcome is so obvious. Many of these interactions are therefore ‘theoretical’ but their probability is high.

Some drugs with only minimal antimuscarinic properties sometimes cause difficulties if given with other antimuscarinics. A patient taking isopropamide iodide developed urinary retention needing catheterisation, only when trazadone 75 mg daily was also taken, but not when either drug was taken alone.1 Trazadone is usually regarded as having minimal antimuscarinic effects. Another case describes acute psychosis in an elderly woman taking hyoscine and meclozine, both of which have antimuscarinic effects.2

If the central antimuscarinic effects caused by the use of antimuscarinic drugs are not clearly recognised for what they are, there is the risk that antipsychotics may be prescribed to treat them. Many antipsychotics also have antimuscarinic adverse effects so that matters are simply made worse. If the patient then demonstrates dystonias, akathisia, tremor and rigidity, even more antimuscarinics may be added to control the extrapyramidal effects, which merely adds to the continuing downward cycle of drug-induced problems.

In addition to the obvious and very well recognised drugs with antimuscarinic effects, a study of the 25 drugs most commonly prescribed for the elderly identified detectable antimuscarinic activity (using an antimuscarinic radioreceptor assay) in 14 of them, 9 of which (codeine, digoxin, dipryidamole, isosorbide dinitrate, nifedipine, prazosin, ranitidine, theophylline, and warfarin) produced levels of antimuscarinic activity that have been shown to cause significant impairment in tests of memory and attention in the elderly.3 Thus the problem may not necessarily be confined to those drugs that have well recognised antimuscarinic properties.

### Antimuscarinics + Areca (Betel nuts)

The control of the extrapyramidal (parkinsonian) adverse effects of fluphenazine and flupenthixol with procyclidine was lost in two patients when they began to chew areca.

### Clinical evidence

An Indian patient receiving depot fluphenazine (50 mg every three weeks) for schizophrenia, and with mild parkinsonian tremor controlled with procyclidine 5 mg twice daily, developed marked rigidity, bradykinesia and jaw tremor when he began to chew areca. The symptoms were so severe he could barely speak. When he stopped chewing areca his stiffness and abnormal movements disappeared. Another patient receiving depot flupenthixol developed marked stiffness, tremor and akathisia, despite taking

After Barkin RL, Stein ZLG. South Med J (1989) 82, 1547, and others. The categorization is not exclusive; some of these drugs are used for a range of effects. There are many other antimuscarinic drugs.
up to 20 mg of procyclidine daily, when he began to chew areca. The symptoms vanished within 4 days of stopping the areca.1

Mechanism
Areca contains arecoline, an alkaloid with cholinergic activity, which could therefore oppose the antimuscarinic (anticholinergic) actions of procyclidine. As the procyclidine was being used to control the extrapyramidal adverse effects of the two antipsychotics, opposing its action allowed the adverse effects to re-emerge and worsen.

Importance and management
Direct information seems to be limited to this report but the interaction would seem to be established and clinically important. Patients taking antimuscarinic drugs for the control of drug-induced extrapyramidal (parkinsonian) adverse effects, or Parkinson’s disease, should avoid areca. The authors of this report suggest that a dental inspection for the characteristic red stains of the areca may possibly provide a simple explanation for the sudden and otherwise mysterious deterioration in the symptoms of patients. Betel is traditionally chewed by those from the continent of Asia, and the East Indies. Symptoms seem to develop over a period of 2 weeks, and resolve fairly rapidly (within a week).

Antimuscarinics + SSRIs
Eight patients developed delirium when given fluoxetine, paroxetine or sertraline with benzatropine, in the presence of an antipsychotic (usually perphenazine or haloperidol). Other patients taking the combination remained symptom free.

Clinical evidence, mechanism, importance and management
Five patients became confused and developed delirium when given an antipsychotic, an SSRI (4 taking fluoxetine and one taking paroxetine) and benzatropine. No peripheral antimuscarinic toxicity was seen. The delirium developed within 2 days in two cases, but took several weeks to appear in another. The authors of this report attributed this to an interaction between the SSRIs and benzatropine, speculating that the SSRIs may have inhibited the metabolism of the benzatropine thereby increasing its toxicity. Alternatively they suggest a possible additive central antimuscarinic effect. They also very briefly mention two other patients who became delirious when given an unnamed antipsychotic and either sertraline or paroxetine with benzatropine.1 It is noteworthy that 4 of the first group of patients were given perphenazine and one haloperidol,1 both of which have been involved in additive antimuscarinic interactions (see ‘Antipsychotics + Antimuscarinics’, p.708). Also note that adverse interactions have been reported with the use of ‘antipsyhtics and SSRIs’, (p.712). Another case describes delirium in a 17-year-old boy,8 interactions have been reported with the use of ‘antipsychotics and antimuscarinic drugs for the control of drug-induced extrapyramidal (parkinsonian) adverse effects, or Parkinson’s disease, should avoid areca. The authors of this report suggest that a dental inspection for the characteristic red stains of the areca may possibly provide a simple explanation for the sudden and otherwise mysterious deterioration in the symptoms of patients. Betel is traditionally chewed by those from the continent of Asia, and the East Indies. Symptoms seem to develop over a period of 2 weeks, and resolve fairly rapidly (within a week).

Apomorphine + Antihypertensives
The hypotensive adverse effects of apomorphine may possibly be increased by nitrates, calcium-channel blockers and alpha blockers. There is some evidence that ACE inhibitors, beta blockers and diuretics do not increase the risk of hypotension. Nevertheless, caution is advised with all antihypertensives, and patients should be told about the symptoms of orthostatic hypotension and what to do should they occur.

Clinical evidence
(a) ACE inhibitors
A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 25 patients taking ACE inhibitors [not specifically named]. One patient experienced symptomatic hypotension.1

(b) Alpha blockers
A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 24 patients taking alpha blockers [not specifically named] when compared with placebo (decrease in systolic BP of 23 versus 13 mmHg at 40 minutes post dose).1 One patient experienced symptomatic hypotension.1

(c) Beta blockers
A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 26 patients taking beta blockers [not specifically named]. One patient experienced syncope and one had symptomatic hypotension.1

(d) Calcium-channel blockers
A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 26 patients taking calcium-channel blockers [not specifically named] when compared with placebo (decrease in systolic BP of 17 versus 11 mmHg at 20 minutes post dose).1

(e) Diuretics
A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 21 patients taking diuretics [not specifically named]. One patient experienced symptomatic hypotension.1

(f) Nitrates
1. Short-acting. A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 20 patients taking short-acting nitrates. The apomorphine was given 30 minutes before the patient took their short-acting nitrate. Two patients experienced symptomatic hypotension after their sublingual glyceryl trinitrate.1

2. Long-acting. A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 20 patients taking long-acting nitrates when compared with placebo (decrease in systolic BP of 12 versus 6 mmHg at 50 minutes post dose). Two patients experienced symptomatic hypotension.1

Mechanism
Apomorphine alone may cause postural hypotension, and this is potentially additive with the effects of vasoactive antihypertensives and nitrates.

Importance and management
A potentially clinically relevant interaction resulting in orthostatic hypotension may occur when sublingual apomorphine is given to patients on calcium channel blockers or alpha blockers. Similarly symptomatic hypotension on standing may be more common in patients taking nitrates. Note that the 5-mg dose used in the study was slightly higher than the recommended 2- to 3-mg sublingual dose commonly used for erectile dysfunction. All the patients who had symptomatic hypotension experienced a prodrug of symptoms such as nausea, dizziness, pallor, and/or sweating.1 On the basis of this study the manufacturers suggest caution in patients on antihypertensives and particularly nitrates, which in practice means telling patients what may possibly happen and what to do if adverse effects occur (i.e. do not attempt to stand up, but lie down and raise their
legs until the symptoms resolve). Note that the cardiovascular conditions contraindicating or cautioning either the use of sublingual apomorphine for erectile dysfunction or subcutaneous apomorphine in Parkinsonism should be observed.1,2,3

### Apomorphine + COMT inhibitors

**Entacapone** had no effect on the pharmacokinetics or efficacy of apomorphine in a single-dose study. Similarly, tolcapone had no relevant effect on single-dose apomorphine.

#### Clinical evidence

**Entacapone**

In a placebo-controlled crossover study in 24 patients with Parkinson’s disease a single dose of entacapone 200 mg or 400 mg given 30 minutes before a subcutaneous injection of apomorphine had no effect on the pharmacokinetics of apomorphine. In addition, entacapone had no effect on measures of apomorphine efficacy (tapping test and incidence of dyskinesias).1

**Tolcapone**

Tolcapone 200 mg three times daily for 5 days then 200 mg one hour before sublingual apomorphine 40 mg caused a non-significant increase in the AUC of apomorphine of about 13% in 5 patients with Parkinson’s disease.2

#### Mechanism

*In vitro* and *animal* data suggested that the enzyme catechol-O-methyl transferase (COMT) is involved in the metabolism of apomorphine1 and that COMT inhibitors might increase apomorphine bioavailability. However, the single dose studies above suggest that this metabolic pathway for apomorphine may not be important in humans.

#### Importance and management

The evidence from these single-dose studies suggest that there is no pharmacokinetic interaction between entacapone or tolcapone and apomorphine, and that the drugs can be used together without alteration of the dopamine function, and domperidone is the recommended antiemetic when apomorphine is used for erectile dysfunction, and domperidone is the recommended antiemetic when apomorphine is used for Parkinson’s disease. There is evidence that antidepressants, antiepileptics, and ondansetron do not interact adversely.

### Apomorphine + COMT inhibitors

**Entacapone** had no effect on the pharmacokinetics or efficacy of apomorphine in a single-dose study. Similarly, tolcapone had no relevant effect on single-dose apomorphine.

#### Clinical evidence

**Entacapone**

In a placebo-controlled crossover study in 24 patients with Parkinson’s disease a single dose of entacapone 200 mg or 400 mg given 30 minutes before a subcutaneous injection of apomorphine had no effect on the pharmacokinetics of apomorphine. In addition, entacapone had no effect on measures of apomorphine efficacy (tapping test and incidence of dyskinesias).1

**Tolcapone**

Tolcapone 200 mg three times daily for 5 days then 200 mg one hour before sublingual apomorphine 40 mg caused a non-significant increase in the AUC of apomorphine of about 13% in 5 patients with Parkinson’s disease.2

#### Mechanism

*In vitro* and *animal* data suggested that the enzyme catechol-O-methyl transferase (COMT) is involved in the metabolism of apomorphine1 and that COMT inhibitors might increase apomorphine bioavailability. However, the single dose studies above suggest that this metabolic pathway for apomorphine may not be important in humans.

#### Importance and management

The evidence from these single-dose studies suggest that there is no pharmacokinetic interaction between entacapone or tolcapone and apomorphine, and that the drugs can be used together without alteration of the apomorphine dose. However, further data are required from longer-term studies, as is recommended by the manufacturers.4-6

2. Ondo WG, Hunter C, Vuong KD, Jankovic VJ. The pharmacokinetic and clinical effects of tolcapone when they were taking a combined oral contraceptive (ethinylestradiol 30 micrograms, levonorgestrel 150 or 250 micrograms). The clinical importance of this is uncertain.1

### Apomorphine + Miscellaneous

The hypotensive adverse effects of apomorphine may possibly be increased by alcohol. The concurrent use of other drugs used for erectile dysfunction or dopamine agonists or antagonists is not recommended. However, domperidone, and prochlorperazine are said not to interact when apomorphine is used for erectile dysfunction, and domperidone is the recommended antiemetic when apomorphine is used for Parkinson’s disease. There is evidence that antidepressants, antiepileptics, and ondansetron do not interact adversely.

#### Clinical evidence, mechanism, importance and management

**Alcohol**

The manufacturers say that interaction studies in subjects given apomorphine (for erectile dysfunction) found that alcohol increased the incidence and extent of hypotension (one of the adverse effects of apomorphine). They also point out that alcohol can diminish sexual performance.1

**Antidepressants**

The manufacturers say that no studies about interactions between apomorphine and antidepressants have been undertaken, but clinical experience in erectile dysfunction suggests that no interaction occurs.1

**Antiepileptics**

The manufacturers say that no studies about interactions between apomorphine and antiepileptics have been undertaken, but clinical experience in erectile dysfunction suggests that no interaction occurs.1

#### Other dopamine antagonists

The manufacturers say that apomorphine should not be given with centrally-acting dopamine antagonists1 because potentially they may antagonise the effects of apomorphine. Such drugs would include some antipsychotics. Some manufacturers recommend that if neuroleptics are necessary in patients with Parkinson’s disease receiving dopamine agonists, the dopamine agonist should be progressively reduced (and then stopped), as sudden withdrawal may cause neuroleptic malignant syndrome.2-4

The manufacturer of APO-go specifically notes that there is a potential interaction between clozapine and apomorphine, although they say that clozapine may also be used to reduce the symptoms of neuropsychiatric complications of Parkinson’s disease.2 See also prochlorperazine in (c) above, and ‘Levodopa + Antipsychotics’, p.683.

1. Other dopamine agonists

The manufacturers say that apomorphine should not be given with other centrally-acting dopamine agonists.1 See ‘Table 18.1’, (p.672) for a list of these drugs.

**Other drugs used for erectile dysfunction**

The manufacturers say that no formal studies have been done with a combination of apomorphine and other drugs used for erectile dysfunction but...
there seems to be no evidence of problems, nevertheless they do not recommend concurrent use. Other drugs used for this condition include alprostadil, mosixylyte, papaverine, phenolamine, and the phosphodiesterase inhibitors such as sildenafil.

**Bromocriptine and other dopamine agonists + Antiemetics**

Domperidone and metoclopramide would be expected to reduce the prolactin-lowering effect of bromocriptine. Metoclopramide, but not domperidone, would be expected to reduce the effect of any dopamine agonist.

**Clinical evidence, mechanism, importance and management**

(a) *Antiemetic effect*

Dopamine agonists frequently cause nausea and vomiting on starting treatment. The manufacturers of bromocriptine, lisuride, and pergolide state that if necessary this may be reduced by taking a peripheral dopamine antagonist such as domperidone. Metoclopramide is not considered a suitable antiemetic for use in Parkinson’s disease because it crosses the blood brain barrier and has central dopamine antagonist effects, and may therefore reduce the efficacy of dopamine agonists in this condition, see also ‘Levodopa + Antiemetics’, p.682. The manufacturers of cabergoline, ropinirole, and rotigotine advise against the use of metoclopramide for this reason.

(b) *Prolactin-lowering effect*

Both domperidone and metoclopramide are dopamine antagonists and can raise prolactin levels, sometimes causing galactorrhea, gynaecomastia or mastalgia. They would therefore be expected to reduce the prolactin-lowering effect of bromocriptine. However, an early study in 10 patients with Parkinson’s disease given single doses of bromocriptine 12.5 to 100 mg found that pretreatment with a single 60-mg dose of metoclopramide had no consistent effect on plasma bromocriptine levels or on the clinical or hormonal response although this does not seem to have been studied in a multiple dose study. Nevertheless, it would be prudent to monitor the efficacy of bromocriptine if domperidone or metoclopramide are required.

**Bromocriptine and other dopamine agonists + Ergot derivatives**

Because cabergoline is an ergot derivative, the manufacturers have looked at what happens if other ergot derivatives are used concurrently, but have so far found no evidence of changes in the efficacy or safety of cabergoline. Nevertheless they do not recommend concurrent use. Similarly, the manufacturers of bromocriptine do not recommend concurrent use of other ergot derivatives.

**Bromocriptine and other dopamine agonists + Food**

Food did not alter the pharmacokinetics of bromocriptine, cabergoline or lisuride. These dopamine agonists are usually taken with food to try and improve their tolerability.

**Clinical evidence**

(a) *Bromocriptine*

Taking a single dose of bromocriptine 7.5 mg after breakfast did not alter the bromocriptine AUC compared with the fasted state, although it slightly reduced the maximum plasma level in a study in 7 healthy subjects.

(b) *Cabergoline*

The pharmacokinetics of cabergoline did not change when a single dose of cabergoline 1 mg was taken after breakfast compared with the fasting state in a study in healthy subjects.

(c) *Lisuride*

Thirty healthy subjects were given lisuride 200 micrograms orally while fasting or with food. It was found that food did not significantly modify either the pharmacokinetics or the pharmacodynamics of the lisuride.

**Bromocriptine and other dopamine agonists + Antipsychotics**

Some antipsychotics have dopamine antagonist actions, which would be expected to inhibit the efficacy of dopamine agonists such as bromocriptine. Careful monitoring is required if combined use is considered necessary.

**Clinical evidence, mechanism, importance and management**

Many antipsychotics have dopamine antagonist properties and can cause movement disorders (extrapyramidal effects). For this reason, these drugs can reduce the efficacy of dopamine agonists used in Parkinson’s disease, and exacerbate the disorder. This interaction is well established for levo-dopa: see ‘Antipsychotics’, (p.683), which discusses the relative tendency for various classical and atypical antipsychotics to cause this effect. It would equally well be anticipated for any dopamine agonist. Therefore, the manufacturers of bromocriptine, cabergoline, lisuride, pergolide, pramipexole, ropinirole and rotigotine all caution against concurrent use with dopamine antagonist antipsychotics. If an antipsychotic is required for psychosis in Parkinson’s disease, the risk-benefit ratio should be carefully assessed, and an antipsychotic chosen that has a lower risk of extrapyramidal effects such as an atypical antipsychotic. Similarly, the prolactin-lowering effects of bromocriptine, cabergoline and quinagolide are expected to be reduced by dopamine antagonist antipsychotics. Dopamine agonists may also lessen some of the effects of antipsychotics: for a case of reduced efficacy see ‘Antipsychotics + Bromocriptine’, p.710.

Mechanism

None.

Importance and management

Food had no effect on the pharmacokinetics of the ergot dopamine agonists studied, and as rotigotine is given transdermally, food is not expected to affect its pharmacokinetics. The manufacturers of bromocriptine, cabergoline and lisuride recommend that they are taken with food. They commonly cause nausea and vomiting, especially on starting therapy, and taking them with food may improve tolerability. They commonly cause nausea and vomiting, especially on starting therapy, and taking them with food may improve tolerability.

Bromocriptine + Griseofulvin

Evidence from a single patient, who was taking bromocriptine for acromegaly, suggests that its effects can be opposed by griseofulvin.

Clinical evidence, mechanism, importance and management

In a study of the effects of bromocriptine used for the treatment of acromegaly, one patient who initially had a good response to bromocriptine developed resistance to the drug. After a number of months it was found that this patient had subsequently been given griseofulvin 500 mg daily for the treatment of a fungal nail infection. When the griseofulvin was stopped, the bromocriptine was again effective. The mechanism of this interaction and its general importance are unknown, but prescribers should be aware of it when treating patients with bromocriptine.

Bromocriptine and other dopamine agonists + Macrolides

Erythromycin markedly increases bromocriptine plasma levels, and a case of toxicity has been reported. Bromocriptine toxicity also occurred in a patient given josamycin. Clarithromycin increases cabergoline levels, and erythromycin would be expected to interact similarly. Erythromycin had no effect on lisuride levels.

Clinical evidence

(a) Bromocriptine

1. Erythromycin. Erythromycin estolate 250 mg four times daily for 4 days increased the peak plasma levels and the AUC of a single 5-mg oral dose of bromocriptine by about 360% and 268%, respectively, in 5 healthy subjects. Another report describes 2 women taking levodopa/carbidopa and bromocriptine for parkinsonism in whom the disease was better controlled when erythromycin was added. Bromocriptine plasma levels were found to be 40 to 50% higher while they were taking erythromycin. An elderly woman taking levodopa and bromocriptine 15 mg developed psychotic symptoms when she took erythromycin, which were attributed to bromocriptine toxicity.

2. Josamycin. An elderly man with Parkinson’s disease, well-controlled for 10 months with daily levodopa/benserazide, bromocriptine 70 mg and domperidone, was additionally given josamycin 2 g daily for a respiratory infection. Shortly after the first dose he became drowsy with visual hallucinations, and began to show involuntary movements of his limbs, similar to the dystonic and dyskinetic movements seen in choreoathetosis. These adverse effects (interpreted as bromocriptine toxicity) disappeared within a few days of withdrawing the josamycin.

(b) Cabergoline

The concurrent use of cabergoline 1 mg daily and clarithromycin 400 mg daily significantly increased the AUC of cabergoline by 163% and increased the maximum level by 176% in healthy subjects. Preliminary results from a study in patients with Parkinson’s disease also showed that clarithromycin increased the bioavailability of cabergoline by about 2 to 4-fold.

(c) Lisuride

Twelve healthy subjects were given lisuride 200 micrograms orally or 50 micrograms as a 30 minute intravenous infusion after taking erythromycin [dose unknown] twice daily for 4 days. Preliminary results showed that erythromycin did not significantly modify either the pharmacokinetics or the pharmacodynamics of the lisuride.

Mechanism

The ergot dopamine agonists bromocriptine and cabergoline undergo extensive metabolism, most likely by the cytochrome P450 isoenzyme CYP3A4. Erythromycin and clarithromycin (and potentially other macrolides, with the exception of azithromycin) inhibit this metabolism, thus significantly elevating bromocriptine and cabergoline plasma levels.

Importance and management

Information seems to be limited to these reports, but the pharmacokinetic interaction would appear to be established. Concurrent use should be well monitored if any of these macrolides (clarithromycin, erythromycin, josamycin) is added to bromocriptine or cabergoline treatment. Note that azithromycin does not normally cause enzyme inhibition and so may not interact. Moderately increased levels may be therapeutically advantageous, but grossly elevated levels can be toxic. The authors of one report suggest reducing the bromocriptine dose, while in another case the dose was reduced by 50% to avoid toxicity. Preliminary data suggest that dosage adjustments are not needed if lisuride is given with erythromycin.

4. Montastruc JL, Rascol A. Traitement de la maladie de Parkinson par doses élevées de bromocriptine + Proton pump inhibitors

Bromocriptine + Octreotide

Octreotide modestly increases the bioavailability of bromocriptine, whereas bromocriptine does not appear to alter octreotide pharmacokinetics.

Clinical evidence, mechanism, importance and management

The combined use of bromocriptine 5 mg twice daily and subcutaneous octreotide 200 micrograms twice daily increased the bioavailability of bromocriptine by about 40%, without altering its clearance or half-life. The pharmacokinetics of octreotide were unchanged. This effect may contribute to the increased efficacy of combined treatment in acromegaly shown in some studies. Bear it in mind when considering combined therapy.

Bromocriptine + Proton pump inhibitors

A single case describes worsening mobility, which was attributed to an interaction between lansoprazole and bromocriptine.
same patient later received bromocriptine and omeprazole without problems.

Clinical evidence, mechanism, importance and management

A 73-year-old man taking levodopa/benserazide and bromocriptine for Parkinson’s disease was given lansoprazole 15 mg daily to treat reflux oesophagitis. Two days later, the patient exhibited akinesia (more motor difficulties and slowness in movements) associated with frequent falls. Lansoprazole was discontinued, with disappearance of the symptoms the day after. About 3 months later the patient was prescribed omeprazole 20 mg daily, which caused no aggravation of Parkinson’s disease over the following 6 months.

The authors attribute this case to a possible interaction between lansoprazole and bromocriptine, although any mechanism is unclear, especially as omeprazole was given without problems.

This single unexplained case seems unlikely to be of clinical significance.

Bromocriptine + Sympathomimetics

A healthy postpartum woman taking bromocriptine developed very severe headache and marked hypertension after also taking phenylpropanolamine. Similarly another woman developed seizures with cerebral vasospasm, and a third developed a severe headache, hypertension and severe cardiac dysfunction after also taking isometheptene. A fourth patient taking bromocriptine developed psychosis when pseudoephedrine was added.

Clinical evidence

Two healthy women who had given birth 3 to 4 days previously, developed severe headaches while taking bromocriptine 2.5 mg twice daily for milk suppression. After additionally taking three 65-mg doses of isometheptene mucate, the headache of one of them markedly worsened, and hypertension with life-threatening ventricular tachycardia and cardiac dysfunction developed. The other woman took two 75-mg doses of phenylpropanolamine, and developed grand mal seizures and cerebral vasospasm.

A 32-year-old woman took two 5-mg doses of bromocriptine for milk suppression without any adverse effects following the birth of a child. Within 2 hours of taking a third dose with phenylpropanolamine 50 mg she awoke with a very severe headache and was found to have a blood pressure of 240/140 mmHg. She was given 5 mg of intramuscular morphine and her blood pressure became normal within 24 hours. Another 5-mg dose of bromocriptine taken 48 hours after the original dose of phenylpropanolamine had the same effect, but the blood pressure rise was less severe (160/120 mmHg).2

A woman who had recently given birth and who had taken bromocriptine 2.5 mg twice daily for 9 days without problems became psychotic shortly after starting to take pseudoephedrine 60 mg four times daily.3

Mechanism

Not understood. Severe hypertension occasionally occurs with either bromocriptine or phenylpropanolamine given alone. Shortly after giving birth some individuals show increased vascular reactivity, and it could be that all of these factors conspired together to cause these adverse effects.2 Psychosis occasionally occurs after giving birth or on bromocriptine alone, so that in the latter case the addition of pseudoephedrine may have been coincidental.3

Importance and management

Although evidence is limited, this interaction would be predicted on the basis of the known pharmacokinetics of cabergoline. It would be prudent to monitor toxicity and efficacy in any patient on cabergoline requiring itraconazole, or similar potent inhibitors of CYP3A4 (see ‘Bromocriptine and other dopamine agonists + Macrolides’, p.678). Itraconazole is a potent inhibitor of this isoenzyme, and would therefore be expected to increase cabergoline levels.

COMT inhibitors + MAOIs

In a single dose study, there was no adverse effect on heart rate or blood pressure when entacapone was given with moclobemide (a RIMA), but caution is recommended until further clinical experience is gained. The COMT inhibitors may be used with the MAO-B inhibitors (such as selegiline). However, the manufacturers of entacapone and tolcapone contraindicate concurrent use of non-selective MAOIs or a combination of both a RIMA and a MAO-B inhibitor.

Clinical evidence

In a single-dose, placebo-controlled study, moclobemide 150 mg did not change the heart rate or blood pressure at rest or during exercise, when given entacapone 200 mg, compared with either drug alone or placebo. In addition, the plasma concentrations of endogenous noradrenaline (norepinephrine) and adrenaline (epinephrine) were not altered.1

Mechanism

Monoamine oxidase and COMT are the two major enzyme systems involved in the metabolism of catecholamines. Therefore it is theoretically...
possible that the combination of a COMT inhibitor and a non-selective MAOI would result in inhibition of the normal metabolism of catecholamines, with an increase in their effects (e.g. hypertension). Using an MAO-B inhibitor with a RIMA is similar to giving a non-selective MAOI and therefore using these two drugs with a COMT inhibitor would also be likely to inhibit the normal metabolism of catecholamines.

Importance and management

The results of the single-dose study of entacapone and the RIMA moclobemide suggest that no adverse haemodynamic interaction occurs. Nevertheless, this finding needs confirmation in a clinical setting. Until further information is available, caution would be advisable on combined use. The manufacturers of entacapone and tolcapone contraindicate or advise against the use of non-selective MAOIs (e.g. phenelzine, tranylcypromine) and combinations of both a RIMA (e.g. moclobemide) plus an MAO-B inhibitor, such as selegiline. Nevertheless, they state that selegiline alone is compatible with the COMT inhibitors provided not more than 10 mg daily is used. At this dose, selegiline is likely to remain selective for MAO-B.

Clinical evidence

The maximal increase in heart rate during an infusion of adrenaline (epinephrine) was about 80% greater (25 versus 14 bpm) after pretreatment with a single 400-mg dose of entacapone in a study in healthy subjects. Similarly, the maximal increase in heart rate during an infusion of isoproterenol was about 50% greater (40 versus 27 bpm) after pretreatment with the same dose of entacapone. Moreover, more subjects experienced palpitations when pretreated with entacapone, and this study was terminated early because of two cases of ventricular arrhythmias, one requiring treatment with propranolol. There was no change in blood pressure, nor any increase in plasma levels of the sympathomimetics.

Mechanism

Tolcapone and entacapone inhibit the enzyme catechol-O-methyltransferase (COMT), which is concerned with the metabolism of drugs such as adrenaline (epinephrine) and isoproterenol (isoproterenol). There is therefore a possibility of increased serum levels and related adverse effects of these drugs.

Importance and management

The evidence from this single-dose study confirms the theoretical prediction that COMT inhibitors might potentiate the effects of directly-acting sympathomimetics such as adrenaline (epinephrine). Because of this, the manufacturers of entacapone and tolcapone suggest caution if drugs known to be metabolised by COMT are given to patients on COMT inhibitors. Of the sympathomimetics, adrenaline (epinephrine), dobutamine, dopamine, isoproterenol, and noradrenaline (norepinephrine), are specifically named in one or more of the lists, and one manufacturer of entacapone also lists bitolterol and isoetarine (isotharine), and specifically includes the inhaled route of administration. See also ‘COMT inhibitors + Sympathomimetics; Indirectly-acting’, below.

A single case report describes severe hypertension in a patient given entacapone and intravenous ephedrine. Tolcapone did not alter the effect of ephedrine in one study.

Clinical evidence

(a) Entacapone

A 76-year-old woman with Parkinson’s disease taking levodopa/carbidopa and entacapone 200 mg five times daily, was given 3 mg of intravenous ephedrine during cataract surgery to correct a low blood pressure of 85/35 mmHg. Her blood pressure immediately rose to 225/125 mmHg. The patient needed several doses of hydralazine over the following 140 minutes before her blood pressure returned to normal.

(b) Tolcapone

The manufacturer notes that tolcapone did not alter the effect of ephedrine (route of administration not stated) on haemodynamic parameters or plasma catecholamine levels, either at rest or during exercise.

Mechanism

COMT inhibitors may inhibit the normal metabolism of ephedrine (and the catecholamines it releases at adrenergic nerve endings), which could result in a marked exaggeration of its normal effects. See also ‘COMT inhibitors + Sympathomimetics; Directly-acting’, above.

Importance and management

The single case report with entacapone and intravenous ephedrine appears to be the only evidence that COMT inhibitors could potentiate the effect of indirectly-acting sympathomimetics such as ephedrine. The manufacturer of tolcapone states that ephedrine and tolcapone can be used concurrently. Nevertheless, some caution may be warranted with intravenous ephedrine.

no evidence that combined drug use had any relevant effect on haemodynamics or on free adrenaline (epinephrine) or noradrenaline (norepinephrine) plasma levels. The combination was well tolerated in all subjects.\(^1\)

(b) Tolcapone

In one study, healthy subjects were given desipramine 25 mg three times daily for 3 days then 50 mg three times daily for 10 days. For the last 5 days they were also given levodopa/carbidopa 100/25 mg three times daily and either a placebo or tolcapone 200 mg three times daily. The addition of tolcapone to combined treatment with levodopa/carbidopa and desipramine did not lead to any changes in haemodynamics or catecholamine levels, nor to any changes in desipramine pharmacokinetics.\(^2\)

Mechanism

Both COMT inhibitors and drugs with noradrenaline re-uptake inhibitory activity can impair the inactivation of catecholamines, so in theory the effects of catecholamines may be increased by concurrent use. However, this did not appear to occur in the above studies.

Importance and management

In these pharmacological studies, no important interaction between entacapone and imipramine or between tolcapone and desipramine was detected. Nevertheless, the manufacturer of entacapone says there is limited clinical experience of the use of entacapone with tricyclic antidepressants, and they therefore recommend caution.\(^3\) Similarly, the manufacturers of tolcapone suggest that caution should be exercised with desipramine\(^4\) and any drugs that are potent noradrenaline (norepinephrine) uptake inhibitors such as maprotiline and venlafaxine.\(^5\)

**COMT inhibitors; Entacapone + Iron compounds**

Entacapone formed chelates with iron *in vitro*. The manufacturer recommends that iron preparations and entacapone are given 2 to 3 hours apart.

Clinical evidence, mechanism, importance and management

An *in vitro* study\(^1\) found that entacapone formed chelates with iron. Although the clinical relevance of this does not appear to have been assessed, the manufacturers recommend that entacapone and iron preparations should be taken at least 2 to 3 hours apart.\(^2\)

**Levodopa + Antacids**

Antacids do not appear to interact significantly with immediate-release levodopa, but they may reduce the bioavailability of modified-release preparations of levodopa.

Clinical evidence

(a) Immediate-release preparations

One study found that 15 mL of an aluminium/magnesium hydroxide antacid, given 30 minutes before levodopa, to a patient with a prolonged gastric emptying time, caused a threefold increase in levodopa serum levels, which was associated with a marked improvement in symptoms.\(^1\) Another patient was able to reduce his levodopa dose when taking antacids, without affecting symptom control.\(^1\) A further study found that the maximum plasma concentration of levodopa was raised by 20% when 20 mL of an antacid was given before the levodopa.\(^2\)

However, when 8 patients (only 3 with Parkinson’s disease) were given Mylanta (containing aluminium/magnesium hydroxide and simeticon), 30 minutes before, and/or with levodopa, only occasional increases in bioavailability were seen. One of the 3 patients with Parkinson’s disease who had shown improved bioavailability while on antacids had his levodopa dose lowered and continued to take Mylanta, but the parkinsonian symptoms worsened and the levodopa was increased back to the original dose.\(^3\) Another study, in 15 parkinsonian patients taking dopamine agonists (e.g. bromocriptine) and levodopa/carbidopa who were given six 30-mL doses of aluminium hydroxide daily, inferred that the antacid had no significant effect on levodopa bioavailability, because of the lack of clinical fluctuations in effect.\(^4\)

(b) Sustained-release preparations

In a study using Madopar HBS, a sustained-release preparation of levodopa and benserazide, the concurrent use of an unnamed antacid reduced the levodopa bioavailability by about one-third in healthy subjects.\(^5\) The manufacturers of Madopar CR state that antacids reduce the bioavailability of levodopa from the controlled-release preparation in comparison with conventional Madopar.\(^6\)

Mechanism

The small intestine is the major site of absorption for levodopa, and delayed gastric emptying appears to result in low plasma levodopa levels, probably because levodopa can be metabolised in the stomach. In theory, antacids may reduce gastric emptying time, and increase levodopa absorption.\(^1\) It is not known why antacids reduced absorption from the slow-release preparation.\(^7\)

Importance and management

The overall picture is that concurrent use need not be avoided with standard preparations, although some individuals may be affected so the outcome should be monitored. With modified-release preparations it would seem advisable to avoid concurrent administration (1 to 2 hours is usually enough in other similar cases of interactions with antacids). Again, the outcome should be monitored.

**Levodopa + Anticholinesterases; Centrally acting**

Reports describe cases of a worsening of Parkinson’s disease in patients given donepezil or tacrine. Other centrally acting anticholinesterases may exacerbate or induce extrapyramidal symptoms, including worsening of Parkinson’s disease. In contrast, one study found that donepezil did not affect the control of Parkinson’s disease, and actually caused a non-significant increase in levodopa levels.

Clinical evidence

(a) Donepezil

Donepezil 5 mg daily for 15 days caused a modest 30% increase in the AUC\(_{0-4}\) of levodopa in a placebo-controlled study in 23 patients with Parkinson’s disease taking levodopa/carbidopa. There was no change in carbidopa pharmacokinetics, and the pharmacokinetics of donepezil did not differ between the patients with Parkinson’s disease and a control group of healthy subjects. There was no obvious difference in adverse effects between patients with Parkinson’s disease and the control subjects, and no evidence that donepezil significantly altered motor activity in those treat-
ed with levodopa/carbidopa. This latter finding is in contrast to a report which found a worsening of Parkinson’s disease, which responded to levodopa/carbidopa, in 3 of 9 patients who had taken donepezil for 24 weeks.

(b) Tacrine
The mild parkinsonism of an elderly woman with Alzheimer’s disease worsened, leading to severe tremor, stiffness and gait dysfunction within 2 weeks of doubling her tacrine dosage from 10 mg to 20 mg four times daily. This improved when levodopa/carbidopa was started, but the tremor returned when tacrine was increased to 30 mg four times daily. The symptoms disappeared when the tacrine dosage was reduced to 20 mg four times daily.

Mechanism
Parkinsonism is due to an imbalance between two neurotransmitters, dopamine and acetylcholine, in the basal ganglia of the brain. Centrally acting anticholinesterases increase the amount of acetylcholine in the brain, which could lead to an exacerbation of parkinsonian symptoms. Levodopa improves the situation by increasing the levels of dopamine. It is not known why donepezil modestly increased the levels of levodopa.

Importance and management
Direct information seems to be limited, but the reports of worsening Parkinson’s disease are consistent with the known pharmacology of these drugs and the biochemical pathology of Parkinson’s disease. Be aware that if donepezil or tacrine is given to any patient with parkinsonism, whether taking levodopa or any other anti-parkinson drug, the disease may possibly worsen. The antiparkinson drug dosage may need increasing and/or the dosage of the anticholinesterase may need reducing. Other centrally acting anticholinesterases (galantamine, rivastigmine) may also worsen Parkinson’s disease.

Levodopa + Antiemetics
Although metoclopramide can increase the rate of levodopa absorption, it may also antagonise its effects by aggravating symptoms of Parkinson’s disease, so metoclopramide should generally be avoided in patients with Parkinson’s disease. However, two studies found no evidence that metoclopramide altered the efficacy of levodopa.

(c) Phenothiazine antiemetics
Phenothiazines block the dopamine receptors in the brain and can therefore upset the balance between cholinergic and dopaminergic components within the striatum and substantia nigra. As a consequence they may not only induce the development of extrapyramidal (parkinsonian) symptoms, but they can aggravate parkinsonism and antagonise the effects of levodopa used in its treatment. See ‘Levodopa + Antipsychotics’, p.683. Phenothiazines, used in smaller doses as antiemetics, such as prochlorperazine, can also be used in this way. For this reason drugs of this kind are generally regarded as contraindicated in patients with Parkinson’s disease, and there are other more suitable alternatives, see (d) below.

(d) Non-interacting antiemetics
Antiemetics that are generally considered useful in patients with Parkinson’s disease include cyclizine and 5-HT₃ antagonists such as ondansetron and domperidone which do not affect dopamine, and domperidone as discussed above. However, note that rare cases of extrapyramidal adverse effects have been reported with domepsine, which may be of relevance in patients with Parkinson’s disease.

Clinical evidence, mechanism, importance and management
(a) Domperidone
Domperidone is a dopamine antagonist similar to metoclopramide. However, since it acts on the dopamine receptors in the stomach wall, and unlike metoclopramide, it does not readily cross the blood-brain barrier, it does not appear to oppose the effects of levodopa within the brain, although some extrapyramidal symptoms have been observed. It may even slightly increase the bioavailability and effects of levodopa (by stimulating gastric emptying). Domperidone can therefore be used to control the nausea and vomiting associated with levodopa treatment of Parkinson’s disease.

(b) Metoclopramide
Metoclopramide is a dopamine antagonist that can cause extrapyramidal disturbances (parkinsonian symptoms), especially in children and young adults, and possibly also in the elderly, where the effects may be misdiagnosed as Parkinson’s disease. On the other hand, metoclopramide stimulates gastric emptying, which can result in an increase in the bioavailability of levodopa. The outcome of these two effects (possible antagonism resulting in aggravation of Parkinson’s disease, or potentiation resulting in increased bioavailability) is uncertain, and it is generally considered that metoclopramide should be avoided in Parkinson’s disease. However, in one open study, metoclopramide 30 to 60 mg daily in divided doses for a range of 4 to 16 weeks caused no change in mean total disability scores in 10 patients with Parkinson’s disease taking levodopa. Similarly, in a controlled trial in 7 patients, the incidence and severity of levodopa-induced involuntary movements was unchanged and additional acute dyskinesias did not appear when metoclopramide was also given. Nevertheless, if alternative antiemetics are unsuitable for a patient with Parkinson’s disease and consequently metoclopramide is given, it would seem prudent to monitor the outcome closely.

Levodopa + Antimuscarinics
Antimuscarinics and other drugs with antimuscarinic effects, such as the tricyclics, may modestly reduce the rate, and possibly the extent, of absorption of levodopa. One case describes levodopa toxicity, which occurred after the withdrawal of an antimuscarinic.

Clinical evidence
A study in 6 healthy subjects and 6 patients with Parkinson’s disease found that trihexyphenidyl 2 mg twice daily for 3 days lowered the peak plasma levels of a 500-mg dose of levodopa by 42% in the healthy subjects and 17% in the patients, although the interaction was present in only about half of the subjects. The AUC was reduced in both groups by less than 20%. A study in 6 patients with Parkinson’s disease taking levodopa plus carbidopa or benserazide found that orphenadrine caused either a delay, a reduction, or an increase in levodopa absorption in 3 patients.
study in 4 healthy subjects found that *imipramine* 25 mg four times daily for 3 days reduced the peak plasma concentration of a single 500-mg dose of levodopa by about 50%, but did not appear to alter the extent of absorption. See also ‘Levodopa + Triyclic antidepressants’, p.690 for other non-antimuscarinic interactions of the tricyclics.

A patient who needed 7 g of levodopa daily while taking *homatropine* developed levodopa toxicity when the *homatropine* was withdrawn, and he was subsequently restabilised on only 4 g of levodopa daily.4

**Mechanism**

The small intestine is the major site of absorption for levodopa. Delayed gastric emptying, which can be caused by antimuscarotics, appears to result in lower plasma levodopa levels and thus lower brain levodopa levels. This is because the gastric mucosa has more time to metabolise the levodopa to dopamine and therefore less is available for absorption.5

**Importance and management**

Antimuscarotics are commonly given with levodopa, and they are of established benefit. However, limited evidence suggests they might sometimes reduce levodopa efficacy. Levodopa preparations are now more usually given in conjunction with a dopa decarboxylase inhibitor to minimise metabolism in the gastric mucosa. This would be expected to minimise the effects of any interaction. However, note that one of the above studies included a dopa-decarboxylase inhibitor, yet still found an effect on levodopa absorption. There is certainly no need to avoid concurrent use, but it would be prudent to be alert for any evidence of a reduced levodopa response if antimuscarotics are added, or for levodopa toxicity if they are withdrawn.6

**Levodopa + Antipsychotics**

Phenothiazines, butyrophenones, diphenylbutylpiperidines and thioxanthenes can oppose the effects of levodopa because of their dopamine antagonist properties, causing deterioration of motor function in Parkinson’s disease. The antipsychotic effects and extrapyramidal adverse effects of these drugs can be opposed by levodopa. Of the atypical antipsychotics, risperidone and olanzapine cause deterioration in motor function in Parkinson’s disease. Ziprasidone may act similarly, and there have been reports with quetiapine. Clozapine does not have this effect.

**Clinical evidence, mechanism, importance and management**

(a) **Classical antipsychotics**

Phenothiazines (e.g. fluphenazine, perphenazine, prochlorperazine, and trifluoperazine), *butyrophenones* (e.g. haloperidol, droperidol) *diphenylbutylpiperidines* (e.g. pimozide) and *thioxanthenes* (e.g. flupenthixol and zuclopenthixol) block the dopamine receptors in the brain and can therefore upset the balance between cholinergic and dopaminergic components within the striatum and substantia nigra. As a consequence they may not only induce the development of extrapyramidal (parkinsonian) symptoms, but they can aggravate parkinsonism and antagonise the effects of levodopa used in its treatment.4,5 For this reason drugs of this kind are generally regarded as contraindicated in patients being treated for Parkinson’s disease, or only used with great caution in carefully controlled conditions. The extrapyramidal symptoms that frequently occur with the **phenothiazines** have in the past been treated without much success with levodopa. However, the levodopa may also antagonise the antipsychotic effects of the **phenothiazines**,6 and other dopamine-antagonist antipsychotics. Consider also ‘Levodopa + Antiemetics’, p.682.

(b) **Atypical antipsychotics**

Of the atypical antipsychotics, both *risperidone* and *olanzapine* have caused deterioration of motor function in patients with Parkinson’s disease. There have also been reports of deterioration in motor function with *quetiapine*. There is far less experience with *ziprasidone*, but it may have a propensity to cause extrapyramidal adverse effects that is similar to olanzapine.

Low-dose *clozapine* appears to cause little deterioration in motor function, and may improve tremor. It therefore remains the preferred antipsychotic for patients with Parkinson’s disease and levodopa-induced psychosis. Note that individual reports and studies of the use of these antipsychotics in patients with Parkinson’s disease are numerous. The reader is referred to a recent review on the topic.7

1. Duvoisin RC. Diphenidol for levodopa induced nausea and vomiting. *JAMA* (1972) 221, 1408.

**Levodopa + Baclofen**

Unpleasant adverse effects (hallucinations, confusion, headache, nausea) and worsening of the symptoms of parkinsonism have occurred in patients on levodopa who were given baclofen.

**Clinical evidence**

Twelve patients with parkinsonism on levodopa plus a dopa-decarboxylase inhibitor were additionally given baclofen. The eventual baclofen dosage was intended to be 90 mg daily, but the adverse effects were considerable (visual hallucinations, a toxic confusional state, headaches, nausea) so that only 2 patients reached this dosage, and 2 patients withdrew because they could not tolerate these adverse effects. The mean dosage for those who continued was 45 mg daily. Rigidity was aggravated by an average of 46% and functional capacity deteriorated by 21%.3

A patient with Parkinson’s disease taking levodopa/carbidopa, orphenadrine and diazepam became acutely confused, agitated, incontinent and hallucinated when given a third dose of baclofen (in all 15 mg). The baclofen was stopped, but on the following night she again hallucinated and became confused. The next day she was given two 2.5-mg doses of baclofen but she became anxious and hallucinated with paranoid ideas.2

**Mechanism**

Not understood. The toxicity seen appears to be an exaggeration of the known adverse effects of baclofen.

**Importance and management**

Information appears to be limited to these reports, but they suggest that baclofen should be used very cautiously in patients taking levodopa.

**Levodopa + Benzodiazepines and related drugs**

On rare occasions it seems that the therapeutic effects of levodopa can be reduced by chloridiazepoxide, diazepam or nitrazepam.

**Clinical evidence**

Various benzodiazepines [dose unstated] were given to 8 patients with Parkinson’s disease in addition to their levodopa treatment. In 5 of the patients (3 taking *chloridiazepoxide*, 1 taking *nitrizepam*, 1 taking oxazepam) no interactions were seen. However, the other 3 patients (1 taking diazepam, 2 taking nitrazepam) experienced transient disturbances in the control of their Parkinson’s disease, which lasted up to...
3 weeks in the case of the patient taking diazepam. Other cases of a reversible loss of control of Parkinson’s disease have been seen in 3 patients taking diazepam and 4 patients taking chlordiazepoxide. In one further case, a patient taking chlordiazepoxide experienced falls associated with a worsening of parkinsonian symptoms while taking chlordiazepoxide. She recovered 5 days after the chlordiazepoxide was withdrawn.

In contrast, a case-control study of patients with Parkinson’s disease taking levodopa therapy did not find a statistically significant increase in the required dose of antiparkinsonian drug treatment in the 180 days after starting a benzodiazepine.

Mechanism
Not understood, although animal studies have shown that benzodiazepines can decrease the levels of dopamine in the striatum.

Importance and management
Not established. Given the widespread use of benzodiazepines in patients taking levodopa, any major or common interaction would be expected to have come to light by now. It would therefore seem that this interaction is fairly rare, and on the basis of one of the reports cited above, possibly only transient. There is no need to avoid concurrent use, but bear these reports in mind in the case of an unexpected response to treatment.

Levodopa + Beta blockers
The concurrent use of levodopa and beta blockers normally appears to be favourable, but be aware that, as with all antihypertensives, additive hypotensive effects can occur.

Clinical evidence, mechanism, importance and management
Most of the effects of the combined use of levodopa and beta blockers seem to be favourable, although additive hypotension can be a problem. Dopamine derived from levodopa stimulates beta-receptors in the heart, which can cause arrhythmias. These receptors are blocked by pramipexole and other beta blockers. An enhancement of the effects of levodopa and a reduction in tremor has been described in 23 out of 25 patients taking pramipexole, but not in 9 patients taking oxprenolol, or in another placebo-controlled study in 18 patients taking pramipexole. Early evidence showed that growth hormone levels were substantially raised by pramipexole or practolol [now withdrawn due to fatal reactions] in conjunction with levodopa, but no clinical relevance for this has been demonstrated.

Levodopa + Bromocriptine and other dopamine agonists
The combined use of levodopa and dopamine agonists can increase efficacy and adverse effects in Parkinson’s disease, therefore doses of both drugs should be slowly adjusted to optimise therapy. A study suggests that bromocriptine can moderately alter levodopa levels whereas there was no pharmacokinetic interaction between levodopa and cabergoline, pramipexole or ropinirole. An isolated report describes the development of the serotonin syndrome when levodopa/carbidopa was added to treatment with bromocriptine.

Clinical evidence
(a) Bromocriptine
A study in 20 patients with Parkinson’s disease taking levodopa/carbidopa found that overall there was no difference in plasma levodopa levels after bromocriptine was also taken, although some patients had either significant elevations or significant reductions in levels. However, the only adverse clinical change found was an increase in dyskinesias in the patients with elevated levodopa levels. An earlier study found no pharmacokinetic interaction between levodopa/carbidopa and bromocriptine, but it should be noted that this was a single-dose study and may not reflect long-term concurrent use. A patient with parkinsonism, who had been taking bromocriptine 60 mg daily for nearly 3 years, was also given levodopa/carbidopa (25/250 mg daily increasing over a week to 75/750 mg) while the bromocriptine dose was reduced to 20 mg daily. On the seventh day he started shivering, and developed myoclonus of the trunk and limbs, hyporeflexia, patellar clonus, tremor, diaphoresis, anxiety, diarrhoea, tachycardia and had a temperature of 37.9°C with a blood pressure of 180/100 mmHg. The serotonin syndrome was suspected. The patient responded to treatment with the 5-HT antagonist methylsergide.

A case of pathological gambling was attributed to the combined use of bromocriptine and levodopa/carbidopa in a 54-year-old woman.

(b) Cabergoline
Levodopa/carbidopa 25/250 mg daily did not cause a clinically significant change in the pharmacokinetics of cabergoline 2 mg daily when the combination was given to patients newly diagnosed with Parkinson’s disease. Similarly, cabergoline (in increasing doses up to 4 mg once daily) for 8 weeks had no effect on the absorption, AUC or elimination half-life of levodopa in another group of patients with fluctuating Parkinson’s disease who were taking levodopa/carbidopa.

(c) Pergolide
The manufacturer notes that the use of pergolide in patients on levodopa may cause and/or exacerbate pre-existing states of dyskinesia, confusion, and hallucinations. Also, they say that stopping pergolide abruptly in patients on levodopa may precipitate the onset of hallucinations and confusion.

(d) Pramipexole
Patients on a stable dose of levodopa/carbidopa were given increasing doses of pramipexole or placebo for 7 weeks. Pramipexole 1.5 mg daily (and 4.5 mg daily had no effect on levodopa bioavailability. As pramipexole enhances the actions of levodopa the manufacturer suggests reducing the dose of levodopa as the dose of pramipexole is increased.

(e) Ropinirole
In patients on a stable dose of levodopa with a dopa-decarboxylase inhibitor, ropinirole had no effect on the pharmacokinetics of levodopa, except for a small clinically irrelevant 16% increase in maximum level. Similarly, levodopa had no effect on the pharmacokinetics of ropinirole in another group of patients. As the dose of ropinirole is increased, the dose of levodopa may be reduced gradually, by around 20% in total.

(f) Rotigotine
The manufacturer of rotigotine reports that levodopa and carbidopa had no effect on the pharmacokinetics of rotigotine and similarly, rotigotine had no effect on the pharmacokinetics of either levodopa or carbidopa. However, as with other dopamine agonists, rotigotine may cause and/or exacerbate dyskinesia in patients taking levodopa and may potentiate the dopaminergic adverse reactions of levodopa.

Mechanism
Additive dopaminergic effects would be expected. The serotonin syndrome is thought to occur because of increased stimulation of the 5-HT receptors in the brainstem and spinal cord. A syndrome resembling neuroleptic malignant syndrome (which has similar symptoms to the serotonin syndrome) can occur when a dopamine agonist like bromocriptine is
withdrawn abruptly. It is therefore possible that the effects of reducing the bromocriptine dose were additive with those of levodopa, which can displace serotonin from the nerve endings.1 Pathological gambling has been associated with the misuse of levodopa and dopamine agonists alone, but an association is not clearly established.

Importance and management

The combined use of levodopa and ergot dopamine agonists can increase efficacy in Parkinson’s disease, but adverse effects such as hallucinations and dyskinesias may also be increased, and the dose of both drugs should be gradually adjusted to optimise therapy. If the decision is made to withdraw the dopamine agonist, this should be done slowly, over several days. The serotonin syndrome described with levodopa and bromocriptine appears to be an isolated incident and not of general importance. Similarly, the case of gambling with levodopa/bromocriptine is probably not of general importance, except to say that use of dopaminergic drugs should be considered as a possible contributing factor in a patient with pathological gambling.

Levodopa + COMT inhibitors

Entacapone and tolcapone increase the AUC of levodopa given with benserazide or carbidopa. This may require a reduction in the levodopa dose to avoid symptoms of dopamine excess when first starting the COMT inhibitor. Tolcapone increases the levels of benserazide, but neither entacapone nor tolcapone alters carbidopa pharmacokinetics.

Clinical evidence

(a) Levodopa

Entacapone1,2 and tolcapone3,4 have been shown to increase the AUC and prolong the elimination half-life of levodopa (as levodopa/benserazide or levodopa/carbidopa) without altering the maximum levodopa level. COMT inhibitors can therefore improve the clinical condition of patients with Parkinson’s disease, which is mainly seen as a decrease in ‘off’ time.5 However, as levodopa levels are raised, there may be an accompanying increase in the adverse effects of levodopa (e.g. dyskinesias, nausea, vomiting, orthostatic hypotension, hallucinations).6,8

(b) Benserazide or carbidopa

The effects of COMT inhibitors on the pharmacokinetics of dopa-decarboxylase inhibitors has also been studied. Neither entacapone5 nor tolcapone6 altered the pharmacokinetics of carbidopa. However, tolcapone increased the serum levels of benserazide in patients with Parkinson’s disease.10 The benserazide levels remained within the usual range in patients taking levodopa products containing benserazide 25 mg and tolcapone 200 mg three times daily. However, with a 50-mg dose of benserazide the AUC of benserazide was increased 4.8-fold with standard-release preparation and 2.3-fold with a controlled-release preparation.10

Mechanism

When levodopa is given with a dopa-decarboxylase inhibitor such as carbidopa or benserazide, COMT becomes the major enzyme for metabolising levodopa, so inhibiting COMT delays the breakdown of levodopa.

Importance and management

When starting a COMT inhibitor, all patients should be informed of the symptoms of excess levodopa, and what to do if they occur. The manufacturers of entacapone suggest that if entacapone is started, the daily dose of levodopa should be reduced by about 10 to 30% (within the first few days or weeks) to accommodate these potential adverse effects.7,11 This can be done by either extending the dosing intervals and/or by reducing the amount of levodopa per dose. Patients on levodopa/benserazide may require a greater dose reduction than those on levodopa/carbidopa because entacapone increases the bioavailability of standard levodopa/benserazide preparations by 5 to 10% more than standard levodopa/carbidopa.7 The manufacturers of tolcapone say that the average reduction in the daily dose of levodopa required on starting tolcapone was 30%, and that greater than 70% of patients on levodopa doses above 600 mg daily required such a reduction.8,12 The clinical significance of the increase in benserazide levels is unknown, but the manufacturers advise good monitoring for benserazide adverse effects.12

**Levodopa + Carbidopa**

An isolated report describes a reduction in the effects of levodopa caused by carbidopa.

### Clinical evidence, mechanism, importance and management

A patient who had been treated surgically for melanoma, continued to have intermittent carbidopa treatment (200 mg intravenously daily) for sporadic positive melanuria. He later developed Parkinson’s disease, and was started on levodopa, which had no effect on his melanoma. However, each time he was treated with carbidopa he complained that the effects of the levodopa/carbidopa were reduced and his Schwab and England score (measures of activities of daily living) fell by as much as 25%. A subsequent double-blind study on the patient using a modified Columbia Score confirmed this. The reasons are not understood, but since the serum dopamine levels remained unchanged it is suggested that competition between the two drugs at the blood-brain barrier may be the explanation. Be alert for the need to modify levodopa treatment if carbidopa is used concurrently. However, note also that the manufacturers contraindicate levodopa in those with a history of malignant melanoma because there is some suggestion that levodopa may activate this malignancy, although some consider that this is unlikely from the available evidence.

### Levodopa + Food

The fluctuations in response to levodopa experienced by some patients may be due to the timing of meals and the type of diet, particularly the protein content, both of which can reduce the effects of levodopa. The effects of levodopa can be reduced by the amino acid methionine, and the blood levels of levodopa can be reduced by the amino acid tryptophan.

#### Clinical evidence

**a) Effects of meals**

A study in patients with Parkinson’s disease taking levodopa found that if taken with a meal, the mean absorption of levodopa from the gut and the peak plasma levels were reduced by 27 and 29% respectively, and the peak plasma level was delayed by 34 minutes. Another study found that peak plasma levodopa levels were reduced if the levodopa was taken with food rather than when fasting.

**b) Effects of protein**

A study in healthy subjects found that a low-protein meal (protein 10.5 g) caused a small reduction in levodopa absorption when compared with the fasting state, but also found that a high-protein meal (protein 30.5 g) was no different to the fasting state. Other studies have found that a high daily intake of protein reduces the effects of levodopa (with or without a dopa-decarboxylase inhibitor), compared with a lower intake of protein.

(c) Effects of specific amino acids

A study found that the clinical response to a constant intravenous infusion of levodopa in 4 patients was unchanged by glycine and lysine but was reduced by phenylalanine, leucine and isoleucine, although the plasma levodopa levels remained unchanged.

Fourteen patients treated with levodopa for Parkinson’s disease were given a low-methionine diet (0.5 g daily) for a period of 8 days. Seven patients were given additional methionine (4.5 g daily), while the other 7 were given placebo. Five out of the 7 given methionine 4.5 g daily showed definite worsening of the symptoms (gait, tremor, rigidity, etc.). The symptoms subsided when the methionine was withdrawn, although this took 7 to 10 days in one patient. Three out of the 7 given placebo (while on the low-methionine diet) showed some subjective improvement.

The blood levels of levodopa were markedly reduced in normal healthy subjects when levodopa 500 mg was taken with 1 g of tryptophan. The clinical importance of this was not assessed.

### Mechanism

(a) Meals that delay gastric emptying increase the potential for peripheral metabolism of levodopa in the gut, which reduces the amount available for absorption. In addition (b) some large neutral amino acids arising from the digestion of proteins can compete with levodopa for transport into the brain so that the therapeutic response may be reduced, whereas other amino acids (c) do not have this effect.

#### Importance and management

An established interaction, but unpredictable. Since the fluctuations in the response of patients to levodopa may be influenced by what is eaten and when, a change in the pattern of drug and food administration on a trial-and-error basis may be helpful. Note that the manufacturers of Madopar recommend taking with food or slowly increasing the dose in the early stages of treatment to control anorexia, nausea, vomiting, and diarrhoea. Multiple small doses of levodopa and distributing the intake of proteins may also diminish the effects of these interactions. Diets that conform to the recommended daily allowance of protein (said to be 800 mg/kg in this report) are reported to reduce this adverse drug-food interaction.

The amino acid methionine is used therapeutically, and although information about its interaction with levodopa is very limited, it indicates that large doses of methionine should be avoided in patients being treated with levodopa.

8. Daniel PM, Moorhouse SR, Pratt OE. Do changes in blood levels of other aromatic aminocids influence levodopa therapy? Lancet (1976) i, 95.
Ferrous sulfate can reduce the bioavailability of levodopa and carbidopa, and may possibly reduce the control of Parkinson’s disease.

**Clinical evidence**
A study in 9 patients with Parkinson’s disease found that a single 325-mg dose of ferrous sulfate reduced the AUC of levodopa by 30% and reduced the AUC of carbidopa by more than 75%. There was a trend towards an increase in disability, suggesting a worsening of disease, but this did not reach statistical significance. Some, but not all of the patients had some deterioration in the control of their disease.

In another study, 8 healthy subjects were given a single 250-mg dose of levodopa, with and without a single 325-mg dose of ferrous sulfate, and the plasma levodopa levels were measured for the following 6 hours. Peak plasma levodopa levels and the levodopa AUC were reduced by 55% and the AUC was reduced by 51%. Those subjects who had the highest peak levels and greatest absorption when given levodopa alone, showed the greatest reductions when additionally given ferrous sulfate.

**Mechanism**
Ferrous iron rapidly oxidises to ferric iron at the pH values found in the gastrointestinal tract. Ferric iron binds strongly to carbidopa and levodopa to form chelation complexes that are poorly absorbed.

**Importance and management**
Information appears to be limited to these single-dose and *in vitro* studies. The importance of this interaction in patients taking both drugs long-term awaits further study but the extent of the reductions in absorption (30 to 50%), and the hint of worsening control, suggests that this interaction may be of clinical importance. Be alert for any evidence of this. Separating the administration of the iron and levodopa as much as possible is likely to prove effective, as this appears to be an absorption interaction. More study is needed.

**Levodopa + Isoniazid**
There is evidence that isoniazid can control the reduction of Parkinson’s disease in patients taking levodopa. An isolated case report describes hypertension, tachycardia, flushing and tremor in a patient attributed to concurrent use of levodopa and isoniazid.

**Clinical evidence**
Following the observation that levodopa-induced dyskinesias were reduced by isoniazid in one patient, a further study was undertaken in 20 others taking levodopa plus a dopa-decarboxylase inhibitor. It was found that isoniazid (average dose 290 mg daily, range 100 to 800 mg daily) reduced the dyskinesias of 18 of the 20 patients. However, the reduction in dyskinesias was accompanied by an intolerable worsening of parkinsonism, shown by decreased mobility and greater ‘off’ periods. The reduction in mobility was so severe that the isoniazid had to be stopped immediately in several cases and was discontinued after an average of 5.2 weeks in all the patients. Control of parkinsonism was then restored. Another patient taking levodopa/carbidopa similarly had a deterioration in the control of parkinsonism within 1 to 2 weeks of starting isoniazid/rifampicin (*Rifinah*). When the antitubercular drugs were stopped, the patient’s motor performance improved (‘on’ period lengthened by 75%), the levodopa AUC rose by 37%, its half-life doubled, and the maximum plasma levels fell by 33%.

An isolated report describes a patient on levodopa who developed hypertension, agitation, tachycardia, flushing and severe non-parkinsonian tremor after starting to take isoniazid. He recovered when the isoniazid was stopped.

**Mechanism**
Not understood. Metabolic studies in one patient suggest that isoniazid inhibits dopa-decarboxylase, although other mechanisms have been proposed. The isolated case of hypertension and tachycardia is also not understood, but it has been suggested that it may have been due to a weak monoamine oxidase inhibitory effect of the isoniazid metabolites. See ‘MAOIs or RIMAs + Levodopa’, p.1136, for further explanation.

**Levodopa + MAO-B inhibitors**
No serious interaction occurs between levodopa and selegiline, although the dose of levodopa may need to be reduced when selegiline is added. Levodopa does not affect rasagiline clearance.

**Clinical evidence**

(a) Rasagiline
The manufacturer notes that levodopa had no effect on rasagiline clearance.

(b) Selegiline
The combination of levodopa and selegiline has been very extensively used. No serious hypertensive reactions of the kind seen with ‘non-selective MAOIs and levodopa’, (p.1136) seem to occur. No adverse pharmacokinetic interactions have been reported, and serious adverse interactions are said to be lacking. Many studies have reported beneficial effects of this combination, but one has suggested that it may result in increased mortality. Urinary retention has also been suggested as being associated with this drug combination. Selegiline potentiates the effects of levodopa, so the usual adverse effects (dyskinesias, nausea, agitation, confusion, hallucinations, headache, postural hypotension, cardiac arrhythmias, and vertigo) may be increased, particularly if the levodopa dose is too high.

**Mechanism**
MAO-B inhibitors prevent the metabolism of dopamine, therefore additive dopaminergic effects occur with levodopa.

**Importance and management**
No adverse interactions occur if levodopa and selegiline are given concomitantly. However, the manufacturers say that after adding selegiline a reduction in the dose of levodopa is usually required to avoid symptoms of

---

levodopa excess (about 10 to 30% is suggested). Reduction of the levodopa dose should be gradual, in steps of 10% every 3 to 4 days.

**Levodopa + Methylisopropylamine**

Methylisopropylamine can increase the effects of levodopa and permit a reduction in the dosage in some patients taking levodopa alone, but it may also worsen dyskinesias in others. Interaction would not be expected to be significant in a patient taking levodopa with benzerazine or carbidopa but this does not appear to have been studied. A small increase in the hypertensive effects of methylisopropylamine may also occur.

**Clinical evidence**

(a) **Effects on the response to levodopa**

A double-blind crossover study in 10 patients with Parkinson's disease who had been taking levodopa alone for 12 to 40 months, found that the optimum daily dose of levodopa fell by 68% with methylisopropylamine 1920 mg daily, and by 50% with methylisopropylamine 800 mg daily.

Other reports in patients taking levodopa alone describe reductions in the levodopa dosage of up to 30% and 70% during concurrent treatment with methylisopropylamine. Another report states that the control of Parkinson's disease improved during the concurrent use of methylisopropylamine in some patients taking levodopa alone, but the dyskinesias were worsened in others.

Methylisopropylamine on its own can cause a reversible parkinsonian-like syndrome.

(b) **Effects on the response to methylisopropylamine**

A study in 18 patients with Parkinson's disease taking levodopa alone found that combined use of levodopa and methylisopropylamine lowered the blood pressure. The doses used did not affect the systolic blood pressure when given alone. Daily doses of 1 to 2.5 g of levodopa with methylisopropylamine 500 mg caused a 12.6/6 mmHg fall in blood pressure. No change in the control of the Parkinson's disease was seen, but the study lasted only a few days.

**Mechanism**

(a) Methylisopropylamine inhibits the breakdown of levodopa outside the brain (by dopa decarboxylase) so that more is available to exert its therapeutic effects.

(b) The increased hypotension may simply be due to the additive effects of the two drugs.

**Importance and management**

Well documented. Concurrent use need not be avoided but the outcome should be well monitored. In patients on levodopa alone, the use of methylisopropylamine may allow a reduction in the dosage of the levodopa (the reports cited1–3 quote figures of between 30 and 70%) and may enhance the control of Parkinson's disease, but it should also be borne in mind that in some patients dyskinesias may be worsened. However, in the presence of carbidopa or benserazide the dopa decarboxylase effects of methylisopropylamine would be expected to be less significant and so it seems unlikely that a dose reduction of levodopa would be required. The increased hypotensive effects seem to be small, but they too should be checked.

**Levodopa + Mirtazapine**

An isolated report describes the development of serious psychosis, which was attributed to an interaction between levodopa and mirtazapine.

**Clinical evidence, mechanism, importance and management**

A 44-year-old woman taking levodopa/carbidopa, pergolide, selegiline and memantine for Parkinson's disease, was started on mirtazapine in increasing doses ranging from 15 to 60 mg daily over 24 days, for depression, anxiety, social withdrawal and sleep disturbance. She initially improved, but then major depression and psychosis developed, and on day 26 she attempted self-strangulation. She recovered when the mirtazapine, selegiline and selegiline were stopped and low-dose clozapine started. The authors concluded that the reaction was attributable to dopamine-induced psychosis triggered by the addition of mirtazapine to levodopa.1

**Levodopa + Papaverine**

Case reports describe a deterioration in the control of parkinsonism in patients taking levodopa when given papaverine, but a controlled trial failed to confirm this interaction.

**Clinical evidence**

(a) **Levodopa effects reduced**

A woman with long-standing parkinsonism, well controlled on levodopa (with the later addition of carbidopa), began to show a steady worsening of her parkinsonism within a week of additionally starting papaverine 100 mg daily for cerebral vascular insufficiency. The deterioration continued until the papaverine was withdrawn. The normal response to levodopa returned within a week. Four other patients had a similar response.1 Two other similar cases have been described in another report.2

(b) **Levodopa effects unchanged**

A double-blind crossover trial in 9 patients with parkinsonism taking levodopa (range 100 to 750 mg daily) plus a dopa-decarboxylase inhibitor did not find any changes in disease control when they also took papaverine hydrochloride 150 mg daily for 3 weeks. Two patients were also taking bromocriptine 40 mg daily and two trihexyphenidyl 15 mg daily.3

**Mechanism**

Not understood. One suggestion is that papaverine blocks the dopamine receptors in the striatum of the brain, thereby inhibiting the effects of the levodopa.
levodopa. Another is that papaverine may have a reserpine-like action on the vesicles of adrenergic neurones (i.e. it can deplete dopamine stores).

### Importance and management

Direct evidence seems to be limited to the reports cited. Concurrent use can apparently be eventful. However, in the light of the reports of adverse interactions it would be prudent to monitor the outcome closely. Carefully controlled trials can provide a good picture of the general situation, but may not necessarily identify the occasional patient who may be affected by an interaction.

### Levodopa + Penicillamine

Penicillamine can raise plasma levodopa levels in a few patients. This may improve the control of the parkinsonism but the adverse effects of levodopa may also be increased.

#### Clinical evidence, mechanism, importance and management

A patient with Parkinson’s disease taking levodopa with a dopa-decarboxylase inhibitor [probably carbidopa] had a 60% increase in his levodopa plasma levels after taking penicillamine 600 mg daily. This resulted in improved control of symptoms but with an increase in dyskinesia. It was noted that this patient had slightly low serum copper and ceruloplasmin levels. Another study also saw improvements in 2 patients with Parkinson’s disease taking levodopa when they also took penicillamine, but levodopa levels were apparently not measured. Again it was noted that the patients had slightly low copper and ceruloplasmin levels.

This limited evidence suggests that the concurrent use of levodopa and penicillamine need not be avoided, and in some patients parkinsonian symptoms may be improved. However, if both drugs are given, monitor the effects as an increase in the adverse effects of levodopa is also possible.

### Levodopa + Phenytoin

The therapeutic effects of levodopa can be reduced or abolished by phenytoin.

#### Clinical evidence, mechanism, importance and management

A study in 5 patients taking levodopa 630 to 4600 mg (four also taking carbidopa 150 to 225 mg daily) for Parkinson’s disease, found that when they also took phenytoin in doses of up to 500 mg daily for 5 to 19 days the levodopa-induced dyskinesias were relieved, but the beneficial effects of the levodopa on parkinsonism were reduced or abolished. The patients became slow, rigidity re-emerged, and some of them became unable to get out of a chair. Within 2 weeks of stopping the phenytoin, their parkinsonism was again well controlled by the levodopa. Despite many suggestions, the mechanism of this interaction is not understood. Information seems to be limited to this study, nevertheless it would seem prudent to monitor concurrent use for any evidence of reduced levodopa efficacy.

### Levodopa + Pyridoxine (Vitamin B₆)

The effects of levodopa are reduced or abolished by pyridoxine, but this interaction does not occur when levodopa is given with the dopa-decarboxylase inhibitors carbidopa or benserazide, as is usual clinical practice.

#### Clinical evidence

(a) **Levodopa**

A study in 25 patients taking levodopa alone found that if they were given high doses of pyridoxine (750 to 1000 mg daily), the effects of the levodopa were reduced within 24 hours, and were completely abolished within 3 to 4 days. Daily doses of pyridoxine 50 to 100 mg also reduced or abolished the effects of levodopa, and an increase in the signs and symptoms of parkinsonism occurred in 8 out of 10 patients taking only 5 to 10 mg of pyridoxine daily.

The antagonism of the effects of levodopa (given without a dopa-decarboxylase inhibitor) by pyridoxine has been described in numerous other reports.

(b) **Levodopa/carbidopa**

A study in 15 patients with Parkinson’s disease taking long-term levodopa found that a single 250-mg oral dose of levodopa produced a peak dopa level of 600 nanograms/mL. When pyridoxine 50 mg was also given, the peak plasma levels of dopa fell by almost 70%. When the levodopa was given with carbidopa 50 mg the peak plasma dopa levels were 1300 nanograms/mL and were not significantly affected by pyridoxine.

The results from a subset of these patients have been reported elsewhere. The absence of an interaction in the presence of a dopa-decarboxylase inhibitor is confirmed in another report.

#### Mechanism

The conversion of levodopa to dopamine within the body requires the presence of pyridoxal-5-phosphate (derived from pyridoxine) as a co-factor. When dietary amounts of pyridoxine are high, the peripheral metabolism of levodopa by dopa-decarboxylase is increased so that less is available for entry into the CNS, and its effects are reduced accordingly. Pyridoxine may also alter levodopa metabolism by Schiff-base formation. However, in the presence of dopa-decarboxylase inhibitors such as carbidopa or benserazide, this peripheral metabolism of levodopa is reduced and much larger amounts are available for entry into the CNS, even if quite small doses are given. So even in the presence of large amounts of pyridoxine, the peripheral metabolism remains unaffected and the serum levels of levodopa are virtually unaltered.

#### Importance and management

A clinically important, well documented and well established interaction, but principally of historical interest now since levodopa is rarely used alone. The problem of this interaction can be totally solved by using levo-
dopa with a dopa-decarboxylase inhibitor such as carbidopa or benserazide. In the rare cases that levodopa is used alone, pyridoxine in doses as low as 5 mg daily can reduce the effects of levodopa and should therefore be avoided. Warn patients about proprietary pyridoxine-containing preparations such as multivitamins and supplements. Some breakfast cereals are fortified with pyridoxine and other vitamins, but the amounts are usually too small to matter (e.g. a 30 g serving of Kellogg’s Corn Flakes or Rice Krispies (UK products) contains only about 0.6 mg of pyridoxine). There is no good clinical evidence to suggest that a low-pyridoxine diet is desirable, and indeed it may be harmful since the normal dietary requirements are about 2 mg daily.

1. Duvoisin RC, Yahr MD, Coté LD. Pyridoxine reversal of L-dopa effects in parkinsonism. 

Levodopa + Rauwolfia alkaloids

The effects of levodopa are opposed by rauwolfia alkaloids such as reserpine.

Clinical evidence, mechanism, importance and management

Reserpine and other rauwolfia alkaloids deplete the brain of monoamines, including dopamine, thereby reducing their effects.1 This can lead to parkinsonian-like symptoms, and may oppose the actions of administered levodopa. There are not only sound pharmacological reasons for believing this to be an interaction of clinical importance, but a reduction in the antiparkinsonian activity of levodopa has been observed in patients given reserpine.2 The rauwolfia alkaloids should be avoided in patients with Parkinson’s disease, whether or not they are taking levodopa.

Levodopa + Spiramycin

The plasma levels of levodopa (given with carbidopa) are reduced by spiramycin, thereby reducing its therapeutic effects.

Clinical evidence

The observation of a patient with Parkinson’s disease taking levodopa/carbidopa whose condition became less well-controlled when treated with spiramycin, prompted further study. Levodopa/carbidopa 250/25 mg was given to 7 healthy subjects after they had taken spiramycin 1 g twice daily for 3 days. The spiramycin reduced the AUC of levodopa by 57%, and maximum plasma levels fell from 2162 to 1680 nanograms/mL (not significant). The relative bioavailability of levodopa was only 43%. The plasma levels of the carbidopa were barely detectable.[1]

Mechanism

Not fully established. In some way spiramycin markedly reduces the absorption of carbidopa, possibly by forming a non-absorbable complex in the gut or by accelerating its transit through the gut. As a result, not enough carbidopa is absorbed to inhibit the peripheral metabolism of the levodopa by dopa-decarboxylase, so that the effects of the levodopa are reduced.[1]

Importance and management

Information is very limited, but the interaction appears to be established and of clinical importance. The management of this interaction is unclear, but since it appears to be due to an effect on absorption it would seem prudent to try to separate the dosing of these two drugs by as much as possible, although this may be difficult with some levodopa regimens. Monitor the outcome of concurrent use on the control of Parkinson’s disease. It is not known whether other macrolide antibacterials behave in a similar way, or whether spiramycin affects levodopa/benserazide preparations. More study is needed.

Levodopa + SSRIs

The use of an SSRI is often beneficial in parkinsonian patients taking levodopa to treat the depression associated with the disease. However, sometimes parkinsonian symptoms are worsened.

Clinical evidence

Four patients taking levodopa 375 to 990 mg daily, a dopa-decarboxylase inhibitor [drug and dose not stated] and amantadine [dose not stated], had a deterioration in the control of their parkinsonism when they were also given fluoxetine 20 mg daily for 8 to 11 weeks. The fluoxetine was withdrawn and their motor performance was restored. The antidepressant efficacy of fluoxetine was not found to be substantial in any of the 4 patients.1 Another patient taking levodopa developed frequent hallucinations after the addition of fluoxetine. They resolved when the fluoxetine was withdrawn.2 In a retrospective study of 23 parkinsonian patients who were given fluoxetine up to 40 mg daily, 20 patients had no change in the control of their parkinsonism but 3 others experienced a worsening in their Parkinson’s disease signs.2 These are just a few of the reports on the onset or worsening of Parkinson’s with SSRIs, and a number of reviews have been published about the extrapyramidal effects of SSRIs.[3,4]

Mechanism

Not understood. Extrapyramidal effects are rare but recognised adverse effects of SSRIs.[3,4]

Importance and management

Although the information is limited, it seems that in some cases parkinsonism can be worsened by SSRIs. Concurrent use is valuable and need not be avoided, but monitor the outcome and withdraw the SSRI if necessary.

Levodopa + Tricyclic antidepressants

The concurrent use of levodopa and the tricyclics is usually uneventful although two unexplained hypertensive crises have occurred when imipramine or amitriptyline was used with levodopa/carbidopa. See also ‘Levodopa + Antimuscarinics’, p.682 for interactions due to the antimuscarinic effects of tricyclic antidepressants.

Clinical evidence

A hypertensive crisis (blood pressure 210/110 mmHg) associated with agitation, tremor and generalised rigidity developed in a woman taking 6 tablets of levodopa/carbidopa 100/10 mg daily the day after she started to take imipramine 25 mg three times daily. The imipramine was stopped and she recovered over the following 24 hours. The same reaction occurred again when she was later accidentally given amitriptyline 25 mg three times daily.1 A similar hypertensive reaction (a rise from 190/110 to 270/140 mmHg) occurred over 34 hours in another woman taking amitriptyline 20 mg at night when she was given levodopa/carbidopa 50/5 mg and metoclopramide 10 mg, both three times a day. This resolved when all three drugs were stopped.2
A few cases of the serotonin syndrome and other serious CNS disturbances have been seen when selegiline was given with tricyclic antidepressants, fluoxetine or venlafaxine. One of the manufacturers of selegiline contraindicates its use with any antidepressant drug, while another advises avoiding SSRIs and venlafaxine, and using caution with tricyclics. See also ‘MAO-B inhibitors + MAOIs or RIMAs’, p.692 for information on selegiline and MAOIs. The manufacturer of rasagiline specifically recommends avoiding the concurrent use of fluoxetine or fluvoxamine and recommends caution on the concurrent use of any antidepressant.

Clinical evidence
A. SSRIs
(a) Citalopram
In a double-blind randomised study 18 healthy subjects were given citalopram 20 mg or a placebo daily for 10 days followed by 4 days with concurrent selegiline 10 mg daily. There was no evidence of changes in vital signs or in the frequency of adverse events, but the bioavailability of the selegiline was slightly reduced by about 30% in the presence of citalopram. The authors of this report concluded that no clinically relevant interaction occurred between selegiline and citalopram.9

(b) Fluoxetine
A woman with Parkinson’s disease taking selegiline, bromocriptine and levodopa/carbidopa was also given fluoxetine 20 mg. Several days later she developed episodes of shivering and sweating in the mid-afternoon, which lasted several hours. Her hands became blue, cold and mottled and her blood pressure was elevated (200/120 mmHg). These episodes disappeared when both fluoxetine and selegiline were stopped, and did not reappear when the fluoxetine alone was restarted.2 A case of mild serotonin syndrome has been described in a woman taking levodopa and selegiline a few days after starting fluoxetine,3 and a possible case of the serotonin syndrome has been described in another patient taking selegiline and fluoxetine.5

Other patients have become hyperactive and apparently manic,2 have developed ataxia,5 or developed a tonic-clonic seizure and headache, flushed, palpitations, and a blood pressure of 250/130 mmHg (a pseudophaeochromocytoma syndrome),6 all after the concurrent use of fluoxetine and selegiline.5 These reports contrast with a retrospective study of 23 patients with parkinsonism, who received both selegiline and fluoxetine without any serious adverse effects occurring, although worsening confusion was noted in 5 patients.7

(c) Fluvoxamine
The manufacturer of selegiline notes that serious reactions similar to those seen with fluoxetine have occurred in patients receiving selegiline and fluvoxamine.8

(d) Paroxetine
A retrospective study of patients with Parkinson’s disease taking selegiline 5 to 10 mg daily (and other antiparkinsonian drugs such as levodopa/carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of paroxetine 10 to 40 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.3 However, the manufacturers of selegiline note that serious reactions similar to those seen with fluoxetine have occurred in patients receiving selegiline and paroxetine.8,10

(e) Sertraline
A retrospective study of patients with Parkinson’s disease taking selegiline 5 to 10 mg daily (and other antiparkinsonian drugs such as levodopa/carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of sertraline 25 to 100 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.3 However, the manufacturers of selegiline note that serious reactions similar to those seen with concurrent fluoxetine have occurred in patients receiving selegiline and sertraline.8,10

B. Tetracyclic antidepressants
For a case report of a hypertensive crisis, which was attributed to the concurrent use of maprotiline, selegiline and ephedrine, see ‘MAO-B inhibitors + Symptomhemitics; Indirectly-acting’, p.693.

C. Tricyclic antidepressants
Between 1989 and 1994 the FDA in the USA received 16 reports of adverse interactions between selegiline and tricyclic antidepressants, which were attributed to the serotonin syndrome.11 The manufacturers very briefly describe severe CNS toxicity in one patient given selegiline and amitriptyline (hypperxia and death), and in another given protriptyline (tremor, agitation, restless sleep, followed by unresponsiveness and death).8,10,12 They state that related adverse events including hypertension, syncope, asystole, diaphoresis, seizures, changes in behaviour and mental status, and muscular rigidity have also been reported in some patients receiving selegiline and various tricyclics.8,10 A further report describes the serotonin syndrome in a woman given nortriptyline and selegiline concurrently.13 However, these warnings need to be balanced by other reports indicating that these reactions are uncommon. One study based on the findings of 45 investigators treating 4,568 patients with selegiline and antidepressants [not specifically named but possibly including the tricyclics] found that only 11 patients (0.24%) experienced symptoms considered to represent the serotonin syndrome, and only 2 patients (0.04%) experienced symptoms considered to be serious.14 Another small retrospective study designed to evaluate tolerability and efficacy of combining selegiline and tricyclic antidepressants [not specifically named] identified 28 patients who had taken both drugs.11 In total, 17 patients definitely benefited and 6 patients possibly benefited from taking the combination. Another retrospective study of 25 occasions of combined tricyclic-selegiline use found no cases of the serotonin syndrome.4

D. Miscellaneous antidepressants
(a) Trazodone
A retrospective study of patients with Parkinson’s disease taking selegiline 5 to 10 mg daily (and other anti-parkinsonian drugs such as levodopa/carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of trazodone 25 to 150 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.9

(b) Venlafaxine
A man developed the serotonin syndrome 15 days after stopping selegiline 50 mg [daily] and within 30 minutes of starting venlafaxine 37.5 mg.15

Mechanism
Not fully understood. In some cases the symptoms seen appear to be consistent with the serotonin syndrome, which is typified by CNS irritability, increased muscle tone, shivering, altered consciousness and myoclonus, and appears to be associated with the use of more than one serotonergic
Marked orthostatic hypotension has been seen in two patients taking iproniazid or tranylcypromine/trifluoperazine when given selegiline. When the RIMA moclobemide is given with selegiline, restriction of dietary tyramine is necessary, and there may be an increased risk of hypertensive reactions. Some manufacturers of MAO-B inhibitors contraindicate the concurrent use of MAOs or RIMAs.

**Clinical evidence, mechanism, importance and management**

(a) **MAOIs**

In a pilot study, one patient taking iproniazid 150 mg daily developed severe orthostatic hypotension on two occasions within an hour of taking selegiline 5 mg. Two other patients (one on tranylcypromine/trifluoperazine and one on tranylcypromine/trifluoperazine plus isocarboxazid) did not have this reaction to selegiline 5 mg twice daily. The authors mention another patient who similarly developed postural hypotension on two occasions within 2 hours of taking selegiline 5 mg. He had stopped taking tranylcypromine/trifluoperazine, 4 weeks previously. The reasons are not understood. This evidence suggests that selegiline should be given with caution to patients taking, or who have recently stopped, non-selective MAOs. One UK manufacturer of selegiline and the manufacturer of rasagiline actually contraindicate the concurrent use of non-selective MAOs. At least 14 days should elapsed between stopping rasagiline and starting an MAOII.

(b) **RIMAs**

A study in 24 healthy subjects, designed to assess the safety and tolerability of giving moclobemide 100 to 400 mg and selegiline 5 mg twice daily, sequentially or combined, found that the adverse effects were no greater under steady-state conditions than with either drug alone, but the sensitivity to tyramine was considerably increased. The mean tyramine sensitivity factor for moclobemide alone was 2 to 3, selegiline alone was 1.4, and moclobemide plus selegiline was 8 to 9 (and even 18 in one subject). The reason is, that when taken together, the moclobemide inhibits MAO-A while selegiline inhibits MAO-B, so that little or no MAO activity remains available to metabolise the tyramine. However, unexpectedly, the combined effect was more than additive. Selegiline had no effect on the pharmacokineti of moclobemide. In a clinical trial using tyramine restriction, one of 5 selegiline recipients and one of 5 selegiline/moclobemide recipients reported symptomatic hypotension, and there was no increase in blood pressure in any patient.

In practical terms this means that patients taking moclobemide with selegiline should be given the same dietary restrictions for tyramine-rich foods and drinks (see ‘tyramine-rich foods’, (p.1151) and ‘tyramine-rich foods’, (p.1153)), that relate to the non-selective MAOs such as phenelzine and tranylcypromine. However, because of the potential risks the manufacturer of moclobemide contraindicates this combination. On the basis of work done on the pig it is suggested that if selegiline is replaced by moclobemide, the dietary restrictions can be relaxed after a wash-out period of about 2 weeks. If switching from selegiline to moclobemide, a wash-out period of 1 to 2 days is sufficient.

**MAO-B inhibitors + Dextromethorphan**

The manufacturer of rasagiline suggests that its use with dextromethorphan should be avoided. Similarly, some consider that patients taking selegiline should try to avoid dextromethorphan. These warnings are based on the serious adverse reactions (the serotonin syndrome or similar) that have rarely occurred when dextromethorphan has been used with non-selective MAOIs or RIMAs.

**References**

MAO-B inhibitors + Pethidine (Meperidine)

A case of fluctuating stupor and agitation, with muscle rigidity, sweating and a raised temperature has been reported when pethidine was used with selegiline. This case is similar to cases reported with the older non-selective MAOIs or RIMAs and pethidine. The manufacturers say that selegiline and rasagiline should not be used with pethidine.

Clinical evidence, mechanism, importance and management

A patient taking selegiline 5 mg twice daily, pergolide, levodopa/carbidopa, imipramine and desipramine was treated with pethidine beginning on postoperative day one for 4 days in doses of 75 to 150 mg daily. On the second day he became increasingly restless and irritable, progressing to delirium on the fourth day, with fluctuations between stupor and severe agitation associated with muscular rigidity, sweating and a raised temperature. The patient remained normotensive. Both pethidine and then selegiline were stopped, with full recovery.1 This case is similar to various cases described with ‘older nonselective MAOI inhibitors and pethidine’, see (p.1140). US information states that other serious reactions including death have occurred with the combination of selegiline and pethidine.2

On the basis of this evidence the manufacturers of selegiline3 and rasagiline4 contraindicate concurrent use with pethidine, which is a prudent precaution. The manufacturers of rasagiline additionally say that pethidine should not be given until 14 days after stopping rasagiline,4 which makes sense since it is an irreversible inhibitor of MAO-B. One manufacturer of selegiline also cautions that tramadol may potentially interact with selegiline,5 which seems a possibility based on evidence of an interaction between ‘tramadol and non-selective MAOIs’. (p.1141). Another manufacturer of selegiline contraindicates concurrent use with all opioids,6 which is probably unnecessary, based on the evidence with non-selective MAOIs, see ‘MAOIs or RIMAs + Opioids; Pethidine (Meperidine)’, p.1140.

5. Elderyl (Selegiline hydrochloride). Orion Pharma (UK) Ltd. UK Summary of product characteristics, July 2006.

MAO-B inhibitors + Tyramine-rich foods

No dietary restrictions are required with the doses of rasagiline and selegiline recommended for use in Parkinson’s disease. An isolated report describes the cheese reaction in a patient taking selegiline 20 mg daily. Thus, at higher doses of selegiline, restriction of the amount of tyramine in the diet may be necessary.

Clinical evidence

(a) Rasagiline

The manufacturer notes that the results of four tyramine challenge studies, together with the results of home monitoring of blood pressure after meals (from 464 patients treated with rasagiline 0.5 mg or 1 mg daily or placebo without tyramine restrictions), and the lack of reported problems in clinical trials without tyramine restriction, indicate that no dietary restrictions are necessary with rasagiline.1 No specific details were provided of any of the studies.

(b) Selegiline

1. Oral selegiline. The pressor response to oral tyramine was not altered by pretreatment with selegiline 10 mg daily in healthy volunteers and patients with Parkinson’s disease.2 However, another study3 found that selegiline 5 mg daily for at least 14 days reduced the dose of oral tyramine required to achieve the cardiovascular threshold (increase in systolic BP of greater than 30 mmHg, a diastolic BP greater than 100 mmHg or a fall in heart rate of greater than 20%) by a factor of 2.8. Nevertheless, this reduction was less than the RIMA moclobemide (4.3) and the MAOI phenelzine (10.3).3 In other studies, higher doses of selegiline (20 or 30 mg daily) increased the sensitivity to oral tyramine by 2- to 4.5-fold.4,5 A patient taking selegiline 20 mg daily was reported to have had a hypertensive reaction (severe headache and rise in blood pressure) after eating macaroni and cheese,6 but this appears to be the only published report of the ‘cheese reaction’ with selegiline.

2. Buccal and transdermal selegiline. The dose of tyramine required to elicit a pressor effect was not altered by pretreatment with buccal selegiline 1.25 mg in healthy subjects.2 Similarly, the pressor response to tyramine up to 200 mg was not significantly altered by pretreatment with a single 24-hour application of transdermal selegiline 7.8 mg/24 hour in healthy subjects.8

Mechanism

Rasagiline and selegiline specifically inhibit MAO-B, which leaves MAO-A still available to metabolise any tyramine in foodstuffs. However, at higher doses the selectivity of selegiline diminishes, and inhibition of the metabolism of tyramine is more likely. Nevertheless, the 2- to 4.5-fold increase in effect of tyramine seen with selegiline 5 to 30 mg daily is still
less than that seen with older non-selective MAOIs, see ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153.

Importance and management

The manufacturer states that no dietary tyramine restrictions are necessary with rasagiline. 1 Similarly, at the recommended doses of conventional or buccal selegiline used in Parkinson’s disease the manufacturers say that no dietary restrictions are necessary, 9-11 and this is supported by the scarcity of adverse reactions normally caused by tyramine-rich foods. For a list of the possible tyramine-content of some foods, see ‘Table 32.3’, (p.1154).

MAO-B inhibitors; Rasagiline + CYP1A2 inhibitors

Ciprofloxacin increases the AUC of rasagiline. Other inhibitors of cytochrome P450 isozyme CYP1A2 are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturer notes that concurrent use of rasagiline and ciprofloxacin increased the AUC of rasagiline by 83%. Ciprofloxacin inhibits the cytochrome P450 isozyme CYP1A2, which is the major enzyme responsible for the metabolism of rasagiline. The clinical relevance of this increase has not been assessed, but until more is known caution is warranted. This caution should be extended to other potent inhibitors of CYP1A2. For a list see ‘Table 1.2’, (p.4).

MAO-B inhibitors; Selegiline + Dopamine agonists

intravenous cocaine in cocaine-dependent subjects. Some physiological effects (blood pressure and heart rate) and subjective effects of cocaine were attenuated by selegiline. 2

No significant pharmacokinetic interaction occurs between selegiline and cabergoline, pramipexole or ropinirole.

Clinical evidence, mechanism, importance and management

(a) Cabergoline

No pharmacokinetic interaction was found to occur between cabergoline 1 mg daily and selegiline 10 mg daily after 22 days of concurrent use in a study in 6 subjects with Parkinson’s disease. 1

(b) Pramipexole

The manufacturers of pramipexole say that no pharmacokinetic interaction occurs with selegiline. 2

(c) Ropinirole

The manufacturers of ropinirole note that a population pharmacokinetic analysis showed a lack of effect of selegiline on ropinirole. 3

MAO-B inhibitors; Selegiline + Hormonal contraceptives or HRT

In a small study, the bioavailability of selegiline was markedly higher (mean of about 20-fold) in women taking combined oral contraceptives than in those not taking contraceptives. In a controlled study, the AUC of selegiline was modestly increased by HRT (60%) and the change was not considered clinically relevant.

Clinical evidence

(a) Combined oral contraceptives

The AUCs of single doses of selegiline 5 to 40 mg were 16 to 45-fold higher in 4 women taking combined oral contraceptives than in 4 women who were not taking contraceptives. Three subjects were taking ethinylestradiol/gestodene 30/75 micrograms, and one was taking a triphasic preparation of ethinylestradiol/levonorgestrel. 1

(b) HRT

The AUC of a single 10-mg dose of selegiline was increased by 60% (which was not statistically significant) following 10 days of HRT (containing estradiol valerate/levonorgestrel 2 mg/250 micrograms) in a cross-over study in 12 young healthy women. There was marked variability in selegiline levels with two women having a threefold increase in AUC, and 3 having a decrease. Other changes in pharmacokinetics of selegiline or its metabolites were small. 2

Mechanism

It was suggested that the combined oral contraceptive inhibited the first pass metabolism of selegiline and so markedly increased its bioavailability. However, this was not found for HRT containing a different estrogenic hormone.

Cocaine and selegiline appear not to interact adversely.

Clinical evidence, mechanism, importance and management

In a study to establish the safety of using selegiline to prevent relapse in cocaine addiction, 5 otherwise healthy intravenous cocaine users were given 0, 20 and 40 mg intravenous doses of cocaine one hour apart follow- ing treatment with selegiline 10 mg or placebo orally. The cocaine increased the heart rate, blood pressure, pupil diameter and subjective indices of euphoria as expected. However, the presence of selegiline reduced pupilary diameter, but did not alter the pupil dilatation or other effects normally caused by cocaine. It was concluded that concurrent use is safe and unlikely to increase the reinforcing effects of cocaine. 1 In another study, transdermal selegiline did not alter the pharmacokinetics of
Importance and management

Although data are limited, it appears that combined oral contraceptives may markedly increase the bioavailability of selegiline. One UK manufacturer advises caution with combined use, and the other suggests the combination should be avoided.4 Although short-term use of menopausal HRT also increased the AUC of selegiline, the changes were modest and were not considered clinically relevant. Nevertheless, the results perhaps need confirming with longer term combined use. One UK manufacturer of selegiline also advises the avoidance of concurrent HRT.4

![Image](image.png)

MAO-B inhibitors; Selegiline + Itraconazole

The concurrent use of selegiline and itraconazole does not appear to alter the pharmacokinetics of either drug.

**Clinical evidence, mechanism, importance and management**

In a randomised placebo-controlled crossover study, 12 healthy subjects were given selegiline 10 mg after taking itraconazole 200 mg daily for 4 days. Itraconazole did not have any significant effects on the pharmacokinetics of selegiline, although the AUC of desmethylselegiline, a primary metabolite, was increased by 11%. The pharmacokinetics of itraconazole were also unaffected. There would appear to be no reason for avoiding concurrent use.1

egiline pharmacokinetics are unaffected by the CYP3A4 inhibitor itraconazole. *Eur J Clin Pharmaco-

Memantine + Miscellaneous

Drugs that make the urine alkaline (e.g. sodium bicarbonate, carbonic anhydrase inhibitors) will reduce the elimination of memantine. Memantine should be used with caution with other NMDA antagonists, such as amantadine, ketamine and dextromethorphan, or concurrent use should be avoided, because of the theoretical increased risk of adverse effects. Memantine is predicted to interact with other drugs eliminated by the same renal tubular secretion mechanism, but no important interaction was seen. Memantine accumulation and an increase in adverse effects. Drugs that could interact via this mechanism include sodium bicarbonate and carbonic anhydrase inhibitors (such as acetazolamide).1

(f) Interactions via cytochrome P450 isoenzymes

The results of *in vitro* studies indicate that memantine is not likely to cause interactions via induction or inhibition of the major cytochrome P450 isoenzymes involved in drug metabolism (CYP1A2, CYP2C9, CYP3A4).1,2 In addition, memantine is not metabolised by this enzyme system, and is therefore not expected to undergo interactions via this mechanism.1

(g) Other drugs eliminated by renal tubular secretion

Memantine is predicted to interact with other drugs that use the same renal cationic transport system leading to increased levels of memantine and/or the other drug. The manufacturer lists cimetidine, ranitidine, hydrochloro-thiazide, metformin, procainamide, quinidine, quinine and triam-
terene as possible examples.1,2 However, in an interaction study, the concurrent use of memantine and hydrochlorothiazide/trimetorene did not result in any change in the steady-state AUC of memantine or trimet-
terene, and the AUC of hydrochlorothiazide showed a modest reduction of about 20%.1 This degree of change is unlikely to be clinically relevant. Therefore, whether any clinically important interactions occur via this mechanism remains to be established.

2. Ebixa (Memantine). Lundbeck Ltd. UK Summary of product characteristics, November 2006.

Piribedil + Clonidine

Clonidine is reported to oppose the effects of piribedil.

**Clinical evidence, mechanism, importance and management**

A study in 5 patients taking piribedil found that concurrent treatment with clonidine (up to 1.5 mg daily for 10 to 24 days) caused a worsening of the parkinsonism (an exacerbation of rigidity and akinesia). The concurrent use of antimuscarinic drugs reduced the effects of this interaction.1 The reason is uncertain.

Pramipexole + Drugs altering its renal clearance

Cimetidine, and possibly amantadine modestly reduce the clearance of pramipexole from the body, and some caution is advised on concurrent use. Probeneicid had a minor effect on pramipexole clearance, which is not clinically relevant.

**Clinical evidence, mechanism, importance and management**

A study in 12 healthy subjects found that multiple doses of cimetidine reduced the total oral clearance of a single 250-microgram dose of prami-
pexole by about 35% and increased its half-life by 40%. A similar reduction in the renal clearance of pramipexole was noted. The authors suggest that cimetidine reduces the renal excretion of pramipexole by inhibiting the active renal organic cation transport system.1 The manufacturer says that cimetidine and other drugs that are eliminated by this route such as amantadine may interact with pramipexole to reduce excretion of either or both drugs.2 The clinical significance of these interactions is
uncertain, and as yet there appear to be no reports of any adverse interactions. Nevertheless, the manufacturers suggest a reduction of the pramipexole dose should be considered when amantadine or cimetidine are given with pramipexole.²

Multiple doses of probenecid given to 12 healthy subjects reduced the clearance of a single 250-microgram dose of pramipexole by 10.3%.¹ This change is not clinically relevant.

---

Platelets usually circulate in the plasma in an inactive form, but following injury to blood vessels they become activated and adhere to the site of injury. Platelet aggregation then occurs, which contributes to the haemostatic plug. Platelet aggregation involves the binding of fibrinogen with a glycoprotein IIb/IIIa receptor on the platelet surface. The activated platelets secrete substances such as adenosine diphosphate (ADP) and thromboxane A\(_2\) that result in additional platelet aggregation and also cause vasoconstriction. Finally a number of platelet derived factors stimulate production of thrombin and hence fibrin through the coagulation cascade (see ‘The blood clotting process’, (p.358)). Opposing this process is the fibrinolysis pathway, which is initiated during clot formation by a number of mediators such as tissue plasminogen activator (tPA) and urokinase. These proteins convert plasminogen to plasmin, which in turn degrades fibrin, the main component of the clot.

Antiplatelet drugs (see ‘Table 19.1’, (below)) reduce platelet aggregation and are used to prevent thromboembolic events. They act through a wide range of mechanisms including:

- prevention of thromboxane A\(_2\) synthesis or inhibition of thromboxane receptors e.g. aspirin inhibits platelet cyclo-oxygenase, preventing synthesis of thromboxane A\(_2\)
- interference with adenosine diphosphate mediated platelet activation e.g. thienopyridines; inhibition of adenosine reuptake e.g. dipyridamole; interference with adenosine metabolism by inhibiting cyclic adenosine monophosphate (cAMP) phosphodiesterase e.g. cilostazol
- interference in the final step in platelet aggregation by stopping fibrinogen binding with the glycoprotein IIb/IIIa receptor on the platelet surface

Therefore some antiplatelet drugs can have beneficial additive effects with other antiplatelet drugs that act via different mechanisms. Furthermore, other drugs such as dextran, heparin, some prostaglandins and sulfonpyrazone also have some antiplatelet activity.

Thrombolytics (see ‘Table 19.1’, (below)) are used in the treatment of thromboembolic disorders. Thrombolytics activate plasminogen to form plasmin, which is a proteolytic enzyme that degrades fibrin and therefore produces clot dissolution.

This section is primarily concerned with those interactions where the activities of antiplatelet drugs or thrombolytics are changed by the presence of another drug. Note that the interactions of high-dose aspirin are covered under analgesics.

Alteplase + Glyceril trinitrate (Nitroglycerin)

Glyceril trinitrate may reduce the thrombolytic efficacy of alteplase, but this is not thought to be clinically relevant.

Clinical evidence, mechanism, importance and management

In a randomised study, 60 patients with acute anterior myocardial infarction were given intravenous alteplase 100 mg over 3 hours, as well as heparin and aspirin. In addition, 27 of the patients were also given intravenous glyceryl trinitrate 100 micrograms/minute for 8 hours. Patients receiving both alteplase and glyceryl trinitrate had signs of reperfusion less often (56%) than the patients who received alteplase alone (76%). In the combined treatment group time to reperfusion was also longer (37.8 versus 19.6 minutes) and the incidence of coronary artery re-occlusion was higher (53% versus 24%). Giving alteplase with glyceryl trinitrate produced plasma levels of tissue plasminogen activator (tPA) antigen that were about two-thirds lower than when alteplase was given alone.1 Improved thrombolysis has been found in another study2 and also in an earlier study in dogs.3

It was postulated that glyceryl trinitrate increased hepatic blood flow and therefore increased the metabolism of alteplase, which resulted in reduced plasma tPA levels.1 However, an in vitro study found that glyceryl trinitrate enhanced the degradation of alteplase, and therefore a mechanism other than increased hepatic blood flow seems likely to be involved.4 It has been suggested that this interaction may not be clinically important,5 and paired thrombolysis has been found in another study2 and also in an earlier study in dogs.3

Anagrelide + Miscellaneous

Anagrelide should not be used with other phosphodiesterase III inhibitors (e.g. milrinone) because of the potential for increased inotropic effects. Inhibitors of CYP1A2 (e.g. fluvoxamine) are predicted to increase anagrelide levels. Some caution might be required with concurrent aspirin and other platelet inhibitors. Whether anagrelide inhibits theophylline metabolism to a clinically relevant extent is not known. No pharmacokinetic interaction occurs with digoxin or warfarin.

Clinical evidence, mechanism, importance and management

(a) Aspirin

Based on in vitro data, anagrelide could have additive effects with drugs that inhibit platelet function, such as aspirin; although in clinical development no such effects were observed. Nevertheless, the manufacturer recommends that the risk/benefit ratio should be assessed before aspirin is used with anagrelide in patients with a high platelet count (greater than 1500 x 10^9/L) and/or a history of haemorrhage.1

(b) CYP1A2 inhibitors and substrates

Anagrelide is principally metabolised by the cytochrome P450 isoenzyme CYP1A2. Drugs that are inhibitors of this isoenzyme are therefore predicted to reduce the clearance of anagrelide, and the manufacturer specifically names fluvoxamine and omeprazole.1 Be aware that increased effects, both beneficial and adverse, might occur. However, note that omeprazole is only a weak CYP1A2 inhibitor, and would not be expected to have much effect on anagrelide. Grapefruit juice has also been predicted to interact via this mechanism,1 but again, it has little clinically relevant effect on CYP1A2. For a list of CYP1A2 inhibitors, see "Table 1.2", (p.4).

Anagrelide is a weak inhibitor of CYP1A2, therefore be aware that it might interact with CYP1A2 substrates, such as theophylline.1

(c) Digoxin

The manufacturer briefly mentions that there was no pharmacokinetic interaction between digoxin and anagrelide.1

(d) Food

Food delays the absorption of anagrelide, but does not alter the overall amount absorbed. The interaction is not clinically relevant.1

(e) Hydroxycarbamide

In a preclinical study in dogs, there was no pharmacokinetic interaction between hydroxycarbamide and anagrelide, therefore no clinical pharmacokinetic interaction is expected.1

(f) Other phosphodiesterase inhibitors

Anagrelide is a cyclic AMP phosphodiesterase III inhibitor, and consequently has positive inotropic effects. The manufacturer recommends against its concurrent use with other phosphodiesterase III inhibitors, because of the potential increased inotropic effects, and they specifically mention amrinone, cilostazol, enoximone, milrinone, and opipramone.1

(g) Warfarin

The manufacturer briefly mentions that there was no pharmacokinetic interaction between warfarin and anagrelide.1

Antiplatelet drugs + Aspirin

There is an increased risk of bleeding if clopidogrel is given with aspirin, but the use of low-dose aspirin and clopidogrel can be beneficial. Ticlopidine increases the antiaggregant effects of aspirin and there is an increased risk of bleeding on concurrent use. Cilostazol appears not to interact to a clinically relevant extent with low-dose aspirin, and the addition of dipyridamole to aspirin does not appear to increase the incidence of bleeding.

Clinical evidence, mechanism, importance and management

(a) Cilostazol

In a randomised, double-blind, placebo-controlled study involving 11 healthy subjects, cilostazol 100 mg twice daily given with aspirin 325 mg daily for 5 days increased the inhibition of ADP-induced platelet aggregation by 23 to 35% when compared with the use of cilostazol alone, but there were no statistically significant additive effects on arachidonic acid-induced platelet aggregation. In addition, no clinically relevant effects on prothrombin times, aPTT or bleeding times occurred when cilostazol was given with or without aspirin. However, there was a minor 22% increase in the AUC of cilostazol when it was given with aspirin.1 The US manufacturers report that in 8 randomised, placebo-controlled trials, in a total of 201 patients receiving cilostazol and aspirin, the incidence of bleeding was no greater than that seen with aspirin and placebo. The most frequent doses and mean duration of aspirin therapy were 73 to 81 mg daily for 137 days (107 patients) and 325 mg daily for 54 days (85 patients).2

These studies suggest that no special precautions are needed if cilostazol is used concurrently with low-dose aspirin, although note that the UK manufacturer of cilostazol recommends that, when given with cilostazol, the daily dose of aspirin should not exceed 80 mg.3

(b) Clopidogrel

A variety of studies have investigated the beneficial effects of using the combination of aspirin with clopidogrel. Although these studies were primarily designed to assess the benefits of concurrent use they did also report on bleeding events. The key findings were:

• In patients with recent acute coronary syndrome (CURE): an increase in major bleeding events following the use of clopidogrel 75 mg daily with aspirin 75 to 325 mg daily compared with aspirin alone (3.7% versus 2.7%, respectively).3

• In patients with recent stroke or transient ischaemic attack (MATCH): an increase in life-threatening bleeding events following the use of clopidogrel 75 mg daily with aspirin 75 mg daily compared with aspirin alone (2.6% versus 1.3%, respectively).5

• In patients with clinically evident cardiovascular disease or multiple atherosclerotic risk factors (CHARISMA): an increase in the risk of moderate and severe bleeding following the use of clopidogrel 75 mg
daily with aspirin 75 to 162 mg daily compared with aspirin alone (moderate 2.1% and 1.3%, respectively, severe 1.7% and 1.3%, respectively). A study in 7 healthy subjects found that clopidogrel 75 mg and aspirin 150 mg daily for 2 days caused a significant 3.4-fold increase in bleeding time relative to baseline, and when the clopidogrel dose was increased to 300 mg there was a 5-fold increase in bleeding time. Spontaneous haemorrhrosis of the knee has been associated with the concurrent use of aspirin and clopidogrel in one patient. A report describes two cases, which were complicated by bleeding associated with the combination of aspirin and clopidogrel. In both cases the bleeding was delayed, in that it was not obvious until the end of surgery, causing unanticipated surgical re-exploration. Further reports describe increased perioperative bleeding in patients taking both aspirin and clopidogrel.

The manufacturer of clopidogrel warns that the concurrent use of clopidogrel and aspirin should be undertaken with caution because of the increased risk of bleeding, although the two drugs have been given together for up to one year. They recommend that, in patients taking clopidogrel, the dose of aspirin should not exceed 100 mg daily as higher doses are associated with higher bleeding risks. For patients undergoing surgery, it has been suggested that, if possible, the combined use of clopidogrel and aspirin should be discontinued up to 5 days prior to surgery, although note that this needs to be balanced against the possible adverse effects of stopping such treatment.

(a) Clopidogrel
A study in 10 healthy subjects found that dipyridamole 50 mg three times daily given with a single 180-mg dose of aspirin, or dipyridamole 75 mg three times daily given with aspirin 120 mg maximally inhibited platelet functions but did not prolong the bleeding time. The manufacturer of clopidogrel states that the addition of dipyridamole to aspirin does not increase the incidence of bleeding events.

(b) Ticlopidine
Aspirin combined with ticlopidine appears to inhibit platelet aggregation more than either drug alone. The UK manufacturer of ticlopidine warns that combined use increases the risk of bleeding because there is an increase in platelet antiaggregant activity and aspirin also damages the gastro-duodenal lining, which can cause bleeding. They recommend that clinical monitoring is advisable.

Importance and management
Patients taking bupropion may require dose adjustments if they also take clopidogrel or ticlopidine. Until more is known about this interaction it would seem prudent to monitor for increased bupropion adverse effects (lightheadedness, gastrointestinal effects) and efficacy.

Mechanism
The reduction in bupropion hydroxylation is due to inhibition of its cytochrome P450 isoenzyme CYP2B6-mediated metabolism by clopidogrel or ticlopidine.

Clinical evidence
(a) Clopidogrel
A study in healthy subjects given clopidogrel 75 mg once daily for 4 days found that the AUC of a single 150-mg dose of bupropion was increased by 60% and the AUC of its active metabolite, hydroxybupropion was reduced by 52%.

(b) Ticlopidine
A study in healthy subjects given ticlopidine 250 mg twice daily for 4 days found that the AUC of a single 150-mg dose of bupropion was increased by 85% and the AUC of its active metabolite, hydroxybupropion was reduced by 84%.

Ginkgo biloba has been associated with platelet, bleeding and clotting disorders and there are isolated reports of serious adverse reactions after its concurrent use with antiplatelet drugs such as aspirin, clopidogrel and ticlopidine. An animal study suggests that Ginkgo biloba may also enhance the antithrombotic effects of ticlopidine.

Clinical evidence
(a) Ginkgo biloba
A 70-year-old man developed spontaneous bleeding from the iris into the anterior chamber of his eye within a week of starting to take a Ginkgo biloba tablet twice daily. He experienced recurrent episodes of blurred vision in one eye lasting about 15 minutes, during which he could see a red discol-
2 years along with other medications. Another report was of a stroke in a patient taking multiple drugs including clopidogrel, aspirin and a herbal product containing ginkgo.5

(b) Kangen-Karyu

Kangen-Karyu is a Chinese traditional herbal medicine used for ‘blood stasis’. A study in animals suggested that Kangen-Karyu may augment the antiplatelet and antithrombotic effects of ticlopidine and that the dosage of ticlopidine should be reduced to prevent adverse effects such as thrombotic thrombocytopenic purpura or haemorrhage.4

Mechanism

The reason for the bleeding is not known, but Ginkgo biloba extract contains ginkgolide B, which is a potent inhibitor of platelet-activating factor, which is needed for arachidonate-independent platelet aggregation. On their own, Ginkgo biloba supplements have been associated with prolonged bleeding times,5,6 left and bilateral subdural haematomas,5,7 a right parietal haematoma,7 post-laparoscopic cholecystectomy bleeding,5 and subarachnoid haemorrhage.7 The authors of the first report suggest that the use of aspirin, which is also an inhibitor of platelet aggregation, may have had an additional part to play in what happened.

Importance and management

The evidence from these reports is too slim to forbid patients taking aspirin, clopidogrel or ticlopidine and Ginkgo biloba concurrently, but some do recommend caution,10 which seems prudent. Medical professionals should be aware of the possibility of increased bleeding tendency with Ginkgo biloba, and report any suspected cases.8 Consider also ‘NSAIDs + Ginkgo biloba’, p.148. Similarly caution would seem prudent if Kangen-karyu is used with any antiplatelet drug.

Antiplatelet drugs + NSAIDs

The manufacturers of clopidogrel warn about possible gastrointestinal bleeding if it is used with naproxen or other NSAIDs. There is also an increased risk of bleeding if ticlopidine is given with NSAIDs.

Clinical evidence, mechanism, importance and management

(a) Clopidogrel

A double-blind, placebo-controlled study in 30 healthy subjects given naproxen 250 mg twice daily, found that the addition of clopidogrel 75 mg daily increased faecal blood loss compared with naproxen alone. Six subjects receiving both drugs had bleeding time prolongation factors above 5, which was greater than expected (clopidogrel alone prolongs bleeding by a factor of about 2) and one subject had subcutaneous haemorrhages of moderate intensity after taking clopidogrel with naproxen.1 A report describes intracerebral haemorrhage in an 86-year-old woman after taking celecoxib 200 mg daily with clopidogrel 75 mg daily for 3 weeks. The authors comment that there may possibly have been a pharmacokinetic interaction between clopidogrel and celecoxib mediated via the cytochrome P450 isoenzyme CYP2C9, although the haemorrhage could have been secondary to other factors such as age or the individual drugs.2

Due to the lack of interaction studies with other NSAIDs, it is unclear whether there is an increased risk of gastrointestinal bleeding with all NSAIDs. The manufacturers advise caution if NSAIDs and clopidogrel are given together.3,4

(b) Ticlopidine

The UK manufacturer of ticlopidine warns that concurrent use of NSAIDs increases the risk of bleeding because there is an increase in platelet antiaggregant activity and because NSAIDs damage the gastro-duodenal lining, which can cause bleeding. They recommend that if NSAIDs are necessary, close clinical monitoring is advisable.5

Cilostazol + Clopidogrel

In one study clopidogrel slightly increased levels of cilostazol, without altering platelet count, aPTT, or prothrombin time. However, the effect of concurrent use on bleeding time was not assessed.

Clinical evidence, mechanism, importance and management

The concurrent use of cilostazol 150 mg twice daily and clopidogrel 75 mg daily for 5 days increased the AUC of cilostazol by only 9%, but increased the AUC of the dehydro metabolite of cilostazol by 24% (this metabolite has 3 to 4 times the potency of cilostazol in inhibiting platelet aggregation). No changes in platelet count, prothrombin time or aPTT were seen. However, clopidogrel alone prolonged bleeding time, and it was not possible to determine whether there was an additive effect with cilostazol.6

The UK manufacturer suggests caution if cilostazol is given with any drug that inhibits platelet aggregation, and say that consideration should be given to monitoring the bleeding time at intervals.1

Cilostazol + Food

Food increases the bioavailability of cilostazol, which may increase adverse effects.

Clinical evidence, mechanism, importance and management

A randomised, single-dose, crossover study in 15 healthy subjects found that giving cilostazol 100 mg within 10 minutes of a high fat meal caused an increase in the rate and extent of cilostazol absorption. The maximum plasma concentration of cilostazol was increased by about 95%, but the half-life decreased from 15.1 to 5.4 hours, when compared with the fasted state.1 The manufacturer recommends that cilostazol should be taken 30 minutes before or 2 hours after food, because the increase in maximum plasma concentrations of cilostazol when taken with food may be associated with an increased incidence of adverse effects.2,3

Cilostazol + Miscellaneous

Erythromycin, diltiazem and ketoconazole, all inhibitors of the cytochrome P450 isoenzyme CYP3A4, increase the plasma levels of cilostazol. Other inhibitors of CYP3A4 are predicted to interact similarly, but grapefruit juice does not appear to interact significantly. Cilostazol may increase the levels of lovastatin and other substrates of CYP3A4 (and possibly CYP2C19).

Omeprazole, an inhibitor of CYP2C19, increases the bioavailabil-
Clinical evidence, mechanism, importance and management

(a) CYP2C19 inhibitors

In a crossover study 1 in 20 healthy subjects omeprazole 40 mg daily for one week increased the AUC of a single 100-mg dose of cilostazol by a modest 26%. More importantly, the AUC of 3,4-dehydro-cilostazol (a metabolite with 4 to 7 times the activity of cilostazol) was increased by 69%.2,3 Omeprazole inhibits the cytochrome P450 isoenzyme CYP2C19, which is involved in the metabolism of cilostazol, and may possibly also affect the elimination of the active metabolite. For this reason the US manufacturers suggest that the dose of cilostazol should be halved when given with omeprazole;2 while the UK manufacturers contraindicate concurrent use.4 Other CYP2C19 inhibitors such as lanzoprazole may also interact, and therefore concurrent use is contraindicated by the UK manufacturers. The manufacturers also recommend caution with drugs that are substrates of CYP2C19.5

(b) CYP3A4 inhibitors

A study in 16 healthy subjects found that erythromycin 500 mg three times daily increased the maximum plasma level and the AUC of a single 100-mg oral dose of cilostazol by 47% and 73%, respectively. Erythromycin inhibits the cytochrome P450 isoenzyme CYP3A4, by which cilostazol is metabolised, thereby raising its plasma levels.4 Other macrolide antibacterials e.g. clarithromycin (but not azithromycin) would be expected to have a similar effect.2 Diltiazem is also a moderate inhibitor of CYP3A4. When diltiazem 180 mg daily was given with cilostazol 100 mg twice daily the AUC of cilostazol was increased by about 40%.2,3 In a single-dose study, ketoconazole 400 mg caused a greater than two-fold increase in the AUC of cilostazol.5 Other potent CYP3A4 inhibitors such as itraconazole are expected to interact similarly.2

In view of these effects the US manufacturers suggest halving the dose of cilostazol in the presence of CYP3A4 inhibitors such as erythromycin, diltiazem, itraconazole, and ketoconazole.6 However, the UK manufacturers contraindicate CYP3A4 inhibitors, and they specifically name erythromycin, diltiazem, ketoconazole, cimetidine, and the protease inhibitors.7 Just why these recommendations differ is not clear. The US manufacturers suggest that other CYP3A4 inhibitors, such as azole antifungals (fluconazole, miconazole), SSRIIs (fluoxetine, fluvoxamine, sertraline) and nefazodone, may also interact.2

(c) Grapefruit juice

Grapefruit juice has been predicted to increase the levels of cilostazol by inhibiting CYP3A4.8 However, the UK manufacturers note that 240 mL of grapefruit juice did not have a notable effect on the pharmacokinetics of cilostazol and it is therefore suggested that this enzyme does not play a significant role in the metabolism of cilostazol or its primary metabolites.4

(d) Lovastatin and other substrates of CYP3A4

In a study in 13 healthy subjects, a single 80-mg oral dose of lovastatin was given before, and then on the final day of a 7-day treatment period with cilostazol 100 mg twice daily. The AUCs of lovastatin and its beta-hydroxy acid metabolite were increased by about 60 and 70%, respectively by cilostazol, but the maximum plasma levels were unaffected.9 At the end of this study (day 9), 12 subjects were given lovastatin 80 mg with a larger 150-mg dose of cilostazol. It was found that the maximum level and the AUC of the lovastatin metabolite were increased by about twofold, suggesting that larger cilostazol doses may have a greater effect.2 Lovastatin is metabolised by the cytochrome P450 isoenzyme CYP3A4 and although cilostazol can inhibit this enzyme, in vitro studies indicate that this occurs only at concentrations several times greater than those found therapeutically. The increases in lovastatin levels described here are lower than those seen with potent CYP3A4 inhibitors (e.g. see ‘Statins + Azoles’, p.1093) but the authors of the study still suggest that the dose of lovastatin may need to be reduced if cilostazol is also taken. Lovastatin decreased the absorption of cilostazol by about 15%, but this was not considered to be clinically relevant.5

The UK manufacturers advise caution when cilostazol is given with drugs that are substrates of CYP3A4 (espied),9 beta blockers, calcium-channel blockers, coronary or peripheral vasodilators, diuretics and HRT have been safely given with cilostazol.6 No special precautions would therefore seem necessary when clopidogrel is given with any of these drugs.

Clinical evidence, mechanism, importance and management

Two studies, one in 12 healthy subjects (average age 67 years) and the other in 12 healthy subjects (average age 23 years), found that the bioavailability of a single 75-mg dose of clopidogrel remained unchanged when it was taken with food or 1 hour after two 400-mg tablets of aluminimum/magnesium hydroxide.3 Another study found that clopidogrel is metabolised by the cytochrome P450 isoenzyme CYP2D6, and that the pharmacodynamics of clopidogrel do not appear to be affected by digoxin.4 One study found that the inhibition of platelet aggregation by clopidogrel was not reduced by acetylsalicylate.1 Data from the CAPRICE study and other clinical studies showed that ACE inhibitors, antidiabetics (insulin, tolbutamide named),3 antiepileptics (phenytoin, named),4 beta blockers, calcium-channel blockers, coronary or peripheral vasodilators, diuretics and HRT have been safely given with clopidogrel.6 No special precautions would therefore seem necessary when clopidogrel is given with any of these drugs.
Clopiprodrel + Statins

Some evidence suggests that atorvastatin, and possibly other CYP3A4-metabolised statins (e.g. simvastatin) may interfere with the antiplatelet actions of clopidogrel, but the data is conflicting and there is currently insufficient evidence to warrant changing practice.

Clinical evidence

Some studies have shown that statins metabolised by CYP3A4 (most notably atorvastatin) can cause a reduction in the antiplatelet activity of clopidogrel, especially during the initial stages of treatment (following the loading dose of clopidogrel), whereas other, mainly retrospective, studies have found no clinical evidence of reduced efficacy. However, the studies are difficult to compare as some have measured platelet function using different techniques and other studies are based on clinical outcome using varying lengths of treatment and end points. Furthermore, up to 25% of patients may not respond at all to clopidogrel and this seems unrelated to treatment with a statin.1

Dose may be an important factor as to whether or not a significant clinical interaction occurs. One study found that a high loading dose of clopidogrel (600 mg) was not affected by statins,2 but there is increased risk of serious bleeding with this dose. Lower doses of statins (e.g. atorvastatin 10 mg daily)3 also appear to be less likely to interact, and one study found that the effect was dose-dependent.4

Some studies have found that atorvastatin attenuates the antiplatelet activity of clopidogrel in patients undergoing coronary artery stenting, 4, 6 or balloon angioplasty.5 However, other studies have found no evidence of an interaction.1, 3, 12 Furthermore, one of the studies reporting an interaction4 has been criticised for, among other things, being small, non-randomised, and using poorly defined study groups.

Simvastatin has also been found to reduce the effects of clopidogrel in patients undergoing coronary artery stenting or balloon angioplasty,6 although other studies have found no interaction.2, 11 The situation with pravastatin is clearer, as several studies have reported a lack of an interaction.2, 5, 7, 8, 11, 12 and there do not appear to be any studies suggesting that an interaction occurs. Similarly, studies including cerivastatin, lovastatin,7, 8, 10 fluvastatin,5, 7, 8, 11 or rosuvastatin9 suggest that they do not interact with clopidogrel. Furthermore, a prospective single centre cohort study in 1651 patients with acute coronary syndromes found that clopidogrel plus a statin was associated with lower 6-month mortality and morbidity compared with the use of clopidogrel alone. There was no significant difference in clinical benefit between a statin predominantly metabolised by the cytochrome P450 isozyme CYP3A4 (said to be atorvastatin, cerivastatin, lovastatin, simvastatin) or a statin not predominantly metabolised by CYP3A4 (fluvastatin, pravastatin, rosuvastatin).13 Similarly, a retrospective examination of data from the CREDO trial suggested that there was no difference in 1-year outcomes in patients given atorvastatin or pravastatin.9 Despite this, some commentators have suggested that there were actually differences at the 28-day endpoint14 and a trend towards differences in the 1-year outcome,15 and suggest that an interaction may therefore have occurred.

Mechanism

Clopidogrel is an inactive prodrug that is metabolised mainly in the liver. The cytochrome P450 isozyme CYP3A4 appears to be primarily responsible for the metabolism and activation of clopidogrel, although other isozymes are also involved. Several statins, including atorvastatin, are also metabolised by CYP3A4 and it has been suggested that these statins may competitively inhibit the activation of clopidogrel.16 However, it has been suggested that the expression and/or activity of CYP3A4 can vary widely between individuals and this, rather than an interaction, may conceivably lead to individual variation in metabolism.14 The effect of CYP3A4-metabolised statins on the antiplatelet effects of clopidogrel may occur only in the loading phase of therapy (within the first 24 hours). It has been suggested that the lack of an interaction in maintenance treatment may be due an adaptation of platelet function or the metabolic capability of the liver or possibly due to upregulation of CYP3A4 in the liver.17

Importance and management

The picture is quite confused and by no means conclusive. Even though the statins metabolised by CYP3A4 appear to reduce the antiplatelet effect of clopidogrel, the overall clinical effect is unclear. The beneficial properties of statins may offset any attenuating effects on the antiplatelet action of clopidogrel.18 Nevertheless, it has been suggested that higher doses of atorvastatin, and perhaps simvastatin, should not be prescribed for patients taking clopidogrel, particularly patients recovering from acute coronary syndrome, stent implantation (particularly a drug-eluting stent), or brachytherapy. The pravastatin or rosuvastatin may be preferred in these patients.15 However, other workers have said, given the marginal interference and high variability, until there is evidence to change clinical practice, there is no need to discontinue the statin use during clopidogrel treatment or to prefer hydrophilic statins in patients with clopidogrel comedication.1, 19, 20

Further prospective studies are needed to determine whether a clinically significant interaction exists. Until then, a change in practice does not seem justified.

8. Saw J, Steinshubl SR, Berger PB, Kereiaakis DJ, Serebruany VL, Brennan D, Topol EF; for the Clopidogrel for the Reduction of Events During Observation (CREDO) Investigators. Lack of adverse reactions normally occur in patients taking beta blockers who undergo dipyridamole–thallium-201 scintigraphy and echocardiography, but case reports suggest that very rarely bradycardia and asystole can occur.

Dipyridamole + Beta blockers

No adverse reactions normally occur in patients taking beta blockers who undergo dipyridamole–thallium-201 scintigraphy and echocardiography, but case reports suggest that very rarely bradycardia and asystole can occur.
Clinical evidence
A 71-year-old woman taking **nadolol** 120 mg daily and bendroflumethiazide, with a 3-week history of chest pain, was given a 300-mg dose of oral dipyridamole as part of a diagnostic dipyridamole-thallium imaging test for coronary artery disease. She was given thallium-201 intravenously, 50 minutes after the dipyridamole, but 3 minutes later, while exercising, she complained of chest pain and then had a cardiac arrest. She was given cardiopulmonary resuscitation and a normal cardiac rhythm was obtained after she was given intravenous aminophylline.1

Adverse interactions occurred in another 2 patients taking beta blockers during diagnostic dipyridamole-thallium stress testing. One patient, who was taking **atenolol**, developed bradycardia then asystole, which was treated with aminophylline and atropine, and the other patient, who was taking **metoprolol**, developed bradycardia, which resolved after she was given aminophylline.2

These reports need to be set in a broad context. A very extensive study of high-dose dipyridamole echocardiography (10 451 tests in 9 122 patients) noted significant adverse effects in only 96 patients, with major adverse reactions occurring in just 7 patients. Three of the 7 developed asystole and two of these patients were taking unnamed beta blockers.3

Mechanism
Not established. One possible explanation is that both drugs have negative chronotropic effects on the heart.

Importance and management
The value and safety of dipyridamole perfusion scintigraphy and echocardiography have been very extensively studied in very large numbers of patients, and reports of bradycardia and asystole, attributed to an interaction between dipyridamole and beta blockers, are sparse. It would therefore appear to be a relatively rare interaction (if such it is).

Dipyridamole + Drugs that affect gastric pH

The effective disintegration, dissolution and eventual absorption of dipyridamole in tablet form depends upon having a low pH in the stomach. Drugs that raise the gastric pH significantly are expected to reduce the bioavailability of dipyridamole.

Clinical evidence, mechanism, importance and management
The solubility of dipyridamole depends very much on the pH. It is very soluble at low pH values and almost insoluble at neutral pH.1 This indicates that dipyridamole needs a low pH in the stomach if solid formulations of the drug are to disintegrate and dissolve adequately. A study in 11 healthy elderly subjects (6 control subjects with a low fasting gastric pH and 5 achlorhydric subjects with fasting gastric pH greater than 5) found that elevated gastric pH reduced the absorption of a single 50-mg oral dose of dipyridamole. In addition, pretreatment with **famotidine** 40 mg increased the gastric pH to above 5 for at least 3 hours, which resulted in reduced dipyridamole absorption. The dipyridamole AUC was reduced by 37% (not statistically significant) and the maximum serum levels were significantly delayed and reduced.2 In another study 20 healthy subjects were given **lansoprazole** 30 mg daily for 5 days and then either:

- a single dose of an extended release preparation of dipyridamole 200 mg with aspirin 25 mg (formulated with tartaric acid to improve bioavailability of dipyridamole if the gastric pH is elevated)
- or a conventional dipyridamole formulation (100 mg given with 81 mg of aspirin, followed 6 hours later by another dose of dipyridamole).

In the presence of **lansoprazole** (gastric pH greater than 4) the relative bioavailability of dipyridamole with conventional tablets was about 50% of that with the buffered extended release tablets.3

A consequential conclusion is that any drug that raises the stomach pH significantly would be likely to reduce the dissolution and absorption of dipyridamole. It would therefore be reasonable to expect that proton pump inhibitors, H₂-receptor antagonists and possibly antacids, which can raise the gastric pH, would interact to reduce the bioavailability of dipyridamole. Further study is needed to find out whether this is a clinically relevant interaction or not.

Dipyridamole + Irbesartan

A study in 13 patients with coronary artery disease found that irbesartan 150 mg daily reduced the extent and severity of perfusion defects after dipyridamole-induced stress.1

Dipyridamole + Xanthines

Caffeine (in tea, coffee, cola, etc.) may interfere with dipyridamole–thallium-201 scintigraphy tests. Similarly, theophylline can also reduce some of the effects of dipyridamole.

Clinical evidence, mechanism, importance and management
Caffeine 4 mg/kg intravenously (roughly equivalent to 2 to 3 cups of coffee), given before dipyridamole–thallium-201 myocardial scintigraphy, caused a false-negative test result in a patient.1 A further study in 8 healthy subjects confirmed that **caffeine** inhibits the haemodynamic response to an infusion of dipyridamole.2 Similarly, oral **theophylline** markedly reduced the diagnostic accuracy of myocardial imaging using dipyridamole.3 In addition, intravenous **aminophylline** accelerated the myocardial washout rate of thallium-201 after a dipyridamole infusion.4

It appears that xanthine derivatives such as **caffeine** and **theophylline** might antagonise some of the haemodynamic effects of dipyridamole because they act as competitive antagonists of adenosine (an endogenous vasodilator involved in the action of dipyridamole).5,6 Due to these opposing effects, parenteral **aminophylline** has been used to treat adverse events associated with intravenous dipyridamole.5,6 and it is recommended that **aminophylline** should be made available before beginning dipyridamole echocardiography.6,7

Patients should therefore abstain from **caffeine** (tea, coffee, chocolate, cocoa, cola, caffeine-containing analgesics etc.)1,2,7 and other xanthine derivatives such as **theophylline** for 24 hours2,8 before dipyridamole testing, and if during the test the haemodynamic response is low (e.g. no increase in heart rate) the presence of **caffeine** should be suspected.4

Glycoprotein IIb/IIIa antagonists + Drugs that affect coagulation

The risk of bleeding with glycoprotein IIb/IIIa antagonists may be increased by heparin and thrombolytics, but low-dose thrombolytic therapy appears less likely to cause a problem.
Clinical evidence, mechanism, importance and management

(a) Abciximab

Although the manufacturers of abciximab recommend concurrent therapy with heparin, they also report that there is an increase in the incidence of bleeding.1,2 A retrospective analysis of 103 patients who presented with acute myocardial infarction and underwent angioplasty with adjunctive abciximab therapy, found that there was a significant increase in major bleeding complications when abciximab was used with full-dose alteplase. A major bleed occurred in 5 of 22 (23%) patients who underwent angioplasty within 15 hours of receiving thrombolytic therapy compared with 0 of 36 patients who underwent elective angioplasty more than 15 hours after fibrinolysis, and 1 of 45 (2%) without prior fibrinolysis. However, the combination of abciximab with low-dose reteplase appeared not to result in the haemorrhagic complications associated with full-dose fibrinolytic therapy, and no increase in bleeding complications were reported in studies using reduced-dose thrombolytic therapy with full-dose abciximab.3,6

The manufacturer of abciximab recommends caution when it is used with other drugs that affect haemostasis, such as heparin, warfarin, thrombolytics and antiplatelet drugs other than aspirin, such as dipyridamole and ticlopidine.1,2

(b) Eptifibatide

In an acute myocardial infarction study involving 181 patients, eptifibatide at the highest infusion rates studied (1.3 and 2 micrograms/kg per minute) appeared to increase the risk of bleeding when given with streptokinase 1.5 million units over 60 minutes. However, the manufacturers state that data on the use of eptifibatide in patients receiving thrombolytics are limited, and in a percutaneous coronary intervention study and an acute myocardial infarction study there was no consistent evidence that eptifibatide increased the risk of major or minor bleeding associated with alteplase.7,8

The UK manufacturer of eptifibatide reports that concurrent use with warfarin and dipyridamole did not appear to increase the risk of major and minor bleeding, and the use of heparin is recommended, but they warn that if eptifibatide is given with heparin, there must be careful monitoring including the aPTT.

Caution must be employed when eptifibatide is used with other drugs that affect haemostasis, including clopidogrel, ticlopidine, dipyridamole, oral anticoagulants or thrombolytics and concurrent or planned use of another glycoprotein IIb/IIIa inhibitor is contraindicated.7,8

Streptokinase + Other thrombolytics

The thrombolytic effects of streptokinase or anistreplase are likely to be reduced or abolished if they are given some time after a dose of streptokinase because of persistently high levels of streptokinase antibodies. There is also an increased risk of hypersensitivity reactions. This may also be true for urokinase.

Clinical evidence

A study in 25 patients who had been given streptokinase for the treatment of acute myocardial infarction, found that 12 weeks later, 24 patients had enough anti-streptokinase antibodies in circulation to neutralise an entire 1.5 million unit dose of streptokinase. After 4 to 8 months, 18 out of 20 still had enough antibodies to neutralise half of a 1.5 million unit dose of streptokinase.1 Further study has suggested that after streptokinase use, anti-streptokinase antibodies fall within 24 hours, but then increase gradually and are significantly raised by 4 days after treatment. The antibody titres reach a peak (approximately 200 times that of pretreatment levels) after 2 weeks and then subsequently decline, but remain above baseline values for at least one year.2 Antibody titres may remain high enough to neutralise the effects of streptokinase for several years after a dose,3,4 and high titres persisting for up to 7.5 years have been reported.5 However, in contrast, another study found that the neutralising antibody titres had returned to control levels by 2 years.6 Increased titres of streptokinase antibodies have also been seen in patients receiving topical streptokinase for wound care,7 intrapleural streptokinase for pleural effusions,8 and following streptococcal infections.9 Apart from the reduced thrombolytic effect, repeated dosing10 or high pre-treatment anti-streptokinase antibody titres11 may increase the risk of allergic reactions.

Anistreplase, like its parent drug streptokinase, has been shown to be neutralised by anti-streptokinase antibodies.12,13 Of 6 patients given urokinase 1.5 million units infused over 30 minutes for recurrent myocardial infarction, rigors occurred in 4 patients and 2 of these also had bronchospasm; they had all previously received streptokinase.14

Mechanism

Streptokinase use causes the production of anti-streptokinase antibodies. These persist in the circulation so that the clot-dissolving effects of another dose of streptokinase given many months later may be ineffective, or less effective, because it becomes bound and neutralised by the antibodies. Many people already have a very low titre of antibodies resulting from previous streptococcal infections, yet this does not usually appear to influence thrombolysis.15

Importance and management

The interaction that results in neutralisation of the thrombolytics is established and clinically important. One author16 says that clinically, therapy is not repeated within a year as it would not work. Given that it has been suggested that the effects may be very persistent, it would seem prudent, if a second use is needed, to use a thrombolytic with less antigenic effects such as alteplase. The British National Formulary says that streptokinase should not be used again beyond 4 days of the first use of either streptokinase or anistreplase.17 In addition, the manufacturer recommends avoidance of streptokinase in patients who have had recent streptococcal infections that have produced high anti-streptokinase titres, such as acute rheumatic fever or acute glomerulonephritis.

Little is known about the increased risk of hypersensitivity reactions.18

4. Lee HS, Cross S, Davidson R, Reid T, Jennings K. Raised levels of antistreptokinase antibody and neutralization titres from 4 days to 54 months after administration of streptokinase or anistreplase. *Eur Heart J* (1993) 14, 84–9.

---

**Ticlopidine + Miscellaneous**

Ticlopidine-induced increases in bleeding times are opposed by methylprednisolone and prednisolone but its effects on platelet function are not affected. Ticlopidine decreases the clearance of phenazine (antipyrine), which suggests that it has mild enzyme-inhibiting effects. Beta blockers, calcium-channel blockers and diuretics are reported not to interact with ticlopidine.

**Clinical evidence, mechanism, importance and management**

(a) **Corticosteroids**

A study involving 14 healthy subjects found that a single 20-mg intravenous injection of methylprednisolone or oral prednisolone 15 mg twice daily for 7 days decreased the prolongation of bleeding times caused by ticlopidine 250 to 500 mg twice daily for 7 days. However, the antiplatelet effects of ticlopidine were not affected. The clinical importance of this interaction is uncertain.

(b) **Phenazine (Antipyrine)**

A study in 10 healthy subjects found that ticlopidine 250 mg twice daily for 3 weeks decreased the clearance of phenazone (a marker of enzyme inhibition or induction). The AUC increased by 14% and the half-life increased by 27%, suggesting that ticlopidine has some mild enzyme-inhibiting effects. This is consistent with the way ticlopidine appears to inhibit the metabolism of ‘theophylline’, but so far no other drugs seem to be affected to a clinically important extent.

(c) **Non-interacting drugs**

The manufacturers of ticlopidine report that in clinical studies in which ticlopidine was given with beta blockers, calcium-channel blockers and diuretics [none of the individual drugs named], no clinically significant adverse interactions were reported.

---

**Ticlopidine + Antacids or Food**

Food causes a moderate increase, and *Maalox* causes a moderate decrease, in the absorption of ticlopidine.

**Clinical evidence, mechanism, importance and management**

In a study in 12 healthy subjects the extent of absorption of a single 250-mg dose of ticlopidine was increased by 20% and occurred more rapidly when ticlopidine was taken after food, when compared with the fasting state. In contrast, 30 mL of *Maalox* [aluminium/magnesium hydroxide] reduced the extent of ticlopidine absorption by about 20%. These modest changes are unlikely to be of much clinical importance.

---

The interactions where the effects of antipsychotic, anxiolytic and hypnotic drugs are affected are covered in this section but there are other monographs elsewhere in this publication where the effects of other drugs are altered by a benzodiazepine or antipsychotic.

(a) Antipsychotics

The antipsychotics are represented by chlorpromazine (and other phenothiazines), haloperidol (and other butyrophenones) and thioxanthenes, and the atypical, or newer, antipsychotic drugs, such as clozapine and risperidone. Their major use is in the treatment of psychoses such as schizophrenia and mania. These are listed in ‘Table 20.1’, (below). Some of the antipsychotics are also used as antiemetics, and for motor tics and hiccups.

The majority of interactions between the older antipsychotics are pharmacodynamic, relating to their effect on dopamine, whilst several of the newer atypical antipsychotics are metabolised to a significant extent by the cytochrome P450 isoenzymes. The concurrent use of other drugs which are inhibitors or inducers of these isoenzymes may result in large changes in plasma levels. In particular, tobacco smoking and caffeine can have an effect on the pharmacokinetics of some of these drugs, leading to adverse effects or lack of therapeutic effect following lifestyle changes.

(b) Benzodiazepines

The anxiolytics include the benzodiazepines and related drugs, cloral hydrate and other drugs used to treat psychoneuroses such as anxiety and tension, and are intended to induce calm without causing drowsiness and sleep. Some of the benzodiazepines and related drugs are also used as antiepileptics and hypnotics. ‘Table 20.1’, (below) contains a list of the benzodiazepines and related drugs. Many benzodiazepines undergo phase I metabolism by \( N \)-dealkylation and hydroxylation and many of the metabolites are active. They may then undergo phase II conjugation, mainly to form glucuronides before being excreted. For example, diazepam is metabolised to nordazepam (desmethyldiazepam), temazepam and oxazepam. The metabolism of diazepam in the liver is also mediated by cytochrome P450 isoform, particularly CYP2C19, and diazepam is excreted mainly as free or conjugated metabolites.

The triazolo-and related benzodiazepines, such as alprazolam, midazolam and triazolam, are mainly metabolised by hydroxylation, mediated by CYP3A4, to active compounds, which then rapidly undergo glucuronide conjugation.

Therefore drugs that affect CYP2C19 may interact with benzodiazepines such as diazepam and those that affect CYP3A4 may interact with midazolam or triazolam.

Benzodiazepines such as lorazepam, oxazepam and temazepam, which are mainly conjugated without prior phase I metabolism, are unlikely to be involved in interactions with inhibitors or inducers of cytochrome P450. Benzodiazepines themselves do not significantly induce cytochrome P450 isoforms, so interactions involving enhanced metabolism of other drugs are not usual.

(c) Non-benzodiazepine hypnotics

Zaleplon, zolpidem and zopiclone are metabolised by several cytochrome CYP450 isoenzymes and it has been suggested that because of this, other drugs which affect a particular isoenzyme such as CYP3A4, may have less effect on their metabolism. However, their pharmacokinetics are affected by potent inducers such as rifampicin and by inhibitors such as the azole antifungals. Buspironone undergoes CYP3A4-mediated metabolism in the liver.
Amisulpride + Lithium

Amisulpride does not appear to affect the pharmacokinetics of lithium. However, limited evidence suggests that lithium may increase the plasma levels of amisulpride.

Clinical evidence, mechanism, importance and management

In a study in 24 healthy subjects, lithium carbonate 500 mg twice daily was given for 7 days to obtain stable lithium serum levels, and then amisulpride 100 mg twice daily or placebo was added for a further 7 days. Amisolpride appeared to have no effect on lithium pharmacokinetics.1 In a pharmacokinetic analysis of amisulpride levels in patients with schizophrenia or schizoaffective disorder, dose-corrected amisulpride plasma levels were 1.8-fold higher in 3 patients taking lithium than in 13 patients taking amisulpride alone.2 Further study is needed to confirm this finding and establish its clinical significance.

Antipsychotics + Antacids or Sucralfate

Antacids containing aluminium/magnesium hydroxide or magnesium trisilicate can reduce the serum levels of chlorpromazine which would be expected to reduce the therapeutic response. Sucralfate and an aluminium/magnesium hydroxide antacid can reduce the absorption of sulpiride. In vitro studies suggest that this interaction may possibly also occur with other antacids and phenothiazines. There seem to be no clinical studies or reports confirming the anecdotal evidence of a possible reduction in the effects of haloperidol by antacids.

Clinical evidence

(a) Haloperidol

In 1982 a questioner in a letter asked whether haloperidol interacts with antacids because he had a patient responding well to treatment with haloperidol who had begun to deteriorate when Amphojel (aluminium hydroxide) was added. In a written answer it was stated1 that there are no reports of this interaction but several clinicians had said that based on clinical impressions oral haloperidol and antacids should not be given together.

(b) Phenothiazines

A study in 10 patients taking chlorpromazine 600 mg to 1.2 g daily showed that 30 mL of Aludros (aluminium/magnesium hydroxide gel) reduced their urinary excretion of chlorpromazine by 10 to 45%.2 A study was prompted by the observation of one psychiatric patient, taking chlorpromazine who relapsed within 3 days of starting to take an unnamed antacid. When 30 mL of Gelusil (aluminium hydroxide with magnesium trisilicate) was given with chlorpromazine suspension to 6 patients, the serum chlorpromazine levels measured 2 hours later were reduced by about 20% (from 168 to 132 nanograms/mL).3 In vitro studies have also found that other phenothiazines (trifluoperazine, fluphenazine, perphenazine, thioridazine) are adsorbed to a considerable extent onto a number of antacids (magnesium trisilicate, bismuth subsalicylate, aluminium hydroxide with magnesium carbonate) but there do not appear to be any clinical studies of the possible clinical effects of these interactions.4

(c) Sulpiride

A study in 6 healthy subjects found that the bioavailability of a single 100-mg dose of sulpiride was reduced by 40% by sucralfate 1 g and by 32% by 30 mL of Simeco (aluminium/magnesium hydroxide and simeticone). When either the sucralfate or the antacid were taken 2 hours before sulpiride the reduction in bioavailability was only about 25%, and no change in bioavailability was seen in one subject when the sucralfate was given 2 hours after the sulpiride.5

Mechanism

Chlorpromazine and other phenothiazines become adsorbed onto these antacids,6,7 which would seem to account for the reduced bioavailability. It is possible that adsorption also occurs with sulpiride, but this has not been proven.

Importance and management

Clinical information seems to be limited to the reports cited. Reductions of up to 45% in serum antipsychotic levels would be expected to be clinically important, but so far only one case seems to have been reported.1 Separating the doses as much as possible (1 to 2 hours) to avoid admixture in the gut should minimise any effects. This may also prove of use in the interactions with haloperidol and sulpiride (although note; the haloperidol interaction is not confirmed). In the case of chlorpromazine an alternative would be to use calcium carbonate-glycine or magnesium hydroxide gel, which seem to affect its gastrointestinal absorption to a lesser extent.8 Other phenothiazines and antacids are known to interact in vitro,9 but the clinical importance of these interactions awaits further study.

Antipsychotics + Anti-epileptics

Haloperidol plasma levels are roughly halved by carbamazepine, phenobarbital and phenytoin. Bromperidol, fluphenazine and diphenhydantoin levels are also reduced by carbamazepine. The plasma levels of chlorpromazine and haloperidol do not appear to be affected by oxcarbazepine. Neurotoxicity has been seen with haloperidol and carbamazepine and haloperidol can raise serum carbamazepine levels. Valproate or valproic acid appear not to interact.

Clinical evidence

(a) Carbamazepine

For mention of carbamazepine toxicity and other adverse reactions following the concurrent use of antipsychotics, see ‘Carbamazepine + Antipsychotics , p.524.

1. Bromperidol. When 13 schizophrenic patients taking bromperidol 12 or 24 mg daily were given carbamazepine 200 mg twice daily for 4 weeks, the plasma levels of bromperidol and reduced bromperidol (a metabolite) were decreased by 37% and 23%, respectively. Despite this fall in levels, the Clinical Global Impression scores (a measure of severity of illness) fell slightly.1

2. Chlorpromazine. Oxcarbazepine was substituted for carbamazepine in 4 difficult to treat schizophrenic patients. All patients were also taking chlorpromazine, and in 3 cases other antipsychotic medication (lithium, zuclopenthixol or clozapine). After 3 weeks of taking the oxcarbazepine all the 4 patients had rises in their chlorpromazine levels, of 28%, 63%, 76%, and 90%, respectively. In one case this rise was associated with increased extrapyramidal adverse effects.2

3. Fluphenazine. A patient receiving intramuscular fluphenazine decanoate 37.5 mg weekly had a rise in serum levels from 0.6 to 1.17 nanograms/mL 6 weeks after stopping carbamazepine 800 mg daily. A moderate improvement in his schizophrenic condition occurred.3

4. Haloperidol. A study in 9 schizophrenics taking haloperidol (average dose 30 mg daily) found a 55% reduction in plasma haloperidol levels (a mean fall from 45.5 to 21.2 nanograms/mL) when they were given carbamazepine for 5 weeks (precise dose not stated). They also took trihexyphenidyl 10 mg daily and oxazepam 30 mg at night as necessary. Carbamazepine serum levels and the control of the disease remained unchanged.4

5. Simeco (aluminium/magnesium hydroxide and simeticone).

Mechanism

Carbamazepine, phenobarbital and phenytoin are recognised enzyme inducers, therefore it seems likely that the reduced plasma bromperidol, chlorpromazine and haloperidol levels occur because their metabolism by the liver is markedly increased by these antiepileptics. Oxcarbazepine does not appear to interact, probably because it is not an enzyme inducer.

Importance and management

The interactions of haloperidol with carbamazepine, phenytoin and phenobarbital are moderately well documented and appear to be clinically important, but only a few patients have been reported to show clinical worsening. Although there are advantages in adding carbamazepine to haloperidol in treating some patients, be alert for the need to increase the haloperidol dosage if any of these antiepileptics is also given. Authors of one study with phenobarbital and phenytoin suggest a two to threefold increase in the haloperidol dosage may be needed. Another study, in which intramuscular haloperidol was used, recommended shortening the interval between injections rather than raising the dosage, but it was not stated by how much. Remember too that if the anticonvulsants are withdrawn it may be necessary to reduce the haloperidol dosage. Also be alert for the development of dystonic reactions and for a rise in serum haloperidol levels. Similar precautions seem necessary with tiotixene, and may be needed with bromperidol and chlorpromazine, but this needs confirmation. Limited evidence suggest that no special precautions are necessary with oxcarbazepine, or if sodium valproate is used with haloperidol.

A case report describes 3 schizophrenic patients taking haloperidol whose treatment was changed from carbamazepine to oxcarbazepine. After 2 weeks their plasma haloperidol levels had dramatically risen (from 6 to 18 nanomol/L, from 6 to 14 nanomol/L and from 17 to 27 nanomol/L). This was accompanied by severe extrapyramidal adverse effects, which necessitated dose reductions in 2 patients. A fall of 45% in haloperidol levels was noted in a study of 7 patients taking haloperidol and carbamazepine, and patients also experienced a worsening of clinical symptoms.

A study in Japanese schizophrenic patients found that carbamazepine reduced the serum haloperidol levels by an unstaed amount, while at the same time the serum carbamazepine levels were raised by about 30%, despite a 25% dose reduction. An associated study by the same group of workers found that concurrent use increased the incidence of QTc lengthening.

Tiotixene. A retrospective study in 42 patients found that the mean clearance of tiotixene in those taking liver enzyme inducer drugs (carbamazepine, phenytoin, primidone) was threefold greater than in the control group. Of the group taking enzyme inducers, 5 patients had non-detectable serum tiotixene levels, and not surprisingly showed no clinical response.

(b) Phenobarbital and/or Phenytoin

A study in epileptic patients, 2 taking phenobarbital, 3 taking phenytoin, and 4 taking both drugs, found that after taking haloperidol 10 mg three times daily for 6 weeks their serum haloperidol levels were about half of those in a control group who were not taking anticonvulsants (19.4 compared to 36.6 nanograms/mL). Antiepileptic levels remained unchanged.

A patient had a marked rise in serum haloperidol levels and clinical improvement when phenytoin 300 mg daily was stopped. A retrospective study found that phenobarbital reduced the haloperidol concentration/dose ratio, suggesting that phenobarbital may affect the metabolism of haloperidol. See also Tiotixene above.

A case-control, retrospective review of patients taking thioridazine 100 to 200 mg daily with either phenytoin, phenobarbital or both drugs found a reduction in both phenobarbital (approximately 25%) and thioridazine levels when taken together. Inconsistent effects were seen on the pharmacokinetics of phenytoin, with a possible trend towards a reduction in phenytoin levels. These results, together with the seizure threshold-lowering effect of phenothiazines, highlights the need to carefully monitor antiepileptic drug levels if phenothiazines are added to, or removed from therapy. See ‘Phenothiazines + Barbiturates’, p.759, for the interaction of phenobarbital with chlorpromazine.

(c) Valproic acid or Valproate

A study in 6 patients given haloperidol 6 to 10 mg daily found no significant interaction with valproic acid. Similarly, haloperidol was not found to interact with valproate in two further studies, although in one of these studies an increase of 64% in haloperidol plasma levels was seen, which was considered not significant. For the interaction of valproic acid with chlorpromazine, see ‘Valproate + Chlorpromazine’, p.577.

Other studies have similarly found 40 to 60% falls in plasma haloperidol levels in patients taking carbamazepine,5,7 with the occasional patient having undetectable levels.5,6 Decreases in plasma haloperidol levels of unspecified amounts have also been described.6,11 A study in 9 patients taking haloperidol 6 mg twice daily who were then given carbamazepine, with the daily dose increased at fortnightly intervals from 100 to 300 and to 600 mg, found a dose-dependent reduction in haloperidol levels. Mean plasma haloperidol levels were reduced by 25%, 61%, and 82%, respectively.13 A few patients have had clinical worsening or increased adverse effects.6,8 Three patients had two to fivefold increases in plasma haloperidol levels and clinical improvement when carbamazepine 1.2 to 4.5 mg daily was stopped, but extrapyramidal adverse effects developed within 1 to 30 days.14 Three cases of neurotoxicity (drowsiness, slurred speech, confusion) have also been described in patients taking haloperidol and carbamazepine.9,15,16
counteract the extrapyramidal adverse effects of antipsychotics may also reduce or abolish their therapeutic effects.

Clinical evidence

The use of antipsychotics with antimuscarinics can result in a generalised, low grade, but not usually serious, additive increase in the antimuscarinic effects of these drugs (blurred vision, dry mouth, constipation, difficulty in urination, see 'Antimuscarinics + Antimuscarinics', p.674). However, sometimes serious intensification takes place. For the sake of clarity these have been subdivided here into (a) heat stroke, (b) constipation and adynamie ileus, (c) atropine-like psychoses, (d) antagonism of antipsychotic effects and (e) miscellaneous effects.

(a) Heat stroke in hot and humid conditions

Three patients were admitted to hospital in Philadelphia for drug-induced hyperpyrexia during a hot and humid period. In each case their skin and mucous membranes were dry and they were tachycardic (120 bpm). There was no evidence of infection.1

Drug combinations implicated in reports of heat stroke, some of them fatal, include:1-5

- chlorpromazine and benzatropine
- chlorpromazine and trifluoperazine
- chlorpromazine, amitriptyline and benzatropine
- chlorpromazine, chlorprothixene and benzatropine
- chlorpromazine, fluphenazine, trihexyphenidyl and benzatropine
- chlorpromazine, trifluoperazine and benzatropine
- haloperidol and benzatropine
- promazine and benzatropine.

The danger of heat stroke in patients taking atropine or atropine-like compounds was recognised in the 1920s, and the warning has been repeated many times.6,7

(b) Constipation and adynamic ileus

Paralytic ileus with faecal impaction (fatal in 6 cases) has been reported in a number of patients taking:

- chlorpromazine and amitriptyline,5 imipramine,9 nortriptyline,10 or trihexyphenidyl9
- haloperidol and benzatropine11
- levomepromazine and imipramine with benzatropine9
- levomepromazine and trihexyphenidyl9
- mesoridazine and benzatropine12
- thioridazine and imipramine with trihexyphenidyl9
- trifluoperazine and benzatropine13 or trihexyphenidyl14
- trifluoperazine and benzatropine with methylphenidate.14

Severe constipation also occurred in a woman given thioridazine, haloperidol and doxepin.15

(c) Atropine-like psychoses

In a double-blind study 3 patients given a phenothiazine and benzatropine for the parkinsonian adverse effects, developed an intermittent toxic confusional state (marked disturbance of short-term memory, impaired attention, disorientation, anxiety, visual and auditory hallucinations) with peripheral antimuscarinics signs.16 Similar reactions occurred in 3 elderly patients given imipramine or desipramine, with trihexyphenidyl,17 and in another man given chlorpromazine, benzatropine and doxepin.15

(d) Antagonism of the antipsychotic effects

A study in psychiatric patients given chlorpromazine 300 to 800 mg daily found that when trihexyphenidyl 6 to 10 mg daily was added, the plasma chlorpromazine levels were reduced from a range of 100 to 300 nanograms/mL to less than 30 nanograms/mL. When the trihexyphenidyl was withdrawn the plasma chlorpromazine levels rose again and clinical improvement was seen.18,19

Other studies confirm that trihexyphenidyl20,21 and orphenadrine22 reduce the plasma levels and effects of chlorpromazine. In contrast to these reports, another found that trihexyphenidyl increased chlorpromazine levels by 41% in 20 young schizophrenics, but no clinical change was seen. The levels dropped again over the first 4 weeks of treatment.23 Some of the beneficial actions of haloperidol on social avoidance behaviour are lost during concurrent treatment with benzatropine, but cognitive integrative function is unaffected.

A study to investigate any possible interaction between procyclidine 5 to 15 mg daily and chlorpromazine, fluphenazine or haloperidol found that the addition of procyclidine caused a transient fall in the serum levels of chlorpromazine, whilst the fall in levels of fluphenazine and haloperidol was maintained for the 4 week treatment period with procyclidine.25

(e) Miscellaneous effects

A study in psychotic patients found that the addition of biperiden 2 mg three times daily or orphenadrine 50 mg three times daily for 3 weeks had no effect on the steady-state levels of perphenazine 24 to 48 mg daily.26

An isolated report describes the development of a hypoglycaemic coma in a non-diabetic patient given chlorpromazine and orphenadrine.27

Mechanism

Antimuscarinic (anticholinergic) drugs inhibit the parasympathetic nervous system, which innervates the sweat glands, so that when the ambient temperature rises the major body heat-losing mechanism can be partially or wholly lost.28 Phenoxybenzamines, thioxanthenes and butyrophenones may also have some antimuscarinic effects, but additionally they impair to a varying extent the hypothalamic thermoregulatory mechanisms that control the body’s ability to keep a constant temperature when exposed to heat or cold. Thus, when the ambient temperature rises, the body temperature also rises. The tricyclics can similarly disrupt temperature control. Therefore in very hot and humid conditions, when the need to reduce the temperature is great, the additive effects of these drugs can make patients unable to control their temperature,4 which can be fatal.

Antimuscarinic drugs also reduce peristalsis, which in the extreme can result in total gut stasis. Additive effects can occur if two or more antimuscarinic drugs are taken.

The toxic psychoses described resemble the CNS effects of atropine or belladonna poisoning and appear to result from the additive effects of the drugs used.

The mechanism for antipsychotic antagonism is not understood. Animal studies suggest that the site of interaction is in the gut.19

Importance and management

Established and well-documented interactions. While these drugs have been widely used together with apparent advantage and without problems, prescribers should be aware that an unspectacular low-grade antimuscarinic toxicity can easily go undetected, particularly in the elderly because the symptoms can be so similar to the general complaints of this group. Also be aware of the serious problems that can sometimes develop, particularly if high doses are used.

- Warn patients to minimise outdoor exposure and/or exercise in hot and humid climates, particularly if they are taking high doses of antipsycho tic/antimuscarinic drugs.
- Be alert for severe constipation and for the development of complete gut stasis, which can be fatal.
- Be aware that the symptoms of central antimuscarinic psychosis can be confused with the basic psychotic symptoms of the patient. Withdrawal of one or more of the drugs, or a dosage reduction and/or appropriate symptomatic treatment can be used to control these interactions.
- Ensure that the concurrent use of antimuscarinics to control the extrapyramidal adverse effects of neuroleptics is necessary29,30 and be aware that the therapeutic effects may possibly be reduced as a result.

Note that tricyclic antidepressants have antimuscarinic adverse effects and may therefore interact similarly. The tricyclics also have other interactions with antipsychotics, see ‘Phenoxybenzamines + Tricyclic antidepressants’, p.760. Some antipsychotics and antimuscarinics prolong the QT interval. Consider also ‘Antimuscarinics + Antimuscarinics’, p.674.

Antipsychotics + Bromocriptine

The concurrent use of bromocriptine with antipsychotics can be successful. However, one report describes the re-emergence of schizophrenic symptoms in a patient when bromocriptine was added to treatment with molindone and imipramine. Another case reports a rise in prolactin levels and deterioration of vision when thioridazine was given with bromocriptine.

Clinical evidence, mechanism, importance and management

Single 2-mg doses of bromocriptine have been found to improve the psychopathology of chronic schizophrenia in patients taking antipsychotics.1 Single 2-mg doses of bromocriptine have been found to improve the psychopathology of chronic schizophrenia in patients taking antipsychotics.2 Single 2-mg doses of bromocriptine have been found to improve the psychopathology of chronic schizophrenia in patients taking antipsychotics.3 Single 2-mg doses of bromocriptine have been found to improve the psychopathology of chronic schizophrenia in patients taking antipsychotics.4

Tea and coffee can cause some drugs to precipitate out of solution in vitro, but so far there is no clinical evidence to show that this normally affects the bioavailability of the drugs nor that it has a detrimental effect on treatment.

Antipsychotics + Coffee or Tea

Tea and coffee can cause some drugs to precipitate out of solution in vitro, but so far there is no clinical evidence to show that this normally affects the bioavailability of the drugs nor that it has a detrimental effect on treatment.

Clinical evidence, mechanism, importance and management

A single report describes 2 patients whose schizophrenia was said to have been exacerbated by an increased consumption of tea and coffee.1 Subsequent in vitro2,3 studies4,5 showed that a number of drugs (chlorpromazine, promethazine, fluphenazine, orphenadrine, promazine, prochlorperazine, trifluoperazine, thioridazine, loxapine, haloperidol, droperidol, prochlorperazine, orphenadrine, promazine) form a precipitate with tea or coffee due to the formation of a drug-tannin complex, which was thought might possibly lower the absorption of these drugs in the gut. Studies with rats also showed that tea abolished the cataleptic effects of chlorpromazine, which did not appear to be related to the presence of caffeine.1 However, the drug-tannin complex gives up the drug into solution if it becomes acidified, as in the stomach.2 Moreover, a clinical study of this interaction showed that the plasma levels of chlorpromazine, fluphenazine, trifluoperazine and haloperidol in a group of 16 patients were unaffected by the consumption of tea or coffee. Their behaviour also remained unchanged.6 A study in 12 healthy subjects also concluded that there was no significant decrease in plasma levels of a single 5-mg dose of fluphenazine given with either tea, coffee, or water.7 So there appears to be little or no direct evidence that this physicochemical interaction is normally of any clinical importance.

Chlorpromazine levels can be reduced to subtherapeutic concentrations by lithium. The development of severe extrapyramidal adverse effects or severe neurotoxicity has been seen in one or more patients given lithium with various antipsychotics Sleep-walking has been described in some patients taking chlorpromazine-like drugs and lithium.
A large-scale retrospective study of the literature over the period 1966 to 1996 using the Medline database identified 41 cases of neurotoxic adverse effects in 41 patients with low therapeutic concentrations of lithium. Of these patients, 10 were taking haloperidol. Another retrospective study using both Medline and the spontaneous reporting system of the FDA in the US, over the period 1969 to 1994, identified 237 cases of severe neurotoxicity involving lithium, of which 59 also involved the concurrent use of haloperidol. Other reports describe encephalopathic syndromes (lethargy, fever, tremulousness, confusion, extrapyramidal and cerebellar dysfunction), neuromuscular symptoms, impaired consciousness and hyperthermia, delirium, severe extrapyramidal symptoms and organic brain damage in patients taking haloperidol with lithium. In one study it was found that of the 13 patients who were taking haloperidol, 5 developed neurotoxic reactions, and they were receiving higher doses of haloperidol (average dose was 59 mg) than the 8 patients who did not develop such symptoms (average dose was 34.9 mg). The sudden emergence of extrapyramidal or other adverse effects with lithium and haloperidol has also been described in other studies.

In contrast to the reports cited above, there are others describing successful and unequivail. A retrospective search of Danish hospital records found that 425 patients had taken both drugs and none of them had developed serious adverse reactions. A small rise in serum lithium levels occurs in the presence of haloperidol, but it is almost certainly of little or no clinical significance.

A large-scale retrospective study of the literature over the period 1966 to 1996 using the Medline database identified 41 cases of neurotoxic adverse effects in 41 patients with low therapeutic concentrations of lithium. Of these patients, 51.2% were also taking at least one antipsychotic drug. Another retrospective study using both Medline and the spontaneous reporting system of the FDA in the US, over the period 1969 to 1994, identified 237 cases of severe neurotoxicity involving lithium, with 188 involving lithium with antipsychotics. The sudden emergence of extrapyramidal or other adverse effects has also been described in other studies. The antipsychotics implicated in this interaction with lithium are amoxapine, bromperidol, chlorprothixene, clozapine, fluphenazine, fluphenazine, levomepromazine, loxapine, mesoridazine, meprobamate, perphenazine, pipotiazine, prochlorperazine, sulpiride, thioridazine, tiofetine, trifluoperazine, and zuclopenthixol. Examples of some cases are cited in a little more detail below.

A study of 10 patients taking fluphenazine, haloperidol or tiofetine found that the addition of lithium worsened their extrapyramidal symptoms. Neurotoxicity (tremor, rigidity, ataxia, tiredness, vomiting, confusion) attributed to interactions between lithium and fluphenazine has been described in another patient. He previously took haloperidol and later took chlorpromazine with lithium, without problem. Irreversible brain damage has been reported in a patient taking fluphenazine decanoate and lithium. Severe neurotoxic complications (seizures, encephalopathy, delirium, abnormal EEGs) developed in 4 patients taking thioridazine 400 mg daily or more and lithium. Serum lithium levels remained below 1 mmol/L. Lithium and other phenothiazines had been taken by 3 of them for extended periods without problems, and the fourth subsequently took lithium and fluphenazine without problems. In one study the concurrent use of lithium and chlorpromazine, perphenazine, or thioridazine was associated with sleep-walking episodes in 9% of patients. Somnolence, confusion, delirium, cretinism, phosphokinase elevation and fever occurred in a man taking lithium when risperidone was given. A retrospective review of 39 patients with a diagnosis of neurotoxicity caused by treatment with lithium and an antipsychotic, found that the onset of symptoms varied from 24 hours to 3 months after taking the two drugs together, with an average delay of 12.7 days. A study in 8 patients found a fourfold increase in half life of molindone when given with lithium.

Mechanism

Not understood. One suggestion to account for the reduced serum levels of chlorpromazine, which is based on animal studies, is that chlorpromazine can be metabolised in the gut. Therefore, if lithium delays gastric emptying, more chlorpromazine will be metabolised before it reaches the circulation. Just why severe neurotoxicity and other adverse effects sometimes develop in patients taking lithium and antipsychotics is not understood. It is the subject of considerable discussion and debate.
Clinical evidence, mechanism, importance and management

(a) Chlorpromazine

A study in schizophrenic patients found that over a 12-week period the serum levels of chlorpromazine were not significantly altered by citalopram 40 mg daily.1

(b) Cyamemazine

A study in patients taking cyamemazine found that fluvoxamine 150 mg daily had no effect on its serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.2

(c) Flupenthixol

Parkinson-like symptoms developed in a patient taking amitripyrine and flupenthixol when fluoxetine was given.3

(d) Fluphenazine

A severe dystonic reaction (painful jaw tightness and throat ‘closing up’) occurred in a man taking fluoxetine 40 mg daily when he took fluphenazine 2.5 mg on two consecutive nights.4

(e) Haloperidol

1. Citalopram. A study in schizophrenic patients found that over a 12-week period the serum levels of haloperidol were not significantly altered by citalopram 40 mg daily.1

2. Escitalopram. Escitalopram is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, and may therefore inhibit haloperidol metabolism. The manufacturers say that consideration should be given to reducing the dose of haloperidol.2

3. Fluoxetine. A woman taking haloperidol 2 to 5 mg daily for 2 years with only occasional mild extrapyramidal symptoms began to experience severe extrapyramidal symptoms (tongue stiffness, parkinsonism, akathisia) shortly after starting to take fluoxetine 40 mg twice daily and was virtually incapacitated for 3 days. Both drugs were stopped and she recovered over a period of one week.2 Three other patients developed movement disorders after receiving both drugs,2,9

In one case severe antimuscarinic adverse effects also occurred.8 A report describes 8 patients who had a 20% rise in plasma haloperidol levels when fluoxetine 20 mg daily was added. Although no overall increase in extrapyramidal effects was seen, one patient developed tremor, and another developed akathisia.10 Similarly 15 patients showed an increase of nearly 30% in haloperidol plasma levels after fluoxetine was given, and 5 of 17 patients had aggravated parkinsonian symptoms.3 An other report describes a more than 100% rise in plasma haloperidol levels when fluoxetine was given, and another developed akathisia.10 Similarly 15 patients showed an increase of nearly 30% in haloperidol plasma levels after fluoxetine was given, and 5 of 17 patients had aggravated parkinsonian symptoms.3

Clinical evidence, mechanism, importance and management

(a) Chlorpromazine

A study in schizophrenic patients found that over a 12-week period the serum levels of chlorpromazine were not significantly altered by citalopram 40 mg daily.1

(b) Cyamemazine

A study in patients taking cyamemazine found that fluvoxamine 150 mg daily had no effect on its serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.2

(c) Flupenthixol

Parkinson-like symptoms developed in a patient taking amitripyrine and flupenthixol when fluoxetine was given.3

(d) Fluphenazine

A severe dystonic reaction (painful jaw tightness and throat ‘closing up’) occurred in a man taking fluoxetine 40 mg daily when he took fluphenazine 2.5 mg on two consecutive nights.4

(e) Haloperidol

1. Citalopram. A study in schizophrenic patients found that over a 12-week period the serum levels of haloperidol were not significantly altered by citalopram 40 mg daily.1

2. Escitalopram. Escitalopram is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, and may therefore inhibit haloperidol metabolism. The manufacturers say that consideration should be given to reducing the dose of haloperidol.2

3. Fluoxetine. A woman taking haloperidol 2 to 5 mg daily for 2 years with only occasional mild extrapyramidal symptoms began to experience severe extrapyramidal symptoms (tongue stiffness, parkinsonism, akathisia) shortly after starting to take fluoxetine 40 mg twice daily and was virtually incapacitated for 3 days. Both drugs were stopped and she recovered over a period of one week.2 Three other patients developed movement disorders after receiving both drugs,2,9

In one case severe antimuscarinic adverse effects also occurred.8 A report describes 8 patients who had a 20% rise in plasma haloperidol levels when fluoxetine 20 mg daily was added. Although no overall increase in extrapyramidal effects was seen, one patient developed tremor, and another developed akathisia.10 Similarly 15 patients showed an increase of nearly 30% in haloperidol plasma levels after fluoxetine was given, and 5 of 17 patients had aggravated parkinsonian symptoms.3

Clinical evidence, mechanism, importance and management

(a) Chlorpromazine

A study in schizophrenic patients found that over a 12-week period the serum levels of chlorpromazine were not significantly altered by citalopram 40 mg daily.1

(b) Cyamemazine

A study in patients taking cyamemazine found that fluvoxamine 150 mg daily had no effect on its serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.2

(c) Flupenthixol

Parkinson-like symptoms developed in a patient taking amitripyrine and flupenthixol when fluoxetine was given.3

(d) Fluphenazine

A severe dystonic reaction (painful jaw tightness and throat ‘closing up’) occurred in a man taking fluoxetine 40 mg daily when he took fluphenazine 2.5 mg on two consecutive nights.4

(e) Haloperidol

1. Citalopram. A study in schizophrenic patients found that over a 12-week period the serum levels of haloperidol were not significantly altered by citalopram 40 mg daily.1

2. Escitalopram. Escitalopram is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, and may therefore inhibit haloperidol metabolism. The manufacturers say that consideration should be given to reducing the dose of haloperidol.2

3. Fluoxetine. A woman taking haloperidol 2 to 5 mg daily for 2 years with only occasional mild extrapyramidal symptoms began to experience severe extrapyramidal symptoms (tongue stiffness, parkinsonism, akathisia) shortly after starting to take fluoxetine 40 mg twice daily and was virtually incapacitated for 3 days. Both drugs were stopped and she recovered over a period of one week.2 Three other patients developed movement disorders after receiving both drugs,2,9

In one case severe antimuscarinic adverse effects also occurred.8 A report describes 8 patients who had a 20% rise in plasma haloperidol levels when fluoxetine 20 mg daily was added. Although no overall increase in extrapyramidal effects was seen, one patient developed tremor, and another developed akathisia.10 Similarly 15 patients showed an increase of nearly 30% in haloperidol plasma levels after fluoxetine was given, and 5 of 17 patients had aggravated parkinsonian symptoms.3

Antipsychotics + SSRIs

On the whole no significant adverse interactions appear to occur between the antipsychotics and the SSRIs. However, a number of case reports describe extrapyramidal adverse effects following the use of fluoxetine or paroxetine with an antipsychotic, and galactorrhoea and amenorrhoea developed in one patient givenloxapine and fluvoxamine. Fluoxetine and fluvoxamine appear to raise haloperidol levels, which may increase adverse effects. Thioridazine levels are expected to be increased with fluoxetine, fluvoxamine, or paroxetine treatment with a risk of QT interval prolongation.

No changes in the plasma levels of haloperidol or clozapine were seen when orlistat was also given.

Clinical evidence, mechanism, importance and management

In a study, 8 patients who had experienced weight gain as a result of treatment with haloperidol (2), clozapine (2), clomipramine (3), desipramine (1), or carbamazepine (2), and were given orlistat 120 mg three times daily for 8 weeks. There was no significant changes in the plasma levels of the antipsychotics and steatorrhoea, which occurred in three patients, had no effect on their bioavailability.1 Although an interaction appears to be unlikely, due to the small numbers involved in this study, it would be advisable to monitor patients for reduced absorption of antipsychotic drugs until more data is available.

noted that all three patients were also taking benzatropine (see ‘Antimuscarinics + SSRIs’, p.675). Another limited study also observed that fluvoxamine caused a rise in the serum levels of haloperidol.2

5. Paroxetine. In one study the sedative effects and impairment of psychomotor performance caused by haloperidol 3 mg were not increased by paroxetine 30 mg.15

6. Sertraline. In a randomised, placebo-controlled study, 21 healthy subjects were given a single 2 mg dose of haloperidol on days 2 to 25. On days 9 to 25 the subjects were given sertraline, increased over 7 days to 200 mg daily. All subjects took psychomotor tests on days 1, 2 and 25 to assess the effect of haloperidol. Their cognitive function was impaired for 6 to 8 hours after taking the haloperidol, but this effect had disappeared after 23 hours. Overall, sertraline did not appear to worsen the cognitive impairment caused by haloperidol.16 Another study found similar pharmacodynamic results, and also found that the pharmacokinetics of haloperidol are unaffected by sertraline.17 In contrast, a study in 16 hospitalised patients who were taking haloperidol found that the addition of sertraline 50 mg daily for 2 weeks resulted in an increase in plasma haloperidol concentrations, and a reduction in the plasma concentrations of the metabolite, reduced haloperidol.18

(f) Levomepromazine
A study in patients taking levomepromazine found that fluvoxamine 150 mg daily did not affect its serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.2 A further study in 15 patients also found that there was no significant change in the pharmacokinetics of fluvoxamine when given with levomepromazine in doses of 5 to 25 mg daily. Additionally, patients in this study found that the levomepromazine counteracted the insomnia caused by fluvoxamine.19

A study in three groups of 8 healthy subjects taking citalopram 40 mg daily for 10 days found that a single 50 mg oral dose of levomepromazine increased the initial steady-state levels of the primary metabolite of citalopram (desmethylecitalopram) by 10 to 20%, which was not considered to be clinically significant.20

A study in schizophrenic patients found that over a 12-week period the serum levels of levomepromazine were not significantly altered by citalopram 40 mg daily.1

(g) Loxapine
A 38-year-old woman developed amenorrhea, followed shortly by galactorrhoea, about 6 weeks after starting to take fluvoxamine and loxapine. The galactorrhoea resolved within 3 weeks of stopping the fluvoxamine, and menstruation occurred one week later. Her prolactin levels were found to be 80 micrograms/L (normal 4 to 30 micrograms/L).21

(h) Metopimazine
A French regional pharmacovigilance centre reported 37 cases of extrapyramidal adverse effects linked to concurrent use of an SSRI and a neurollepetic. In 2 cases metopimazine was given.22

(i) Molindone
An elderly woman taking molindone 10 mg twice daily developed severe and disabling extrapyramidal symptoms (severe bradykinesia, tremor, inability to feed herself, delirium) within about 2 weeks of starting paroxetine 10 mg daily. The symptoms resolved when molindone was stopped, and no problems occurred when fluoxetine alone was started.23

(j) Pericyazine
A New Zealand study describes a patient who developed extrapyramidal symptoms when given pericyazine and fluoxetine.7

(k) Perphenazine
1. Citalopram. A study in schizophrenic patients found that over a 12-week period the serum levels of perphenazine were not significantly altered by citalopram 40 mg daily.1

2. Fluoxetine. The combination of perphenazine and fluoxetine was found to be effective in the treatment of psychotic depression in 30 patients, and the adverse effects (which included dry mouth, blurred vision, constipation, tremor or rigidity, orthostasis and hypotension) were thought to be easier to tolerate than an antipsychotic with a tricyclic antidepressant.24 However, one woman developed marked extrapyramidal symptoms within 2 weeks of starting perphenazine 4 mg twice daily and fluoxetine 20 mg daily.25

3. Paroxetine. The effects of a single 100-microgram/kg oral dose of perphenazine on the performance of psychomotor tests were assessed after 4, 6, 8 and 10 hours in 5 subjects. The tests were then repeated after the subjects also took paroxetine 20 mg daily for 10 days. The scores for these tests were worsened by the perphenazine when compared with a placebo and further worsened by the presence of the paroxetine. In addition to over-sedation and impairment of the performance of psychomotor tests and memory, 2 of the subjects developed akathisia 10 hours after taking both drugs. The AUC of the perphenazine was increased sevenfold and the maximum plasma levels sixfold.26

(l) Pimozide
See ‘Pimozide + SSRIs’, p.762.

(m) Sulpiride
Parkinson-like symptoms developed in a patient taking sulpiride and maprotiline when fluoxetine was also given.2

(n) Thioridazine
A study in schizophrenic patients found that over a 12-week period the serum levels of thioridazine were not significantly altered by citalopram 40 mg daily.1

A study in 10 schizophrenic patients found that when fluvoxamine 50 mg daily was added to established treatment with thioridazine 30 to 200 mg daily, thioridazine plasma levels were increased by 225%. There were no reported changes in either clinical status or adverse effects.28

(o) Tiotixene
A study in 10 healthy subjects found that paroxetine 20 mg daily for 3 days did not significantly affect the pharmacokinetics of a single 20-mg dose of tiotixene.29

(p) Trifluoperazine
A New Zealand study describes a patient who developed extrapyramidal symptoms when given trifluoperazine and fluoxetine.1

(q) Zuclopenthixol
A study in schizophrenic patients found that over a 12-week period the serum levels of zuclopenthixol were not significantly altered by citalopram 40 mg daily.1

Mechanism
Movement disorders and raised antipsychotic serum levels seem most common with fluoxetine and paroxetine, possibly because they inhibit the metabolism of some antipsychotics by the cytochrome P450 isoenzyme CYP2D6.26 However, the movement disorders may just be a result of the additive adverse effects of antipsychotics and SSRIs. Fluoxetine alone has been shown to occasionally cause movement disorders.7,30

Galactorrhoea is a known adverse effect of loxapine, but just why fluvoxamine apparently increased this effect is not understood.33

Importance and management
On the whole significant interactions between the antipsychotics and SSRIs appear rare (although see thioridazine, below). The combination can be useful and so the isolated cases of extrapyramidal adverse effects should not prevent concurrent use. However, if extrapyramidal effects become troublesome bear this interaction in mind as a possible cause. The significance of the rise in haloperidol levels caused by fluoxetine and fluvoxamine is unclear, be aware that haloperidol adverse effects may be increased in some patients and consider reducing the haloperidol dose if problems occur. The rise in perphenazine levels caused by paroxetine seems to result in a greater number of more serious adverse effects and so consideration should be given to reducing the dose of perphenazine if paroxetine is started. Citalopram may be a suitable alternative as it does not appear to affect perphenazine levels.

Note that, although the studies with thioridazine did not appear to show any clinically significant interaction the US manufacturers of fluoxetine,31 fluvoxamine,32 and paroxetine,33 contraindicate the concurrent use of thioridazine as they suggest that its metabolism (by CYP2D6) may be inhibited by these SSRIs, leading to raised levels and the risk of QT prolongation. The use of thioridazine is also contraindicated for 5 weeks after any clinically significant interaction the US manufacturers of fluoxetine,31 fluvoxamine,32 and paroxetine,33 therefore it cannot be used. You should also be aware that the combination of haloperidol and fluoxetine is not licensed and can cause increased haloperidol levels; further research is needed to confirm this.21
dose of thioridazine may need to be reduced when it is given with escitalopram.2

SSRI antidepressants may lower the seizure threshold, and therefore concomitant use with other drugs, which can also lower the seizure threshold, such as phenothiazines, should be undertaken with caution.3

Tobacco smoking increased the clearance of tiotixene in patients taking enzyme inhibitors or no other drugs, but not in patients taking enzyme inhibitors. Those who smoked were found to need on average 45% more tiotixene than the non-smokers taking no other interacting drugs.8

(d) Tiotixene

Tobacco smoking increased the clearance of tiotixene in patients taking enzyme inhibitors or no other drugs, but not in patients taking enzyme inhibitors. Those who smoked were found to need on average 45% more tiotixene than the non-smokers taking no other interacting drugs.8

Mechanism

Not established. The probable reason is that some of the components of tobacco smoke act as enzyme inducers, which increase the rate at which the liver metabolises these antipsychotics, thereby reducing their serum levels and clinical effects.

Importance and management

Established interactions but of uncertain clinical importance. Be alert for the need to increase the dosages of these antipsychotics in patients who smoke, and reduce the dosages if smoking is stopped.

Clinical evidence, mechanism, importance and management

Lithium does not affect the pharmacokinetics of aripiprazole to a clinically significant extent.

Clinical evidence, mechanism, importance and management

Aripiprazole 30 mg daily was given to 7 healthy subjects for 5 weeks, with lithium carbonate slow-release tablets 1.2 to 1.8 g daily (to give a plasma level of 1 to 1.4 mmol/L) for weeks 3 to 5 of the study. The mean AUC and maximum plasma concentrations of aripiprazole were found to increase by 15% and 19%, respectively, but these changes were not considered to be clinically significant.1

Antipsychotics + Tobacco or Cannabis

Smokers of tobacco or cannabis may need lower dosages of chlorpromazine, thioridazine, haloperidol or tiotixene than non-smokers.

Clinical evidence

(a) Chlorpromazine

A comparative study found that the frequency of drowsiness in 403 patients taking chlorpromazine was 16% in non-smokers, 11% in light smokers, and 3% in heavy smokers (more than 20 cigarettes daily). Another report describes a patient taking chlorpromazine who experienced increased sedation and dizziness and higher plasma chlorpromazine levels when he gave up smoking.2 A study in 31 patients found that the clearance of chlorpromazine was increased by 38% by tobacco smoking, by 50% by cannabis smoking, and by 107% when both tobacco and cannabis were smoked.1

(b) Fluphenazine

A retrospective study in 40 psychotic inpatients found that the plasma fluphenazine levels of non-smokers were more than double those of smokers (1.83 nanograms/mL compared with 0.89 nanograms/mL) when they were given fluphenazine hydrochloride by mouth. The clearance of both oral and intramuscular fluphenazine was 1.67-fold and 2.33-fold greater, respectively, in the smokers than in the non-smokers. No behavioural differences were seen.4

(c) Haloperidol

State-controlled haloperidol levels were found to be lower in a group of 23 cigarette smokers than in another group of 27 non-smokers (16.83 nanograms/mL compared with 28.8 nanograms/mL) and the clearance was increased by 44%.3 Other studies have broadly confirmed these findings.5

(d) Tiotixene

Tobacco smoking increased the clearance of tiotixene in patients taking enzyme inhibitors or no other drugs, but not in patients taking enzyme inducers. Those who smoked were found to need on average 45% more tiotixene than the non-smokers taking no other interacting drugs.6

Aripiprazole + Lithium

Lithium does not affect the pharmacokinetics of aripiprazole to a clinically significant extent.

Clinical evidence, mechanism, importance and management

Aripiprazole 30 mg daily was given to 7 healthy subjects for 5 weeks, with lithium carbonate slow-release tablets 1.2 to 1.8 g daily (to give a plasma level of 1 to 1.4 mmol/L) for weeks 3 to 5 of the study. The mean AUC and maximum plasma concentrations of aripiprazole were found to increase by 15% and 19%, respectively, but these changes were not considered to be clinically significant.1

Aripiprazole + Miscellaneous

Aripiprazole plasma levels are increased by inhibitors, and decreased by inducers, of CYP3A4. Quinidine increases aripiprazole levels. The manufacturers advise caution with drugs that can prolong the QT interval. Food and famotidine do not have a clinically relevant effect on the pharmacokinetics of aripiprazole, and aripiprazole does not affect the pharmacokinetics of dextromethorphan, omeprazole, and warfarin.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers

The manufacturers report that carbamazepine reduced the mean maximum plasma concentration and AUC of aripiprazole 30 mg by 68% and 73%, respectively. They recommend that the dose of aripiprazole is doubled when taken with carbamazepine. Other potent inducers of CYP3A4, such as efavirenz, nevirapine, phenytoin, phenobarbital, primidone, rifabutin, rifampicin and St John’s Wort are expected to have similar effects and an increase in the dose of aripiprazole may also be necessary if these drugs are given.

(b) CYP3A4 inhibitors

Ketoconazole, an inhibitor of CYP3A4, increased the AUC and maximum plasma concentration of aripiprazole by 63% and 37%, respectively. Other potent inhibitors of CYP3A4, such as itraconazole and protease inhibitors would be expected to produce similar or greater increases in aripiprazole levels, and the manufacturers recommend that the dose of aripiprazole should be halved with these drugs. The dose of aripiprazole should also be increased again if the drug is stopped. Moderate inhibitors of CYP3A4, such as diltiazem, may produce more modest increases in aripiprazole levels, and patients should be closely monitored for signs of aripiprazole toxicity, although an initial dose reduction of aripiprazole may not be required.

(c) Famotidine

Famotidine reduces the rate of absorption of aripiprazole but this effect is not clinically significant.

(d) Food

A study in 39 healthy subjects who received 15 mg aripiprazole either after fasting, or 5 minutes after a high-fat breakfast, found no significant changes in the pharmacokinetics of aripiprazole.

(e) QT prolongation

The manufacturers report that in clinical studies the incidence of QT prolongation with aripiprazole was comparable to placebo. Nevertheless, they recommend caution when prescribing aripiprazole with other drugs that may prolong the QT interval or cause electrolyte disturbances, see ‘drugs that prolong the QT interval’, (p.257).

(f) Quinidine

Quinidine, an inhibitor of CYP2D6, has been found to increase the AUC of aripiprazole by 107%, although the maximum concentration was unchanged. It is recommended that the dose of aripiprazole is halved if given concomitantly with quinidine.

(g) Miscellaneous

Aripiprazole 10 to 30 mg daily had no significant effects on the metabolism of dextromethorphan (CYP2D6 and CYP3A4 substrate), warfarin (CYP2C9 substrate) and omeprazole (CYP2C19 substrate). Aripiprazole is not expected to affect CYP1A2-mediated metabolism. The manufacturers therefore conclude that aripiprazole is unlikely to have clinically significant interactions with drugs that are substrates for these isoenzymes.

Aripiprazole + SSRIs and related antidepressants

Fluoxetine and probably paroxetine may cause clinically significant increases in aripiprazole levels. The concurrent use of aripiprazole with SSRIs or venlafaxine has led to adverse effects such as the neuroleptic malignant syndrome and extrapyramidal symptoms.

Clinical evidence, mechanism, importance and management

A study analysing routing samples sent for aripiprazole monitoring noted that the plasma levels of aripiprazole were 44% higher in 5 patients taking inhibitors of the cytochrome P450 isoenzyme CYP2D6, which included 2 patients taking fluoxetine. However, note that they also included levomepromazine in this group, which is not known to be a potent CYP2D6 inhibitor, and may therefore have reduced the true increase seen with fluoxetine. Further, in 6 patients taking escitalopram or citalopram the plasma levels of aripiprazole were found to be 39% and 34% higher, respectively, when compared with patients taking aripiprazole alone.

The manufacturers suggest that potent inhibitors of CYP2D6, such as fluoxetine and paroxetine would be expected to increase aripiprazole levels, and they recommend that the dose of aripiprazole should be halved if these drugs are given. The UK manufacturer suggests that weaker inhibitors of this isoenzyme (they name escitalopram) would only be expected to cause modest increases in aripiprazole levels, and therefore no dosage adjustment would be expected to be required.

Two case reports of extrapyramidal effects in association with aripiprazole treatment have been attributed to an interaction with antidepressants. In the first case the patient, who was taking venlafaxine, trazodone and clonazepam, developed parkinsonian symptoms a few days after starting to take aripiprazole 15 mg daily. Her symptoms resolved on stopping the aripiprazole. The second patient was taking sertraline 200 mg daily, and after starting to take aripiprazole 10 mg daily he developed akathisia. This did not respond to a reduction of aripiprazole dose, but gradually resolved when the aripiprazole was withdrawn.

Neuroleptic malignant syndrome developed in a patient within 2 weeks of starting aripiprazole 30 mg daily and fluoxetine 20 mg daily. The patient had stopped taking the aripiprazole 2 days before admission, fluoxetine was stopped on admission, and he recovered within one week with symptomatic treatment. The authors suggested that fluoxetine may have increased the risk of this syndrome developing by raising aripiprazole levels.

The concurrent use of aripiprazole and SSRIs can be useful, but it is important to remember to adjust the dose if paroxetine or fluoxetine are started or stopped, and be aware that, rarely, adverse effects such as extrapyramidal symptoms and the neuroleptic malignant syndrome may develop.

Aripiprazole + Valproate

Valproate causes a reduction in aripiprazole levels which is not considered to be clinically significant.

Clinical evidence, mechanism, importance and management

Aripiprazole 30 mg daily was given to 6 healthy subjects for 5 weeks, with valproate semisodium (divalproex sodium) daily in doses to achieve a serum valproate level of 50 to 125 mg/L, for weeks 3 to 5 of the study. The mean AUC and maximum plasma concentrations of aripiprazole were found to decrease by 24% and 26%, respectively, and the time to maximum aripiprazole levels was extended by 2 hours. Since aripiprazole and valproate share the same protein binding sites, it was considered likely that the valproate displaced bound aripiprazole leading to increased
Barbiturates + Miscellaneous

Miconazole increases serum pentobarbital levels. The hypnotic effects of pentobarbital are reduced or abolished by the concurrent use of caffeine.

Clinical evidence, mechanism, importance and management

(a) Caffeine

In a placebo-controlled study caffeine 250 mg and pentobarbital 100 mg were given together and alone to 34 patients. It was found that the hypnotic effects of the pentobarbital given with caffeine were reduced, and indistinguishable from those of the placebo. Caffeine stimulates the cerebral cortex and impairs sleep, whereas pentobarbital depresses the cortex and promotes sleep. These mutually opposing actions would seem to explain this interaction. This seems to be only direct study of this interaction, but it is well supported by common experience and the numerous studies of the properties of each of these compounds. Patients given barbiturate hypnotics should avoid caffeine-containing drinks (tea, coffee, cola drinks, etc.) or analgesics at or near bedtime if the hypnotic is to be effective.

(b) Miconazole

High-dose intravenous pentobarbital was given to 5 patients in intensive care to decrease intracranial pressure. When miconazole was also given, all patients had marked rises in plasma pentobarbital levels, and a 50 to 90% reduction in total plasma clearance. This is thought to occur because miconazole inhibits the liver enzymes concerned with the metabolism of the barbiturate, thereby reducing its clearance from the body. It would be prudent to monitor the effects of concurrent use to ensure that plasma barbiturate levels do not rise too high. Note that miconazole oral gel can be absorbed in sufficient amounts to potentially interact. There seems to be no information about other barbiturates.

Benzodiazepines + Alosetron

Alosetron 1 mg twice daily for 2 days had no significant effect on the pharmacokinetics of a single 1-mg dose of alprazolam in 12 healthy subjects. No increase in adverse effects was noted with the combination. No special precautions therefore seem necessary on concurrent use.

Benzodiazepines + Amiodarone

An isolated report describes clonazepam toxicity, which was attributed to the concurrent use of amiodarone.

Clinical evidence, mechanism, importance and management

A 78-year-old man with congestive heart failure and coronary artery disease was taking furosemide, potassium, and calcium supplements, a multivitamin preparation, and amiodarone 200 mg daily for sustained ventricular tachycardia. Two months after clonazepam 500 micrograms at night was added to treat restless leg syndrome he developed slurred speech, confusion, difficulty in waking, dry mouth and urinary incontinence. This was interpreted as clonazepam toxicity. The problems cleared when the clonazepam was stopped. The authors of the report suggest that the amiodarone may have inhibited the oxidative metabolism of the clonazepam by the liver, thereby allowing it to accumulate. They also point out that this patient may have been more sensitive to these effects because of a degree of hypothyroidism caused by the amiodarone. Hypothyroidism is known to decrease the metabolism of drugs that undergo oxidative metabolism by the liver.

This is an unconfirmed and isolated case of doubtful general importance.

Benzodiazepines + Antacids

Although antacids can moderately change the rate of absorption of chlor Diazepoxide, clorazepate and diazepam, no adverse interaction of clinical importance has been reported.

Clinical evidence

In a three-period study 10 healthy subjects were given clorazepate 7.5 mg at night, with either water, or with Maalox 30 mL, or with Maalox 30 mL three times daily before meals. The mean steady-state serum levels of the active metabolite of clorazepate, desmethyldiazepam, were not affected by Maalox, although they varied widely between individuals. This is in line with another report, but contrasts with a single-dose study, in which the peak plasma concentration of desmethyldiazepam was delayed and reduced by about one-third by the use of Maalox. The AUC0-48 was reduced by about 10%.

In another study the absorption of a single dose of chlor Diazepoxide was delayed by Maalox, though the total amount of drug absorbed was not significantly affected. Similar results have been found with diazepam and aluminium hydroxide-containing antacids. Another study found that 40 mL of Aluminium Hydroxide Gel BP and 30 mL of sodium citrate (0.3 mmol/L) marginally hastened the sedative effect of diazepam 10 mg when used as an oral premedication before minor surgery. Magnesium Trisilicate Mixture BPC 30 mL tended to delay sedation.
Mechanism

The delay in the absorption of chlordiazepoxide and diazepam is attributed to the effect of the antacid on gastric emptying. Clarozapate on the other hand is a prodrug, which needs acid conditions in the stomach for conversion by hydrolysis and deacarbonylation to its active form. Antacids are presumed to inhibit this conversion by raising the pH of the stomach contents.3

Importance and management

Most of the reports describe single-dose studies, but what is known suggests that no adverse interaction of any clinical importance is likely if antacids are given with chlordiazepoxide, clarozapate or diazepam. Whether the delay in absorption has an undesirable effect in those who only take benzodiazepines during acute episodes of anxiety, and who need rapid relief is uncertain. Information about other benzodiazepines is lacking. However, no special precautions would seem to be necessary.

Benzodiazepines and related drugs + Antiepileptics; Carbamazepine

The use of benzodiazepines with carbamazepine is common, although some evidence suggests that the effects of the benzodiazepines are sometimes reduced. Levels of alprazolam were reduced by almost 50% and levels of midazolam were markedly reduced and its effects almost abolished by carbamazepine. Single-dose studies have shown that the sedative effects of zopiclone and carbamazepine are additive, however it has been suggested that when taken long-term carbamazepine will reduce the effects of zopiclone.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

A patient with atypical bipolar disorder and panic attacks, given alprazolam 7.5 mg daily, had a reduction of more than 50% in plasma alprazolam levels, from 43 to 19.3 nanograms/mL when given carbamazepine. This was accompanied by a deterioration in his clinical condition, which was managed with haloperidol.1

(b) Clobazam

A study found that carbamazepine reduces the plasma levels of clobazam and increases the levels of norclobazam (the principal metabolite).2 Similarly, a reduction in steady-state clobazam levels, with a rise in norclobazam levels, is described in another study in 6 healthy subjects taking carbamazepine. A 66-year-old man taking carbamazepine and topiramate experienced fatigue, ataxia, impairment of gait and clumsiness while taking clobazam 10 mg daily. His symptoms resolved when the clobazam was stopped.2 When he was later given carbamazepine, topiramate, and clobazam 20 mg daily his carbamazepine level rose from 36.8 to 41.9 micromol/L. The carbamazepine level returned to 35.5 micromol/L 5 days after the clobazam was stopped.4 However, another study in 15 epileptic patients taking carbamazepine alone and another 7 patients taking carbamazepine with clobazam, found that carbamazepine levels were similar in both groups, but levels of carbamazepine metabolites, including the active carbamazepine-10,11-epoxide, were higher in those also taking clobazam. It was suggested that clobazam increased the metabolism of carbamazepine by about 1.5-fold.5

(c) Clonazepam

Clonazepam, in slowly increasing doses up to a maximum of 4 to 6 mg/day given over a 6-week period, had no effect on carbamazepine serum levels. Some patients were also taking phenobarbital.6 A study in 7 healthy subjects found that carbamazepine 200 mg daily given over a 3-week period reduced the plasma levels of clonazepam 1 mg daily from a range of 4 to 7 nanograms/mL down to 2.5 to 4 nanograms/mL, and reduced the half-life by about one-third.7 A retrospective analysis of this interaction in 183 patients found that clonazepam clearance was increased by 22% and carbamazepine clearance was decreased by 20.5% by concurrent use.8

(d) Diazepam

A study found that the plasma clearance of a single 10-mg intravenous dose of diazepam was threefold greater, and the half-life shorter in a group of 9 epileptics when compared to 6 healthy subjects. Seven of the epileptics were taking carbamazepine.9

(e) Midazolam

The pharmacokinetics and pharmacodynamics of a single 15-mg oral dose of midazolam was studied in 6 epileptic patients taking either carbamazepine, phenytoin or both drugs, and in 7 control subjects not taking either antiepileptic. The AUC of midazolam in the epileptics was reduced to 5.7%, and the peak serum levels to 7.4% of the value in the control subjects. The pharmacodynamic effects of the midazolam (subjective drowsiness, body sway with eyes closed and open, as well as formal tests) were also reduced. Most of the epileptics did not notice any effects from taking midazolam, while the control subjects were clearly sedated for 2 to 4 hours, and also experienced amnesia after taking the midazolam.10

B. Non-benzodiazepine hypnotics

A crossover study in 12 healthy subjects given a single 7.5-mg dose of zopiclone and carbamazepine (600 mg found only minor changes in the plasma levels of both drugs. Zopiclone levels were higher and carbamazepine levels slightly lower. Psychomotor tests confirmed that both drugs had sedative effects, which were additive, and in a simulated driving test it was found that co-ordination was impaired and reaction times prolonged.11 However, there do not appear to be any multiple-dose studies. Carbamazepine is a strong inducer of the cytochrome P450 isoenzyme CYP3A4 (by which zopiclone is metabolised) and it is therefore predicted that the effect of long-term carbamazepine treatment would be a reduction in zopiclone serum levels and hypnotic effects.12

Mechanism, importance and management

The midazolam and possibly alprazolam interactions with carbamazepine appear to be of greatest clinical significance. Alprazolam and midazolam are both metabolised by the cytochrome P450 isoenzyme CYP3A4, of which carbamazepine is a known inducer. Much larger doses of midazolam are likely to be needed in the presence of carbamazepine. An alternative sedative may be needed. Triazolam is predicted to interact like midazolam.10

Since norclobazam retains some of the activity of clobazam, the effects of carbamazepine probably have little clinical significance, and the case of carbamazepine toxicity appears to be isolated and is therefore probably of limited importance. The pharmacokinetic changes seen with clobazam seem likely to be too small to be clinically significant, but this needs confirmation.

The evidence for an interaction between zopiclone and carbamazepine is slim, and the effects of long-term use unclear. However, it would seem prudent to be alert for the need to increase the zopiclone dosage in patients taking carbamazepine. More study of this potential interaction is needed.

Benzodiazepines + Antiepileptics; Miscellaneous

The use of benzodiazepines with antiepileptics is common and possibly accompanied by some changes in serum levels, which are normally of limited clinical importance. However, isolated interactions have been reported between chlordiazepoxide or clonazepam and phenobarbital; between clonazepam and lamotrigine or primidone; and between clorazepate and primidone.

Clinical evidence

(a) Felbamate

A retrospective study compared norclozapine level dose ratios in patients taking clonazepam and enzyme-inducing antiepileptics, without felbamate (group B, 28 patients) or with felbamate (group C, 16 patients). When compared with 22 patients (group A) receiving clonazepam alone or with non-enzyme-inducing antiepileptics, the norclozapine level dose ratio of group B was increased twofold and the norclozapine level to dose ratio of group C was increased fivefold, suggesting that felbamate further increased the effect of enzyme-inducing antiepileptics on clonazepam metabolism. However, in 18 healthy subjects, the pharmacokinetics of clonazepam 1 mg every 12 hours were not significantly altered by felbamate 1.2 g every 12 hours for 10 days. No serious adverse reactions were reported.

(b) Lamotrigine

The plasma clonazepam levels in 4 of 8 patients fell by about 38% when they were also given lamotrigine.

(c) Phenobarbital and Primidone

A single case report describes a man given phenobarbital and chlordiazepoxide who became drowsy, unsteady, and developed slurred speech, nystagmus, poor memory and hallucinations, all of which disappeared once the phenobarbital was withdrawn and the chlordiazepoxide dose reduced from 80 to 60 mg daily. Phenobarbital slightly reduces the levels of both clonazepam and its active metabolite, norclozapine.

Clonazepam, in slowly increasing doses up to a maximum of 4 to 6 mg daily, given over a 6-week period to patients taking phenobarbital with or without carbamazepine, had no effect on phenobarbital levels. A study in patients receiving various combinations of phenytoin, phenobarbital and primidone, found that their serum levels were not significantly altered by the addition of clonazepam 3 mg daily for 4 weeks, but the levels of clonazepam were reduced in the presence of the other antiepileptics, particularly phenobarbital and primidone. Depression was reported in one patient and personality changes with irritability and violent behaviour was reported in another. A study found that phenobarbital caused some small changes in the pharmacokinetics of a single dose of clonazepam but only the small increase in clearance was statistically significant. In contrast, an analysis of the serum levels of antiepileptics in children found that those taking clonazepam had markedly higher levels of primidone, and toxicity was seen.

A report suggested that the concurrent use of primidone and clorazepate may have been responsible for the development of irritability, aggression and depression in 6 of 8 patients.

Phenobarbital 100 mg daily for 8 days had no effect on the metabolism of diazepam in a group of healthy subjects. Some modest additive CNS depression may possibly be expected, but the authors of this report make no comment about this.

(d) Tiagabine

Studies in healthy subjects have excluded any pharmacodynamic interaction between tiagabine and triazolam.

Mechanism

Uncertain. Changes in the drug metabolism in some cases or simple additive effects in others seem likely. It has been suggested that felbamate inhibits the clearance of norclozapine.

Importance and management

None of the interactions between the benzodiazepines and antiepileptics described here appear to be of major clinical importance, with the possible exception of the interaction between clonazepam and felbamate. If both drugs are given be aware that additive sedative or other adverse effects may occur. This may also be possible in some rare cases with chlordiazepoxide or clonazepam and phenobarbital; clonazepam and lamotrigine or primidone; and clorazepate and primidone.

one study, and another concluded that it produced no predictable change in phenytoin levels. A single-dose study in healthy subjects found no significant pharmacokinetic interaction between intravenous diazepam 10 mg and intravenous fosphenytoin 1.125 g (or the phenytoin formed by the hydrolysis of fosphenytoin).17

A study in 5 patients given phenytoin 250 to 400 mg daily found that serum clonazepam levels were reduced by more than 50%, and another study found that phenytoin decreased the clearance of clonazepam by about 50%. In a further study phenytoin reduced the plasma levels of clobazam and increased the levels of norclorazepam (the principal metabolite).18 Diazepam17 and oxazepam20 may be similarly affected in epileptic patients given phenytoin.

The pharmacokinetics and pharmacodynamics of a single 15-mg oral dose of midazolam was studied in 6 epileptic patients taking either carbamazepine, phenytoin or both drugs together, and in 7 control subjects not taking either of these antiepileptics. The AUC of midazolam in the epileptic patients was reduced to 5.7%, and the peak serum levels to 7.4% of their value in the control subjects. The pharmacodynamic effects (subjective drowsiness, body sway with eyes closed and open, as well as more formal tests) were also reduced. Most of the epileptic patients did not notice any effect of the midazolam, while the control subjects were clearly sedated for 2 to 4 hours after taking the midazolam, and also experienced amnesia.23

Mechanism

The inconsistency of these reports is not understood. Benzodiazepine-induced changes in the metabolism of phenytoin23,30,14 as well as alterations in the apparent volume of distribution have been suggested as possible mechanisms. Enzyme induction by phenytoin may possibly account for the reduction in serum benzodiazepine levels.

Importance and management

A confusing picture. Concurrent use certainly need not be avoided (it has proved to be valuable in many cases) but monitor the outcome of concurrent use and consider monitoring serum phenytoin levels so that undesirable changes can be detected. Only diazepam, chlordiazepoxide and clonazepam have been implicated, but it seems possible that other benzodiazepines could also interact.

Valproate appears to increase the serum levels of diazepam lorazepam and possibly midazolam, while clonazepam appears to raise valproate levels. Clonazepam clearance may increase and valproate clearance decrease during concurrent use, and increased adverse effects have been seen. An isolated case describes sleepwalking in a patient taking valproate and zolpidem.

Clinical evidence

A. Benzodiazepines

(1) Clonazepam

In one study sodium valproate was reported to have no marked effect on clonazepam, but a study in children found that clonazepam caused an 11% increase in the serum levels of valproate, despite a reduction of at least 10% in the valproate dosage.2

(2) Diazepam

The addition of clonazepam to sodium valproate increased the unwanted effects (drowsiness, absence status) in 9 out of 12 paediatric and adolescent patients.21 An analysis of the clonazepam-valproate interaction in 317 epileptic patients found that concurrent use increased clonazepam clearance by 14% and decreased valproate clearance by 17.9%.2

(3) Oxazepam

Sodium valproate increased the serum levels of free diazepam twofold in 6 healthy subjects.2

(4) Lorazepam

In healthy subjects, lorazepam 1 mg every 12 hours for 3 days had no effect on the pharmacokinetics of valproate semisodium 500 mg every 12 hours. However, valproate semisodium increased the AUC and maximum serum levels of lorazepam by 20% and 8%, respectively. Sedation scores were not affected by concurrent treatment, suggesting that the interaction is not clinically significant.9 A 40% decrease in the clearance of a 2-mg intravenous bolus dose of lorazepam was seen in 6 out of 8 healthy subjects while they were taking valproate 250 mg twice daily. A woman taking valproate, phenytoin, and carbamazepine went into a coma after she received a total of 6 mg of intravenous lorazepam. She promptly recovered on stopping the valproate.8

(5) Midazolam

An in vitro study in which midazolam was added to serum found that the free fraction of midazolam was in the serum from valproate-treated epileptic patients was almost double that found in serum from untreated healthy patients. It was suggested that displacement of midazolam by valproate could result in an increase in midazolam effects.9 Animal studies suggest that pre-treatment with valproate may increase the levels of midazolam in the brain.9

B. Non-benzodiazepine hypnotics

A report describes sleepwalking in a patient when valproate 250 mg twice daily was added to treatment with zolpidem 5 mg at night and citalopram 30 mg daily. The patient stopped the valproate and the sleepwalking episodes resolved. Later, the valproate was restarted causing the sleepwalking to recur. This time the symptoms resolved when the zolpidem was stopped.10

Mechanism

It seems that valproate reduces the glucuronidation of lorazepam,6,7 and therefore benzodiazepines that are mainly metabolised by glucuronide conjugation, such as oxazepam and temazepam are also likely to be affected. It is also thought that valproate may displace midazolam from its

Antipsychotics, Anxiolytics and Hypnotics 719

plasma binding sites. However, this mechanism alone rarely results in clinically significant interactions.

**Importance and management**

Evidence of an adverse interaction between valproate and the benzodiazepines and related hypnotics is sparse, and concurrent use is generally beneficial. However, on rare occasions potentially clinically significant effects have been seen. It has been suggested that the combination of clonazepam and sodium valproate should be avoided. However, a very brief letter points out that neither drug affects the serum concentrations of the other and that clonazepam and valproate can be given together in patients with absence seizures since some patients have an excellent response to the combination. It has been recommended that if clobazam is added to valproate it would be prudent to monitor for any increases in valproate serum levels.

Enhanced sedation has been briefly described during the concurrent use of valproate and unnamed benzodiazepines. 12

**Benzodiazepines and related drugs + Antimuscarinics**

Atropine and hyoscine do not affect the absorption or the sedative effects of diazepam but atropine may slow the absorption of zopiclone.

**Clinical evidence, mechanism, importance and management**

(a) Diazepam

A study in 8 healthy subjects given a single 10-mg oral dose of diazepam showed that serum diazepam levels were not significantly changed by the concurrent use of atropine 1 mg or hyoscine hydrobromide 1 mg, nor were the sedative effects of diazepam altered. 1

(b) Zopiclone

In 12 healthy subjects the absorption of a single 7.5-mg dose of zopiclone was reduced from 22.7 nanograms/mL to 6.5 nanograms/mL and at 2 hours from 49.3 nanograms/mL to 31.9 nanograms/mL by atropine. This was presumably due to altered gut motility. 2 The clinical importance of these findings is not known.

**Benzodiazepines + Antipsychotics**

Marked respiratory depression has been reported in three patients when they were given lorazepam withloxapine, and neuroleptic malignant syndrome has been reported in another three patients taking benzodiazepines and antipsychotics. The effects of lorazepam on psychomotor tests and memory was not affected by concurrent amisulpride. Airways obstruction has been reported in patients given intramuscular levomepromazine with intravenous benzodiazepines. Additive sedative effects appear to occur with zaleplon, zolpidem or zopiclone and some antipsychotics.

**Clinical evidence, mechanism, importance and management**

A. Benzodiazepines

(a) Lorazepam

1. Loxapine. A woman with a manic bipolar affective disorder was admitted to hospital and given lorazepam 2 mg with loxapine 25 mg. After 2 hours she was found to be lethargic with somnolent respiratory, occasional episodic sleep, and an irregular respiration as low as 4 breaths per minute. She was given oxygen and recovered spontaneously within 12 hours. She had experienced no previous problems with lorazepam, and had none when it was later given while she was taking perphenazine. One other case has been reported where patients given intramuscular lorazepam 1 to 2 mg and oral loxapine 50 mg developed prolonged stupor, a significantly lowered respiration rate (8 breaths per minute), and in one case hypotension. Both showed signs of recovery within 3 to 5 hours and both had taken each of these drugs alone without problems.

2. Amisulpride. A single-dose study in 18 healthy subjects found that amisulpride 50 mg or 200 mg did not potentiate or antagonise the effects of a single 2-mg dose of lorazepam on psychomotor performance or memory.

(b) Other benzodiazepines

1. Neuroleptic malignant syndrome. Three cases of neuroleptic malignant syndrome have been reported following the use of diazepam with risperidone, clorazepate with zuclopenthixol and tiapride with clonazepam. In 2 cases this followed the abrupt withdrawal of long-term benzodiazepines. All 3 patients recovered, one without any treatment. These reports are isolated and unexplained. There appears to be no clear reason for avoiding concurrent use, but it should be well monitored.

2. Obstruction of airways. A patient with catacnic schizophrenia was given intravenous diazepam 20 mg followed by intramuscular haloperidol 10 mg and levomepromazine 50 mg. Because of combative behaviour about 50 minutes later, he was given intravenous flunitrazepam 2 mg, and about 2 hours later another dose of both intravenous haloperidol 12 mg and flunitrazepam 5 mg. An hour after the last injection he became mildly cyanotic due to collapse of glossopharyngeal structures and excessive oral and nasal secretions, causing airways obstruction. Four other cases of airways obstruction associated with the combination of intramuscular levomepromazine in doses of 0.52 mg/kg or more and intravenous flunitrazepam or diazepam are also described. A subsequent review of all cases found that there were no cases of airways obstruction in patients who received haloperidol with either levomepromazine or a benzodiazepine. The interaction occurred immediately after the last intravenous injection in one patient and about 25 minutes after intramuscular levomepromazine but onset may be delayed up to 2 hours or more.

B. Non-benzodiazepine hypnotics

(a) Zaleplon

A single 50-mg dose of thioridazine had no effect on the pharmacokinetics of zaleplon 20 mg, and the psychomotor tests showed only short-term additive effects lasting 1 to 4 hours. These short-term CNS additive effects are small and unlikely to be clinically relevant, and so there would seem to be no reason for avoiding concurrent use.

(b) Zolpidem

Single-dose studies found that the pharmacokinetics of 20-mg doses of zolpidem were unaffected by 50 mg of chlorpromazine or 2 mg of haloperidol. The pharmacokinetics of both of these antipsychotics were unaffected by zolpidem, except that in one study the elimination half-life of chlorpromazine was increased from about 5 to 8 hours. Chlorpromazine increased the sedative effects of zolpidem (as indicated by impaired performances of manual dexterity and Stroop’s tests). It seems likely that additive sedation will be seen with other sedative drugs.

(c) Zopiclone

No pharmacokinetic interaction was found when 12 healthy subjects were given a single 7.5-mg oral dose of zopiclone with chlorpromazine 50 mg. However, the overall performance in a number of psychomotor tests
(including digit symbol substitution and simulated driving) was definitely impaired more by the combination of the drugs than by midazolam alone. Zopiclone with chlorpromazine impaired memory and learning, and caused a marked impairment of the performance of the tests. In practical terms this means that patients given chlorpromazine with either of these drugs should be warned that they will almost certainly feel drowsy and be less able to drive or handle potentially hazardous machinery safely.

A single 800-microgram dose of alprazolam was given to 24 healthy subjects who then took aprepitant. A significant reduction in free (and active) midazolam in the plasma since they compete for the binding sites on the plasma albumins. Not understood. It has been suggested that aspirin increases the amount of biotransformed midazolam but this remains unproven. The results also provide evidence for a significant reduction in the plasma levels of intravenously administered CYP3A4 substrates they are given with aprepitant. They also state that the effects of aprepitant on plasma levels of intravenously administered CYP3A4 substrates are expected to be less than the effects on orally administered substrates.1

Benzodiazepines + Aprepitant

Aprepitant inhibits the metabolism of oral midazolam resulting in increased plasma levels. It appears to have less effect on intravenous midazolam. A few days after aprepitant treatment is stopped a transient slight reduction in midazolam plasma levels may occur due to induction of its metabolism. Alprazolam and triazolam are expected to be affected similarly.

Clinical evidence

In a randomised study 16 healthy subjects took either aprepitant 125 mg on day 1 followed by 80 mg daily for 4 days, or 40 mg on day 1 followed by 25 mg daily for 4 days, with a single 2-mg oral dose of midazolam on days 1 and 5. The aprepitant 40/25 mg dosing schedule had no significant effect on the pharmacokinetics of midazolam. However, the aprepitant 125/80 mg dosing schedule increased the AUC of oral midazolam by 126% and 229% on days 1 and 5, respectively, and increased the maximum plasma levels of midazolam by 46% and 94% on days 1 and 5, respectively.1

In a randomised, placebo-controlled study, 24 healthy subjects were given aprepitant 125 mg on day one then 80 mg daily for a further 2 days. A single 2-mg intravenous dose of midazolam was given on days 4, 8 and 15. The 3-day aprepitant regimen increased midazolam levels slightly on day 4 (AUC increased by 25% and clearance reduced by 20%), decreased midazolam levels slightly on day 8 (AUC decreased by 19% and clearance increased by 24%) and had almost no effect by day 15, when compared to placebo.2

Mechanism

Aprepitant inhibits the cytochrome P450 isoenzyme CYP3A4 by which midazolam is metabolised, resulting in increased midazolam levels. The pharmacokinetic effect on intravenous midazolam indicate the effects of aprepitant on systemic rather than on intestinal CYP3A4 activity. Aprepitant is also a mild inducer of CYP3A4,2 however the induction is transient, with maximal effect 3 to 5 days after the end of treatment.

Importance and management

Based on the way midazolam interacts with similarly potent inhibitors of CYP3A4, aprepitant may be expected to increased the drowsiness and length of sedation and amnesia in patients given midazolam. Consider reducing the midazolam dose in patients given aprepitant and monitor the outcome of concurrent use carefully. The manufacturer notes that the potential effects of increased levels of other benzodiazepines metabolised via CYP3A4, such as alprazolam and triazolam, should be considered if they are given with aprepitant. They also state that the effects of aprepitant on plasma levels of intravenously administered CYP3A4 substrates are expected to be less than the effects on orally administered substrates.3

Antipsychotics, Anxiolytics and Hypnotics 721

Benzodiazepines + Aprepitant

The induction of anaesthesia with midazolam is more rapid in patients who have been pretreated with aspirin.

Clinical evidence

A study in patients about to undergo surgery found that pretreatment with aspirin 1 g (given as intravenous lysine acetylsalicylate) one minute before induction shortened the induction time with intravenous midazolam 300 micrograms/kg. Only 60% were ‘asleep’ within 3 minutes of receiving midazolam alone, but 80 to 81% were ‘asleep’ within 5 minutes of receiving midazolam given after the aspirin pretreatment.

Mechanism

Not understood. It has been suggested that aspirin increases the amount of free (and active) midazolam in the plasma since they compete for the binding sites on the plasma albumins.2

Importance and management

Information is limited but what is known shows that the effects of midazolam are increased by aspirin. Be alert for the need to reduce the dosage. However, note also that regular aspirin use may increase the risk of bleeding during surgery, and in some situations this may justify avoidance of aspirin in the week before surgery.3

Benzodiazepines and related drugs + Azoles

Fluconazole, itraconazole and ketoconazole very markedly increase the serum levels of midazolam and triazolam, thereby increasing and prolonging their sedative and amnesic effects. Similar but smaller effects are seen with itraconazole or ketoconazole and alprazolam and with itraconazole and brotizolam. Even less effect is seen with etizolam and itraconazole and no important interaction occurs between estazolam and itraconazole. Small effects are found with the non-benzodiazepine hypnotic, zolpidem, with ketoconazole and even less effects with zopiclone and itraconazole.

No important interaction occurs between bromazepam and fluconazole, temazepam and itraconazole, zolpidem and fluconazole and probably chlor Diazepoxide and ketoconazole.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

1. Itraconazole. A single 800-microgram dose of alprazolam was given to 10 healthy subjects before and after a 6-day course of itraconazole 200 mg daily. The itraconazole increased the AUC and the half-life of alprazolam nearly threefold, and psychomotor function was impaired.
Itraconazole. A study in healthy subjects found that itraconazole 200 mg twice daily decreased the clearance of alprazolam 1 mg by about two-thirds, and prolonged its half-life fourfold, but the maximum serum levels remained unchanged.2

(b) Bromazepam
Bromazepam 100 mg daily for 4 days had no effect on the pharmacokinetics or pharmacodynamics of bromazepam in 12 healthy subjects.3

(c) Brotizolam
A placebo-controlled study in 10 healthy subjects found that itraconazole 200 mg daily for 4 days increased the AUC6-24 and maximum plasma levels of a single 500-microgram dose of brotizolam given on day 4 by about 2.5-fold and 25%, respectively. The elimination half-life of brotizolam was also increased, from 4.51 to 23.27 hours, and sedation was increased.4

(d) Chlordiazepoxide
After taking itraconazole 400 mg daily for 5 days the clearance of chlordiazepoxide 600 micrograms/kg was decreased by 38% in 12 healthy subjects.5

(e) Estazolam
A placebo-controlled study6 found that itraconazole 100 mg daily for 7 days did not affect the pharmacokinetics or pharmacodynamics of a single 4-mg dose of estazolam given to 10 healthy subjects on day 4.

(f) Etizolam
A placebo-controlled study in healthy subjects found that itraconazole 100 mg twice daily for 7 days increased the AUC of a single 1-mg dose of etizolam given on day 6 by about 50%. The elimination half-life of etizolam was also increased, from 12 to 17.3 hours.7

(g) Midazolam
1. Fluconazole. A study in 12 healthy subjects found that fluconazole 200 mg daily for 5 days reduced the clearance of a single 7.5-mg oral dose of midazolam by 51%, and increased the AUC of midazolam 3.5-fold. It was found that the subjects could hardly be wakened during the first hour after taking the midazolam.8 Another study found that a single 150-mg dose of fluconazole increased the serum levels of a single 10-mg dose of midazolam by about 30%.9 Yet another study found that the route of administration of fluconazole (i.e. whether oral or intravenous) made little or no difference to the pharmacodynamic effects of midazolam.10 Fluconazole caused a fourfold increase in plasma midazolam levels in intensive care unit patients receiving midazolam infusions. The interaction was most marked in patients with renal failure.11 These reports contrast with another, which found that fluconazole 150 mg only slightly increased the effects of a single 10-mg dose of midazolam.12

2. Itraconazole. When 9 healthy subjects were given oral midazolam 7.5 mg, before and after taking itraconazole 200 mg daily for 4 days, the itraconazole was found to have increased the AUC of midazolam by about tenfold, increased the peak plasma levels about threefold, and prolonged the half-life from 2.8 to 7.9 hours. The subjects could hardly be wakened during the first hour after taking the midazolam and most of them experienced amnesia lasting several hours.13 A later study found that itraconazole 100 mg daily for 4 days increased the AUC of midazolam six-fold and the peak plasma levels 2.5-fold.14 A further study confirmed the marked effect of itraconazole on oral midazolam, but found that the effects of bolus doses of intravenous midazolam were not increased to a clinically significant extent, although their results suggested that long-term, high-dose infusions of midazolam need to be titrated according to effect to avoid overdosage.8

3. Ketoconazole. When 9 healthy subjects were given oral midazolam 7.5 mg before and after taking ketoconazole 400 mg daily for 4 days, the ketoconazole was found to have increased the AUC of midazolam by almost 17-fold, increased the peak plasma levels about fourfold, and prolonged the half-life from 2.8 to 8.7 hours. The subjects could hardly be wakened during the first hour after taking the midazolam and most of them experienced amnesia lasting several hours.13 Ketoconazole has been shown to reduce the metabolism of midazolam and greatly prolong its effects in another study.15

(b) Temazepam
Itraconazole 200 mg daily was given to 10 healthy subjects for 4 days, with a single 20-mg dose of temazepam on day 4. A very small increase in the temazepam AUC was seen, but the psychomotor tests carried out were unchanged.16

(f) Triazolam
1. Fluconazole. Eight healthy subjects were given fluconazole or a placebo daily for 4 days, with a single 250-microgram oral dose of triazolam on day 4. The AUC of triazolam was increased by 1.6-fold, 2.1-fold, and 4.4-fold by 50, 100, and 200 mg fluconazole, respectively, and the maximum plasma triazolam levels were more than doubled by the 200-mg fluconazole dose. The 100- and 200-mg fluconazole doses both produced significant changes in the psychomotor tests of triazolam, but the 50-mg dose did not.17

2. Itraconazole. The AUC of a single 250-microgram dose of triazolam was increased by about 28-fold after 9 healthy subjects were given itraconazole 200 mg daily for 4 days. Peak plasma levels were increased threefold. Marked changes in psychomotor and other responses were also seen. The subjects had amnesia and were still very tired and confused as long as 17 hours after taking the triazolam.18 Another study found that the interaction persists for several days after taking the itraconazole.19

3. Ketoconazole. A study in healthy subjects found that when they were given triazolam 125 micrograms, after ketoconazole 200 mg taken 17 hours and 1 hour earlier, the triazolam half-life was prolonged (from 4 to almost 18 hours in one subject) and the clearance was increased ninefold. Pharmacodynamic testing found an increase in the impairment of a digit-symbol substitution test, and increased effects on EEG beta activity.20 The AUC of a single 250-microgram dose of triazolam was increased by about 23-fold by ketoconazole 400 mg daily for 4 days. Peak plasma levels were increased threefold. Marked changes in psychomotor and other responses were seen. The subjects had amnesia and were still very tired and confused as long as 17 hours after taking the triazolam.18 Another study similarly found that ketoconazole inhibited the metabolism of triazolam leading to an increase in its sedative effects.21

B. Non-benzodiazepine hypnotics

(a) Zolpidem
1. Fluconazole. In a placebo-controlled study in healthy subjects itraconazole 100 mg twice daily for 2 days had no significant effect on the pharmacokinetics of a single 5-mg dose of zolpidem given with the third dose of fluconazole.22

2. Itraconazole. Itraconazole 200 mg daily or a placebo was given to 10 healthy subjects for 4 days. On day 4 they were also given a single 10-mg oral dose of zolpidem. The mean peak serum levels of the zolpidem were increased by 12.5% and the AUC was increased by 35%, but the performance of a number of psychomotor tests (digit symbol substitution, critical flicker fusion, subjective drowsiness, postural sway) remained unaltered.23 Another study similarly found that itraconazole did not interact significantly with zolpidem.22

3. Ketoconazole. A study in 12 healthy subjects found that following three 200-mg doses of ketoconazole given every 12 hours, the AUC of zolpidem 5 mg was increased 1.7-fold and the subjects were more sedated, as shown by the digit symbol substitution test.22

(b) Zopiclone
Itraconazole 200 mg daily or a placebo was given to 10 healthy young subjects for 4 days. On day 4 they were also given a single 7.5-mg oral dose of zopiclone. The mean peak serum levels of the zopiclone were increased by 29% (from 49 to 63 nanograms/mL), increased its AUC by 73%, and prolonged its half-life from 5 to 7 hours. But despite these increases, there were no statistical or clinical differences between the performance of the psychomotor tests carried out during the placebo and itraconazole phases of the study.24

Mechanism
Itraconazole, ketoconazole, and to a lesser extent fluconazole are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4. The benzodiazepines and zopiclone and zolpidem are, to varying degrees, metabolised by CYP3A4, with the extent of the interaction related to how significant CYP3A4 is in their metabolism. So, for example midazolam, which is predominantly metabolised by CYP3A4 is greatly affected, whereas CYP3A4 is not a significant metabolic route in the metabolism of temazepam, so it is only slightly affected. Other isoenzymes are also involved in the metabolism of zopiclone and zolpidem so they are only moderately affected. The azoles inhibit CYP3A4 in the liver (hence intravenous benzodiazepines can be affected) but studies have also suggested that ketoconazole inhibits metabolism of midazolam15 and...
Importance and management

The interactions between midazolam or triazolam and itraconazole or ketoconazole are established and clinically important. In very broad terms the dosage of midazolam would need to be reduced by about 75% or more in the presence of these antifungals to avoid excessive sedation, and even then the effects would still be expected to be prolonged. Unless appropriate precautions are taken (very reduced dosages) these interactions can be dangerous. Patients taking triazolam or ketoconazole are unlikely to be able to drive (for example) for at least 6 hours after receiving midazolam. Patients should also be warned about the likelihood of increased sedation.

The effects of alprazolam and bromazepam are increased and prolonged by ketoconazole and itraconazole, but the extent of this is less than that seen with midazolam or triazolam. However, some dosage reductions may still be necessary.

The effects of triazolam on temazepam or zopiclone and ketoconazole on chlorozapexide or zolpidem are small and seem unlikely to be clinically significant in most patients.

12. Vanakoski J, Mattila MJ, Vainio P, Ilämaa-Hekiikilä J, Törnwall M. 150 mg fluconazole alone or combined with either propranolol or labetalol are increased, and those taking diazepam and metoprolol have a reduced kinetic visual acuity, which is related to driving ability. Moreover, choice reaction times at 2 hours were also found to be lengthened when taking diazepam and metoprolol, propranolol or atenolol, but at 8 hours they only persisted with diazepam and metoprolol.

(b) Clomethiazole

An 84-year-old woman taking propranolol 40 mg twice daily for hypertension underwent skin grafting. Her pulse was stable (54 to 64 bpm) until the thirteenth day after the operation when she took two oral doses of clomethiazole 192 mg, 9 hours apart. Three hours after taking the second dose her heart rate fell to 43 bpm with a PR interval of 0.24 seconds, and by 5 hours after the dose her pulse rate was down to 36 bpm. Her pulse had risen to 70 bpm twelve hours after stopping both drugs, and had restabilised 2 days later at about 60 bpm with a PR interval of 0.24 seconds. At this time the propranolol was restarted, with haloperidol.

Importance and management

Information about interactions between the benzodiazepines and beta blockers is very limited indeed. The current evidence does not seem to justify any additional caution, but bear this interaction in mind in the case of an unexpected response to treatment. The interaction between propranolol and clomethiazole appears to be an isolated case and therefore probably of limited clinical significance.

Benzodiazepines and related drugs + Beta blockers

Only small and clinically unimportant pharmacokinetic interactions occur between most benzodiazepines and beta blockers, but there is some evidence that patients taking diazepam may possibly be more accident-prone while taking metoprolol. An isolated report describes marked bradycardia when an elderly woman taking propranolol started to take clomethiazole.

Clinical evidence and mechanism

(a) Benzodiazepines

No significant pharmacokinetic interaction occurs between:

- alprazolam and propranolol
- clorazepate and propranolol
- diazepam and atenolol or propranolol
- lorazepam and metoprolol or propranolol
- oxazepam and labetalol or propranolol.

Moderate changes, which seem unlikely to be clinically significant, were found between:

- diazepam and propranolol (diazepam clearance reduced by 17%) or propranolol (diazepam clearance reduced by 18%, AUC increased by 25%)
- bromazepam and metoprolol (bromazepam AUC increased by 35%) or propranolol (bromazepam half-life increased by 22%).

However, studies of psychomotor performance have shown that simple reaction times with oxazepam combined with either propranolol or labetalol are increased, and those taking diazepam and metoprolol have a reduced kinetic visual acuity, which is related to driving ability. Moreover, choice reaction times at 2 hours were also found to be lengthened when taking diazepam and metoprolol, propranolol or atenolol, but at 8 hours they only persisted with diazepam and metoprolol.

- clorazepate
- clorazepate
- diazepam
- diazepam
- lorazepam
- oxazepam
- propranolol
- propranolol
- zolpidem.

Clinical evidence and mechanism

(b) Clomethiazole

An 84-year-old woman taking propranolol 40 mg twice daily for hypertension underwent skin grafting. Her pulse was stable (54 to 64 bpm) until the thirteenth day after the operation when she took two oral doses of clomethiazole 192 mg, 9 hours apart. Three hours after taking the second dose her heart rate fell to 43 bpm with a PR interval of 0.24 seconds, and by 5 hours after the dose her pulse rate was down to 36 bpm. Her pulse had risen to 70 bpm twelve hours after stopping both drugs, and had restabilised 2 days later at about 60 bpm with a PR interval of 0.24 seconds. At this time the propranolol was restarted, with haloperidol.
Benzodiazepines + Black cohosh

The pharmacokinetics of midazolam are unaffected by the use of black cohosh (Cimicifuga).

Clinical evidence, mechanism, importance and management

In a study in 19 healthy subjects given black cohosh extract (standardised to triterpene glycosides 2.5%) 40 mg twice daily for 28 days with a single 8-mg oral dose of midazolam on day 28, there was no change in the pharmacokinetics of midazolam. In addition, black cohosh had no effect on the duration of midazolam-induced sleep. Similarly, in another study in 12 non-smoking healthy subjects given black cohosh root extract (standardised to triterpene glycosides 0.2%) 1090 mg twice daily for 28 days, there was no significant change in the pharmacokinetics of a single 8-mg oral dose of midazolam.

As black cohosh extract does not appear to alter the pharmacokinetics of midazolam, a probe substrate for the cytochrome P450 isoenzyme CYP3A4, it is therefore unlikely that it will alter the pharmacokinetics of other substrates of this isoenzyme, see ‘Table 1.4’, (p.6), for a list.

Benzodiazepines + Buspirone

No adverse interaction appears to occur if buspirone and alprazolam are given together. When buspirone is given with diazepam the adverse effects appear to be mild and short-lived.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects buspirone 15 mg every 8 hours had no effect on the plasma levels of diazepam 5 mg daily for 10 days, but the levels of the metabolite nordiazepam were raised by about 20%. All subjects experienced some mild adverse effects (headache, nausea, dizziness, and in two cases muscle twitching). These symptoms subsided after a few days.

In 12 healthy subjects buspirone 10 mg every 8 hours increased the maximum plasma levels and AUC of alprazolam 1 mg every 8 hours by 7% and 8%, respectively. The maximum plasma levels of buspirone were not altered, but the AUC of buspirone was increased by 29%. However, these changes were within the normal pharmacokinetic variability of these drugs. No unexpected adverse effects were seen.

There would seem to be no reason for avoiding the concurrent use of either diazepam or alprazolam and buspirone.

Benzodiazepines + Calcium-channel blockers

Of the calcium-channel blockers diltiazem and verapamil are known to inhibit CYP3A4, the route by which benzodiazepines such as midazolam and triazolam are metabolised. Increased effects, such as sedation, which have been marked in some cases, have been seen in patients given these drugs. Alprazolam would be expected to interact similarly. There appear to be no clinically significant interactions between other calcium-channel blockers and benzodiazepines.

Clinical evidence

(a) Diazepam

1. Diltiazem. When single doses of diltiazem 5 mg and diltiazem 60 mg were given to 6 subjects it was found that the plasma levels of each drug were not significantly altered by the presence of the other drug. In another study, poor and extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19 (see ‘Genetic factors in drug metabolism’, (p.4)) were given diltiazem 200 mg daily for 3 days before and 7 days after a single 2-mg dose of diazepam. It was found that there were no differences in the interaction between the phenotypes, and both groups showed an increase in the AUC and half-life of diltiazem. However, the clinical effects of the pharmacokinetic changes were not assessed.

2. Felodipine. The pharmacokinetics of a 10-mg intravenous dose of diazepam were unchanged in 12 healthy subjects after they took felodipine 10 mg daily for 12 days but the AUC and peak serum levels of the diazepam metabolite, desmethyl-diazepam, were raised by 14% and 16%, respectively.

3. Nimodipine. The serum levels of diazepam 10 mg daily and nimodipine 30 mg three times daily were unaffected by concurrent use in 24 healthy, elderly subjects, and no clinically relevant changes in haemodynamics, ECG recordings, clinical chemistry or haematology occurred.

(b) Midazolam

1. Diltiazem. After taking diltiazem 60 mg three times daily for 2 days, 9 healthy female subjects were given midazolam 15 mg orally. The AUC of midazolam was increased fourfold, the maximum serum levels doubled, and the half-life increased by 49%. It was almost impossible for the subjects to stay awake for 90 minutes after taking the midazolam. They suffered several hours of amnesia and there was a marked decrease in the performance of pharmacodynamic tests (digit symbol substitution, Mad-dox wing test). Diltiazem 60 mg, given to 15 patients 2 hours before induction of anaesthesia with midazolam and alfentanil, increased the AUC and half-life of midazolam by 15% and 43%, respectively. Tracheal extubation was performed on average 2.5 hours later, when compared with placebo.

2. Lercanidipine. Midazolam appears to increase the absorption of lercanidipine by 40%. The clinical relevance of this interaction is as yet unclear.

3. Nitrendipine. A study in 9 healthy subjects found that the pharmacokinetics and pharmacodynamics of midazolam were unaffected by a single 20-mg dose of nitrendipine.

4. Verapamil. After taking verapamil 80 mg three times daily for 2 days, 9 healthy female subjects were given midazolam 15 mg orally. The AUC of the midazolam was increased threefold, the maximum serum levels were doubled, and the half-life increased by 41%. It was almost impossible for the subjects to stay awake for 90 minutes after taking the midazolam. They suffered several hours of amnesia and there was a marked decrease in the performance of pharmacodynamic tests (digit symbol substitution, Madder wing test).

(c) Temazepam

Diltiazem 40 mg had no little or no effect on the hypnotic effects of temazepam in 16 healthy insomnia.

(d) Triazolam

1. Diltiazem. A study in 7 healthy subjects found that diltiazem 60 mg three times daily for 3 days increased the AUC of a single 250-microgram dose of triazolam 2.3-fold and almost doubled its peak serum levels. Pharmacodynamic tests showed an increase in the sedative effects of triazolam. Another study in 10 healthy subjects found that diltiazem 60 mg three times daily for 2 days increased the AUC of a single 250-microgram dose of triazolam 3.4-fold, and approximately doubled its maximum plasma level and half-life. The pharmacodynamic changes were briefly described as profound and prolonged. In contrast, diltiazem 40 mg was found to have little or no effect on the hypnotic effects of triazolam in 16 healthy insomnia.

2. Isradipine. Isradipine 5 mg daily reduced the AUC of a single 250-microgram dose of triazolam by 20% in 9 healthy subjects, but no difference in the pharmacodynamic effects of triazolam were seen.
Mechanism

The evidence suggests that diltiazem and verapamil inhibit the metabolism of midazolam and triazolam, by the cytochrome P450 isoenzyme CYP3A4, leading to increased serum levels and increased effects.

Importance and management

The interactions between midazolam and diltiazem, midazolam and verapamil, and triazolam and diltiazem are established and clinically important. The authors of one report say that patients on either of these calcium-channel blockers are probably incapable of doing skilled tasks (e.g. car driving) for up to 6 hours after taking midazolam 15 mg, and possibly even after 8 to 10 hours. They suggest that the usual dose of midazolam should be reduced at least 50% to avoid unnecessary deep sleep and prolonged hypnosis, and they also point out that since the half-life of the midazolam is prolonged, the effects will persist regardless of the dose. The same seems likely to be true for triazolam and diltiazem, and the interaction is also predicted to occur with triazolam and verapamil. As for alprazolam, it is also metabolised by CYP3A4, this interaction would be expected to occur although there do not appear to be any clinical reports of an interaction.

No special precautions appear to be necessary when other calcium-channel blockers are given with a benzodiazepine.

Clinical evidence, mechanism, importance and management

Intravenous midazolam 200 micrograms/kg was given to 8 patients receiving long-term treatment with corticosteroids (6 taking prednisolone 2.5 mg to 15 mg daily; 1 taking betamethasone 0.5 mg daily; 1 taking methylprednisolone 48 mg daily) and to 10 other patients not taking corticosteroids. In the patients taking corticosteroids the AUC of midazolam was decreased and the clearance increased, when compared with the patients not taking corticosteroids; however the differences were not significant. The onset of anaesthesia between the two groups was also not different. It was suggested that the trend towards increased midazolam metabolism may be due to induction of the cytochrome P450 isoenzyme CYP3A4 and/or UDP-glucuronosyltransferase. Although the results with intravenous metabolism were not significant the authors note that it is possible that the metabolism of oral midazolam may be more markedly affected.

Benzodiazepines + Dexamfetamine

Dexamfetamine reverses the sedative effects and some of the memory-impairing effects of triazolam.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 20 healthy subjects found that a single 20-mg/70 kg dose of dexamfetamine sulfate reversed the sedative effects of a single 250-micrograms/70 kg dose of triazolam. The study also found that dexamfetamine selectively reversed some of the memory-impairing effects of triazolam.

Benzodiazepines + Disulfiram

An isolated report describes temazepam toxicity due to dexamfetamine. The serum levels of chloridiazepoxide and diazepam are increased by the use of dexamfetamine and some patients may possibly experience increased drowsiness. Alprazolam, oxazepam and lorazepam are either not affected, or only minimally affected, by dexamfetamine.

Clinical evidence

A man taking dexamfetamine 200 mg daily developed confusion, drowsiness, slurred speech and an unsteady gait within a few days of starting to take temazepam 20 mg at night. This was interpreted as temazepam toxicity. The symptoms disappeared when both drugs were stopped.

After taking dexamfetamine 500 mg daily for 14 to 16 days, the plasma clearance of chloridiazepoxide and diazepam were reduced by 54% and 41%, respectively, and the half-lives were increased by 84% and 37%, respectively. The plasma levels of chloridiazepoxide were approximately doubled. Oxazepam was also given following dexamfetamine treatment but changes in oxazepam pharmacokinetics were minimal. There was no difference in the interaction between alcoholic subjects (without hepatic cirrhosis) and healthy subjects.

Other studies show that the pharmacokinetics of lorazepam and alprazolam are unaffected by dexamfetamine.

Mechanism

Dexamfetamine inhibits the initial metabolism (N-demethylation and oxidation) of both chloridiazepoxide and diazepam by the liver so that an alternative but slower metabolic pathway is used. This results in the accumulation of these benzodiazepines in the body. In contrast, the metabolism (glucuronidation) of oxazepam and lorazepam is minimally affected by dexamfetamine so that their clearance from the body remains largely unaffected. The possible interaction between dexamfetamine and temazepam is not understood, as temazepam is also mainly eliminated in the urine as the inactive glucuronide metabolite, and so its metabolism would not be expected to be affected by dexamfetamine.

Benzodiazepines + Colestyramine and Neomycin

The clearance of lorazepam is increased by colestyramine with neomycin.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that neomycin 1 g every 6 hours with colestyramine 4 g every 4 hours reduced the half-life of oral lorazepam from 15.8 to 11.7 hours, and increased the clearance of free lorazepam by 34%. The reasons for these changes are not clear but parallel studies using intravenous lorazepam suggested that neomycin and colestyramine may interfere with the possible enterohepatic circulation of lorazepam.

The clinical importance of this interaction is uncertain but probably small. Other benzodiazepines do not appear to have been studied.

Benzodiazepines + Corticosteroids

The metabolism of oral midazolam may be increased in patients receiving long-term treatment with corticosteroids.
Importance and management

There seems to be only one report (with temazepam) of a clinically significant interaction between disulfiram and the benzodiazepines, and this report is unconfirmed, as the patient did not take temazepam alone. The other reports only describe potential interactions that have been identified by single-dose studies. These do not necessarily reliably predict what will happen in practice. However, it seems possible that some patients will experience increased drowsiness, possibly because of this interaction, and because drowsiness is a very common adverse effect of disulfiram. Reduce the dosage of the benzodiazepine if necessary. Benzodiazepines that are metabolised by similar pathways to diazepam and chlor Diazepoxide, possibly interact in the same way (e.g. bromazepam, clonazepam, clorozaepate, prazepam, ketazolam, clobazam, flurazepam, nitrazepam, medazepam) but this needs confirmation. Alprazolam, oxazepam and lorazepam appear to be non-interacting alternatives.

Benzodiazepines + Echinacea

Echinacea does not appear to alter the AUC and clearance of oral midazolam, although the bioavailability may be increased. Clearance of intravenous midazolam may be increased in patients taking echinacea.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 12 healthy subjects were given *Echinacea purpurea* root 400 mg four times daily for 28 days, with a single 50-microgram/kg intravenous dose of midazolam on day 6, and, 24 hours later, a single 5-mg oral dose of midazolam. The clearance of intravenous midazolam was increased by 42%, and the AUC was reduced by 23%, but there were no significant changes in these parameters after oral dosing. However, the oral bioavailability of midazolam was increased by 50% by echinacea. The authors suggested that the echinacea may have exerted opposing effects on the cytochrome P450 isoenzyme CYP3A in the liver and the intestine, which resulted in this apparent anomaly. In another study given *Echinacea purpurea* 800 mg twice daily for 28 days with a single 8-mg oral dose of midazolam, there was no difference in the ratio of midazolam to its 1-hydroxy metabolite.

The findings of the first study with oral and intravenous midazolam suggest that the effect of echinacea on CYP3A4 substrates might depend on the whether they have high or low oral bioavailability and whether they have high or low hepatic clearance. Further study is needed.

Benzodiazepines + Ethambutol

Ethambutol appears not to interact with diazepam.

Clinical evidence, mechanism, importance and management

A study in 6 patients, newly diagnosed with tuberculosis and taking ethambutol 25 mg/kg, found that although some of the pharmacokinetic parameters of diazepam were different to those obtained in healthy control subjects not taking ethambutol, the differences were not significant. There seems to be nothing in the literature to suggest that ethambutol interacts with other benzodiazepines.

Benzodiazepines + Food

Food can delay and reduce the hypnotic effects of flunitrazepam and loprazolam. Food can markedly enhance the absorption of quazepam.

Clinical evidence, mechanism, importance and management

A study in 2 groups of 8 healthy subjects found that when they took single 2-mg doses of *flunitrazepam* or *lorazolam* 2 hours after an evening meal (spaghetti, meat, salad, an apple and wine) and 1 hour before going to bed, the peak plasma levels of *flunitrazepam* and *lorazolam* were reduced by 42% and 41%, respectively. The time to reach these levels were delayed by 2.5 hours and 3.6 hours, respectively, and the absorption half-lives of the drugs were considerably prolonged. It seems probable therefore that the onset of sleep with these benzodiazepines may be delayed by food.

In a crossover study 9 healthy subjects were given single 20-mg dose of *quazepam* after fasting, 30 minutes after a standard meal, and 3 hours after a standard meal. The peak plasma levels and AUC0-8h for *quazepam* were increased by 3-fold and 2.4-fold, respectively, when given 30 minutes after food, and by 2.5-fold and 2.1-fold, respectively, when given 3 hours after food, when compared with the fasting state. The CNS-depressant effects of *quazepam* were enhanced to a similar extent by administration 30 minutes or 3 hours after food. Another study found similar increases in the bioavailability when *quazepam* was taken 2 hours after food, but did not find any significant difference in the subjective effects of *quazepam*, such as drowsiness, malaise, and calmness, when compared with fasting.

Benzodiazepines + Ginkgo biloba

Ginkgo biloba does not significantly affect the pharmacokinetics of alprazolam.

Clinical evidence, mechanism, importance and management

*Ginkgo biloba* leaf extract 120 mg twice daily for 16 days was given to 12 healthy subjects before and with a single 2-mg dose of alprazolam on day 14. The *Ginkgo biloba* preparation (*Ginkgold*) was standardised to ginkgo flavonol glycosides 24% and terpene lactones 6%. The alprazolam AUC was reduced by 17%, and the maximum concentration was not significantly affected: these findings are unlikely to be of clinical significance.

1. Alprazolam is a probe substrate for the cytochrome P450 isoenzyme CYP3A4 activity, and the findings of this study suggest that Ginkgo biloba is unlikely to have clinically relevant effects on substrates of this isoenzyme, see ‘Table 1.4’, (p.6).

Benzodiazepines + Grapefruit juice

Grapefruit juice can increase the bioavailability of oral diazepam and quazepam but there is evidence that this may be of little practical importance. Midazolam and triazolam levels are also raised by grapefruit juice, and this may be of some clinical significance.
Clinical evidence

A study in 8 healthy subjects found that 250 mL of grapefruit juice increased the AUC and maximum plasma levels of a single 5-mg oral dose of diazepam by 3.2-fold and 1.5-fold, respectively. Another study in 9 healthy subjects found that grapefruit juice increased the AUC of quazepam and its active metabolite, 2-oxoquazepam, by 38% and 28%, respectively, after a single 15-mg oral dose of quazepam, although these increases were not statistically significant. The pharmacodynamic effects of quazepam, such as sedation, were not enhanced by grapefruit juice.2

Grapefruit juice 200 mL was given to 8 healthy subjects followed 60 minutes later by 5 mg of intravenous midazolam or 15 minutes later by 15 mg of oral midazolam. The pharmacokinetics of intravenous midazolam remained unchanged, but the AUC of the oral midazolam was increased by 52%, and its maximum plasma levels rose by 56%. These changes were also reflected in the psychometric measurements made.3

A large scale placebo-controlled study in a total of 120 healthy young medical students used psychomotor tests to measure the effect of benzodiazepines with and without grapefruit juice. Subjects were given midazolam 10 mg or triazolam 250 micrograms with 300 mL of grapefruit juice. Only a minor increase in the benzodiazepine effects occurred with grapefruit juice, and these effects were of little or no practical importance.4

Another study of the interaction between triazolam and grapefruit juice found that the effects of grapefruit juice were much more pronounced when multiple doses of grapefruit juice were given. The triazolam AUC and half-life were increased by about 50% and 6%, respectively, when single doses of grapefruit juice were given, and by about 150% and 50%, respectively, by multiple doses of grapefruit juice. The effect of grapefruit juice on psychomotor tests was also greater after multiple dosing.5

Mechanism

The evidence suggests that grapefruit juice inhibits the metabolism of these benzodiazepines by the cytochrome P450 isoenzyme CYP3A4, so that more is left to enter the circulation. In one study grapefruit juice was found to have a greater effect on the bioavailability and pharmacodynamics of triazolam than on quazepam. This was considered to be because triazolam is metabolised by CYP3A4, while quazepam is metabolised by CYP2C9 as well as by CYP3A4.2

Importance and management

Established interactions. These increases in bioavailability might be expected to increase the extent of the sedation and amnesia due to these benzodiazepines, but in young healthy adults this is apparently of little importance. The clinical effects of the interaction with diazepam appear not to have been investigated. The effects of midazolam and triazolam may be more enhanced than those of other benzodiazepines, because these drugs are more dependent on CYP3A4 for their metabolism (see Mechanism, above). What is not clear is whether other factors such as old age or liver cirrhosis might increase the risk of adverse effects with concurrent use.

Benzodiazepines and related drugs + H2-receptor antagonists

The serum levels of many of the benzodiazepines and related drugs are raised by cimetidine, but normally this appears to be of little or no clinical importance and only the occasional patient may experience an increase in the effects (sedation). The interactions with midazolam, zaleplon, and zolpidem may be more significant, but this is not established. Famotidine, nizatidine and ranitidine do not normally appear to interact with most benzodiazepines. Increased sedation appears to occur with clomethiazole and cimeti- dine.

Clinical evidence

A. Benzodiazepines

(a) Cimetidine

The combined serum level of diazepam and its active metabolite, desmethyl-diazepam, was found to be increased by 75% in 10 patients who took cimetidine 300 mg four times daily for 2 weeks, but reaction times and other motor and intellectual tests remained unaffected. Other reports describe a rise in the plasma levels and/or AUC of diazepam (associated with increased sedation in one report) due to cimetidine, and generalised incoordination has also been described in one individual.

Cimetidine also raises the serum levels of adinazolam, alprazolam, clorazepate, clorazepate, flurazepam, nitrazepam, and triazolam, and reduces the clearance of bromazepam.

Liver cirrhosis increases the effects of cimetidine on the loss of chloridiazepoxide. Confusion has been reported in a 50-year-old man taking clorazepate when he was given cimetidine, and increased sedation has been seen in some patients taking adinazolam and cimeti- dine. Prolonged hypnosis in an elderly woman and CNS toxicity (including lethargy and hallucinations) in a 49-year-old woman have been attributed to an interaction between triazolam and cimeti- dine but this remains unconfirmed.

In contrast, cimeti- dine does not normally interact with clorazepate, clo- diazepam, lorazepam, oxazepam, oxazepam, or temazepam, although prolonged post-operative sedation was seen in one patient given oxazepam and cimetidine.

There is some controversy about whether or not midazolam is affected by cimetidine. An increase in sedation, an increase in midazolam levels and no pharmacokinetic interaction have been reported with the combination.

Similarly, one study found an increase in lorazepam levels with a 400 mg dose of cimeti- dine, but no effect with 200 mg: other studies suggest that no interaction occurs between lorazepam and cimetidine.

(b) Famotidine

Famotidine does not interact with bromazepam, clorazepate, cloridiazepoxide, diazepam, oxazepam, or triazolam.

(c) Nizatidine

Nizatidine does not interact significantly with diazepam.

(d) Ranitidine

Ranitidine does not interact significantly with adinazolam, diazepam, lorazepam, or temazepam. It can modestly increase the bioavailability (by about 10 to 30%) of oral triazolam. There is some controversy about whether or not midazolam is affected by ranitidine. Increases in sedation have been reported on a number of occasions, but a lack of effect has also been documented.

(e) Roxatidine

Roxatidine does not interact with diazepam or its active metabolite, des- methyl-diazepam.

B. Non-benzodiazepine hypnotics

(a) Cimetidine

Cimeti- dine increases plasma levels of zaleplon and slightly increases sleep duration with zolpidem. Cimeti- dine reduces the clearance of clomethiazole and increases sleep duration from a range of 30 to 60 minutes up to at least 2 hours.
Importance and management

The interactions between the benzodiazepine and related drugs and cimetidine are well documented (not all the references are listed here) but normally they appear to be of little clinical importance, although a few patients may be adversely affected (increased effects, drowsiness, etc.) and this may be more common with the non-benzodiazepine hypnotic, clomethiazole, and possibly, midazolam. If symptoms occur in any patient taking a benzodiazepine or related drug and cimetidine, reduce the benzodiazepine dose, or alternatively, use a non-interacting benzodiazepine, such as lorazepam, lormetazepam, oxazepam or temazepam, or a non-interacting H2-receptor antagonist such as ranitidine, famotidine, nizatidine or roxatidine, although note that the effects of oral triazolam are possibly not reduced.

Benzodiazepines and related drugs + Hormonal contraceptives

Hormonal contraceptives can increase the effects of alprazolam, chlordiazepoxide, diazepam, nitratreiazepam and triazolam, and reduce the effects of oxazepam, lorazepam and temazepam, but whether in practice there is a need for dosage adjustments has not been determined. Chlordiazepoxide, diazepam, nitratreiazepam and mebropramab can possibly increase the incidence of breakthrough bleeding.

Clinical evidence

(a) Effects of benzodiazepines and related drugs

A controlled study found that the mean half-life of intravenous chlordiazepoxide 600 micrograms/kg was virtually doubled (11.6 hours com-
pared with 20.6 hours) and the total clearance was almost two-thirds lower in 6 women taking oral contraceptives when compared with 6 women not taking oral contraceptives.

Similar but less marked effects were found in other studies in women taking oral contraceptives given chlordiazepoxide, diazepam, temazepam, ativan and to an even lesser extent with triazolam and nitrazepam. No clinically significant pharmacokinetic changes were seen with bromazepam, clotiazepam, midazolam (given orally intramuscularly or intravenously) or zolpidem.

A controlled study, comparing 7 women taking an oral contraceptive with 8 women not taking oral contraceptives found that the mean half-life of intravenous lorazepam 2 mg was over 50% shorter in the oral contraceptive group (6 hours compared to 14 hours) and the total clearance was over threefold greater.

A smaller increase in the elimination rate was seen in other controlled studies in women taking oral contraceptives and lorazepam, temazepam, and in two other studies small decreases in the half-life of oxazepam were observed.

(b) Effects on contraceptives

A study in 72 patients taking combined oral contraceptives (Rigevidon, Anteovin) found that breakthrough bleeding occurred in 36.1% of patients while taking chlordiazepoxide 10 to 20 mg daily, diazepam 5 to 15 mg daily, nitrazepam 5 to 10 mg daily, meprobamate 200 to 600 mg daily, but no pregnancies occurred. Only three cases of bleeding occurred with diazepam or nitrazepam. The average values for breakthrough bleeding with these two oral contraceptives were 9.1% for Rigevidon and 3.3% for Anteovin in the absence of other drugs. It was possible to establish a causal relationship between the bleeding and the use of the hypnotic in 77% of the cases either by stopping the drug or by changing it for another.

Mechanism

Oral contraceptives affect the metabolism of the benzodiazepines by the liver in different ways: oxidative metabolism is reduced (alprazolam, chlordiazepoxide, diazepam, etc.), whereas metabolism by glucuronide conjugation is increased (lorazepam, oxazepam, temazepam, etc.). Just why these hypnotics should cause breakthrough bleeding is not understood.

Importance and management

Established interactions but of uncertain clinical importance. Long-term use of benzodiazepines that are highly oxidised (alprazolam, chlordiazepoxide, diazepam, etc.) and metabolism by glucuronide conjugation is increased (lorazepam, oxazepam, temazepam, etc.). Just why these hypnotics should cause breakthrough bleeding is not understood.

Benzodiazepines + 5-HT3-receptor antagonists

Lorazepam does not appear to interact with granisetron, and temazepam does not appear to interact with ondansetron.

Clinical evidence, mechanism, importance and management

Lorazepam 2.5 mg given to 12 healthy subjects, clearly affected the performance of a number of psychometric tests. Statistically significant increases occurred in drowsiness, sleepiness, muzziness, clumsiness, lethargy, mental slowness, relaxation, dreaminess, incompetence, sadness, and withdrawal. However, there was very little evidence that granisetron 160 micrograms/kg alone had any effect on the performance of these tests except that clumsiness and inattentiveness were increased, nor was there evidence that granisetron added to the effects of lorazepam when both drugs were taken concurrently.

In a placebo-controlled, crossover study in 24 healthy subjects ondansetron 8 mg did not affect the pharmacokinetics of temazepam 20 mg. The psychomotor performances of the subjects (subjective and objective sedation, memory and other measurements) were not influenced by the presence of the ondansetron.

No additional special precautions would seem to be necessary if either of these pairs of drugs are given.

Benzodiazepines + Influenza vaccines

The pharmacokinetics of alprazolam, chloridazepoxide and lorazepam are not affected by influenza vaccination.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of single doses of oral alprazolam 1 mg, or intravenous lorazepam 2 mg remained unaffected in healthy subjects when the benzodiazepines were given 7 and 21 days after 0.5 mL of an intramuscular trivalent influenza vaccine. Similarly, in another study, neither lorazepam nor chloridazepoxide metabolism was altered when they were given 1 and 7 days after a trivalent influenza vaccine.

Benzodiazepines + Isoniazid

Isoniazid reduces the clearance of both diazepam and triazolam. Some increase in their effects would be expected. No interaction occurs with oxazepam or clotiazepam.

Clinical evidence

(a) Interacting benzodiazepines

A study in 9 healthy subjects found that isoniazid 90 mg twice daily for 3 days increased the half-life of a single 5- or 7.5-mg dose of diazepam from about 34 to 45 hours, and reduced the total clearance by 26%. A study in 6 healthy subjects found that isoniazid 90 mg twice daily for 3 days, increased the half-life of a single 500 microgram dose of triazolam from 2.5 to 3.3 hours, increased the AUC by 46% and reduced the clearance by 43%.2

(b) Non-interacting benzodiazepines

A study in 9 healthy subjects found that isoniazid 90 mg twice daily for 3 days had no effect on the pharmacokinetics of a single 30-mg oral dose of oxazepam.2 Similarly, in another study, the pharmacokinetics of clontiazepam were not altered by isoniazid.3

Mechanism

What is known suggests that isoniazid acts as an enzyme inhibitor, decreasing the metabolism and loss of diazepam and triazolam from the body, thereby increasing and prolonging their effects. Oxazepam which is metabolized by glucuronidation would be unlikely to interact.

Importance and management

Information is limited but the interactions appear to be established. Their clinical importance is uncertain but be alert for the need to decrease the dosages of diazepam and triazolam if isoniazid is started. There seems to be no direct information about other benzodiazepines, but those undergoing high first-pass extraction and/or liver microsomal metabolism may interact similarly. Oxazepam and clontiazepam appear not to interact.

Benzodiazepines + Kava

A man taking alprazolam became semicomatose a few days after starting to take kava, which was suggested to be due to additive sedation. The pharmacokinetics of midazolam were unaffected by kava.

Clinical evidence, mechanism, importance and management

(a) Alprazolam

A 54-year-old man taking alprazolam, cimetidine and terazosin was hospitalized in a lethargic and disoriented state 3 days after starting to take kava, which he had bought from a local health food store. He denied having overdosed with any of these drugs. The patient became alert again after several hours.3 The reason for what happened is not known, but the suggested explanation is that the kava α-pyrones might have had additive sedative effects with those of the alprazolam.1,2 This is an isolated case and its general importance is not known.

(b) Midazolam

In a study in 6 subjects who regularly took 7 to 27 g of kavalactones weekly as an aqueous kava extract, there was no change in the metabolism of a single 8-mg oral dose of midazolam before or after they stopped kava for 30 days.3 Similar results were found in a study in 12 healthy subjects given kava kava root extract 1 g twice daily for 28 days before receiving a single 8-mg dose of oral midazolam.4 In contrast to some in vitro data, these studies show that kava has no effect on the cytochrome P450 isoenzyme CYP3A4, of which midazolam is a probe substrate.5 It is possible that the kava levels achieved clinically are insufficient to affect CYP3A4. The findings of these studies suggest that it is unlikely that kava will alter the pharmacokinetics of other substrates of CYP3A4 (see ‘Table 1.4’, (p.6), for a list).

Benzodiazepines and related drugs + Macrolides

The serum levels and effects of midazolam, triazolam and zopiclone are markedly increased and prolonged by erythromycin. The same interaction has been seen with clarithromycin, josamycin, or troleandomycin but not azithromycin. Alprazolam would be expected to be similarly affected. Other benzodiazepines, and the related hypnotic zaleplon, appear not to interact with the macrolides to a clinically significant extent.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

In a randomised study 12 healthy subjects were found to receive erythromycin 400 mg three times daily for 7 days increased AUC of a single 500-microgram dose of alprazolam on day 8. The alprazolam AUC0-48 was increased by 61% and the half-life increased from 16 to 40.3 hours. However, no increase in sedation was seen.1 The manufacturers predict that other macrolides will interact similarly, and they specifically name erythromycin and troleandomycin.2

(b) Brotizolam

A randomised study in healthy subjects found that erythromycin 400 mg three times daily for 7 days increased AUC of a single 500-microgram dose of brotizolam by 2.5-fold. The elimination half-life was also increased from 9.4 hours to 20.7 hours. However, erythromycin did not affect the changes in psychomotor function associated with brotizolam.3

(c) Diazepam

In a crossover study, 6 healthy subjects were given a single 5-mg oral dose of diazepam after taking erythromycin 500 mg three times daily for one week. The diazepam AUC was increased by a modest 15%, but its pharmacodynamic effects were unchanged.4

(d) Flunitrazepam

In a crossover study, 5 healthy subjects were given a single 1-mg oral dose of flunitrazepam after taking erythromycin 500 mg three times daily for one week. The flunitrazepam AUC was increased by 25% but its pharmacodynamic effects were unchanged.4

(e) Midazolam

1. Azithromycin. A study in 64 healthy medical students found that azithromycin 750 mg had no effect on the metabolism of a 10- or 15-mg dose of midazolam, and did not alter the performance of a number of psychomotor tests.5 A study in 10 healthy subjects given azithromycin 250 mg daily found that some small changes in pharmacokinetics of midazolam 15 mg (a possible small delay in its onset of action), but its pharmacodynamic effects were unaltered.6 Other studies confirm that azithromycin does not interact with midazolam.7,8

2. Clarithromycin. Oral 4 mg and intravenous 50 microgram/kg doses of midazolam were given simultaneously to 16 healthy subjects, before and after they took clarithromycin 500 mg twice daily for 7 days. It was found that clarithromycin reduced the systemic clearance of midazolam by about 64%, which resulted in a doubling of the midazolam-induced sleeping time.9 Similar results were found in another study.8

3. Erythromycin. A study in 12 healthy subjects found that erythromycin 500 mg three times daily for 6 days almost tripled the peak plasma levels of a single 15-mg dose of midazolam, more than doubled its half-life and increased the AUC by more than fourfold. The subjects could hardly be wakened during the first hour after being given the midazolam, and most experienced amnesia lasting several hours.10

The serum levels of a 500-microgram/kg oral dose of midazolam, given to an 8-year-old boy as pre-medication before surgery, were approximately doubled when he was given intravenous erythromycin. He developed nausea and tachycardia, and after 40 minutes (by which point he had received 200 mg of erythromycin) he lost consciousness.11 A patient in a coronary
care unit given 300 mg of intravenous midazolam over 14 hours slept for about 6 days (apart from brief wakening when given flumazenil). The midazolam half-life was increased by about tenfold. This was attributed to an interaction due to the combined effects of erythromycin 4 g daily and amiodarone 1.7 g over 3 days. Other studies and reports have also described this interaction.12-14,15

4. Roxithromycin. In 10 healthy subjects roxithromycin 300 mg daily for 6 days increased the AUC of a single 15-mg dose of midazolam by about 47%, and lengthened the half-life from 1.7 to 2.2 hours. Only minor psychomotor changes were seen.16 A modest increase in the effects of midazolam were seen in another study in subjects given roxithromycin 300 mg, but the effects were very much weaker than those seen with erythromycin.15

Troleandomycin to be a potent inhibitor of triazolam metabolism.19 Repeated visual hallucinations and an increase in peak levels.19,21 Repeated visual hallucinations increased the plasma levels of zaleplon by 34%.25 Increased the maximum plasma levels by about one-third (from 2.8 to 3.33 mg three times daily for 3 days, reduced the clearance of a single 125-microgram dose of triazolam.19 These results were supported by an in vitro study, which confirmed that azithromycin was only a weak inhibitor of triazolam metabolism.19

Clarithromycin. An in vitro study found clarithromycin to be a relatively potent inhibitor of triazolam metabolism. These results were confirmed in practice with 12 healthy subjects, who were given both drugs. The oral clearance of triazolam was reduced by 77% by clarithromycin, when compared with placebo.19

3. Erythromycin. A study in 16 healthy subjects found that erythromycin 333 mg three times daily for 3 days, reduced the clearance of a single 500-microgram dose of triazolam by about 50%, doubled the AUC, and increased the maximum plasma levels by about one-third (from 2.8 to 4.1 nanograms/mL).29 Other reports confirm the marked decrease in clearance and an increase in peak levels.19,21 Reported visual hallucinations and abnormal body sensations occurred in one patient with acute pneumonia and chronic renal failure taking erythromycin 600 mg daily after each dose of triazolam and nitrazepam. These symptoms had not occurred before the addition of erythromycin.22

Josamycin. Josamycin has been reported to increase triazolam levels causing an increase in its effects.23

5. Roxithromycin. A study found that roxithromycin 300 mg had only a slight effect on the effects of triazolam.15

6. Troleandomycin. Troleandomycin 2 g daily given to 7 healthy subjects for 7 days increased the peak triazolam levels by 107%, the AUC by 275% and the half-life from 1.81 to 6.48 hours. Apparent oral clearance was reduced by 74%. Marked psychomotor impairment and amnesia was seen.24 Troleandomycin has been reported to interact similarly in a patient on triazolam, causing an increase in its effects.23 An in vitro study has shown troleandomycin to be a potent inhibitor of triazolam metabolism.18

B. Non-benzodiazepine hypnotics

(a) Zaleplon

The manufacturers say that a single 800-mg dose of erthromycin increased the plasma levels of zaleplon by 34%.25

(b) Zolpidem

In a study in healthy subjects clarithromycin had no effects on the pharmacokinetics of zolpidem or on its sedative effects.26

(c) Zopiclone

Zopiclone 7.5 mg was given to 10 healthy subjects before and after taking erthromycin 500 mg three times daily for 6 days. The erthromycin increased the plasma concentration of the zopiclone fivefold at 30 minutes and twofold at one hour. Peak plasma levels rose by about 40% and occurred at 1 hour instead of 2 hours. The 1-hour and 2-hour AUCs were increased threefold and twofold, respectively, while the total AUC was increased by nearly 80%.27 These pharmacokinetic changes were reflected in some small changes in a number of psychomotor tests.27

Mechanism

Some of the macrolides (notably erythromycin and roxithromycin) are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4. Benzodiazepines, such as midazolam, that are predominantly metabolised by CYP3A4 are affected more than those such as diazepam, where CYP3A4 plays only a minor part in the metabolism. Further, CYP3A4-mediated metabolism occurs in the liver and also in the intestines. Midazolam and triazolam undergo extensive first-pass metabolism (low bioavailability of about 40%) but alprazolam and brotizolam undergo gut first-pass metabolism (bioavailabilities of about 90% and 70%, respectively). Erythromycin causes greater increases in the levels and AUC of midazolam and triazolam than in those of alprazolam and brotizolam, and this may be related to the extent of first-pass metabolism.1 The non-benzodiazepine hypnotics, zaleplon and zopiclone are, to varying degrees, also metabolised by CYP3A4. The macrolides can therefore reduce the metabolism of some of the benzodiazepines and related drugs, raising their serum levels and increasing and prolonging their effects.

Importance and management

The interactions of midazolam with erythromycin and triazolam with clarithromycin, erythromycin or roxithromycin appear to be established, and of clinical importance. The dosages of the midazolam and triazolam should be reduced to 50 to 75% when these antibacterials are used if excessive effects (marked drowsiness, memory loss) are to be avoided. Remember that the hypnotic effects are also prolonged so that patients should be warned about hangover effects the following morning if they intend to drive. Much less is known about the use of midazolam with clarithromycin but similar precautions may be necessary. The manufacturers of zaleplon say that patients should be advised that increased sedation is possible with erythromycin, although a dose adjustment is usually not required.25 Limited information from single-dose studies suggests that erythromycin may increase levels of alprazolam and brotizolam but no pharmacodynamic changes were found. Nevertheless, the manufacturers advise caution if alprazolam is used with a macrolide.2

Azithromycin does not interact with midazolam or triazolam, and the effects of roxithromycin on midazolam and triazolam, and of erthromycin on diazepam, flunitrazepam, nitrazepam, temazepam and zopiclone or clarithromycin on zolpidem appear to be small and unimportant, or the effects negligible, so that no special precautions seem to be necessary.
2. Chapman MH, Woolner DF, Begg EJ, Atkinson HC, Sharman JR. Co-administered oral metoclopramide 10 mg did not increase the rate of absorption of oral diazepam.

3. Wang J-S, Backman JT, Kivistö KT, Neuvonen PJ. Effects of metronidazole on midazolam plasma concentrations at 30 minutes instead of 60 minutes, but in 6 healthy subjects oral metoclopramide 10 mg did not increase the rate of absorption of oral diazepam 0.2 mg/kg. The reason is not understood. The clinical importance of this interaction is not known, but it is probably small.

(b) Zopiclone

The rate of absorption of a single 7.5-mg dose of oral zopiclone was increased by metoclopramide 10 mg given intravenously to 12 healthy subjects. This was presumably because these drugs alter gut motility. Metoclopramide increased the mean plasma levels of zopiclone, from 22.7 to 44.4 nanograms/mL at 1 hour, and from 49.3 to 59.6 nanograms/mL at 2 hours. The clinical importance of these findings is not known.

Benzodiazepines + Metformin

Modafinil reduces triazolam levels. It may therefore also affect the metabolism of other similarly metabolised benzodiazepines such as alprazolam and midazolam. Conversely, modafinil might increase diazepam levels.

Clinical evidence, mechanism, importance and management

A single-dose study, 34 healthy women (all taking an oral contraceptive containing ethinylestradiol and norgestimate) were given a single 125-microgram dose of triazolam, both before and on the last day of taking modafinil (200 mg daily for 7 days then 400 mg daily for 21 days) or placebo. The AUC of triazolam was reduced by almost 60%, its maximum plasma level was reduced by 42% and its elimination half-life was reduced by about 1 hour by modafinil, when compared with placebo.

Modafinil is known to induce the cytochrome P450 3A4 enzyme by approximately 30%. It may therefore affect the metabolism of other benzodiazepines such as alprazolam and midazolam. Conversely, modafinil might increase diazepam levels.

Nefazodone increases the plasma levels and effects of alprazolam, midazolam, triazolam and zopiclone, but not lorazepam.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

A placebo-controlled study in 12 healthy subjects found that nefazodone 200 mg twice daily caused an almost twofold increase in the plasma levels of alprazolam 1 mg twice daily taken for 7 days.1 Another study found that impairment of psychomotor performance and increased sedation occurred when nefazodone was given with alprazolam.2 A case report describes benzodiazepine withdrawal symptoms in a woman taking alprazolam after nefazodone was withdrawn following several years of concurrent use. She needed an alprazolam dosage increase from 500 micrograms to 4 mg daily to control her symptoms.3

(b) Lorazepam

A placebo-controlled study in healthy subjects given nefazodone 200 mg twice daily found no changes in the pharmacokinetics of lorazepam 2 mg twice daily.1 Another study showed that psychomotor performance was not further impaired and no additional sedation occurred when nefazodone was given with lorazepam.2

(c) Midazolam

A study in 10 healthy subjects found that both the AUC and the maximum plasma level of a single 10-mg dose of midazolam were increased about fivefold and twofold, respectively, when they took nefazodone 200 mg twice daily.4

(d) Triazolam

A study in 12 healthy subjects found that the maximum plasma levels, the halflife and the AUC of a single 250-microgram dose of triazolam were increased 1.7-fold, 4.6-fold, and 4-fold, respectively, by nefazodone 200 mg twice daily.5 Another study showed that impairment of psychomotor performance and increased sedation occurred when nefazodone was given with triazolam.2

B. Non-benzodiazepine hypnotics

An 86-year-old woman taking diltiazem, irbesartan, lorazepam, and pravastatin started taking nefazodone 50 mg twice daily, increasing to 500 mg daily in divided doses, for the treatment of a major depressive episode. Be-cause of associated insomnia, zopiclone was added, starting at 15 mg each night, but this was reduced after 5 days to 7.5 mg because of morning drowsiness. Plasma levels of S-zopiclone and R-zopiclone were 107 nanograms/mL and 20.6 nanograms/mL, respectively, at this time. After several months, nefazodone was replaced by venlafaxine. The S-zopiclone and R-zopiclone levels were again measured and found to be only 16.9 nanograms/mL and 1.45 nanograms/mL, respectively.6

Mechanism

Nefazodone appears to inhibit the oxidative metabolism of alprazolam, midazolam, triazolam and zopiclone by the cytochrome P450 isoenzyme CYP3A4 so that they accumulate in the body. Lorazepam is unaffected because it is primarily excreted as a conjugate.

Importance and management

The interactions of nefazodone with alprazolam, midazolam, triazolam and zopiclone are established and clinically important. The practical consequences are that the effects of alprazolam, midazolam and triazolam are expected to be increased but the extent is uncertain. Be alert for any evidence of any psychomotor impairment, drowsiness etc. and reduce the benzodiazepine dosage if necessary. More study is needed. Lorazepam does not interact with nefazodone. There seems to be no direct information about other benzodiazepines and related drugs.

Diclofenac reduces the dose of midazolam needed to produce sedation and hypnosis. Diazepam has a small effect on the pharmacokinetics of diclofenac, ibuprofen and naproxen. Diazepam and indometacin appear not to interact adversely, although feelings of dizziness may be increased. Zaleplon and ibuprofen appear not to interact.

Clinical evidence, mechanism, importance and management

(a) Diazepam

1. Diclofenac. In a study in 8 healthy subjects, diazepam increased the AUC of diclofenac by 60% while the clearance was reduced by 36%.1 The effects of diazepam on diclofenac appeared to depend on the time of administration and may reflect time-dependent effects of diazepam on gastrointestinal function. More study is needed.

2. Ibuprofen. A study in 8 healthy subjects investigating the effects of diazepam on ibuprofen pharmacokinetics found that the ibuprofen half-life was increased from 2.39 to 3.59 hours and the clearance was reduced by about one-third when diazepam and ibuprofen were given at 10 pm, but no effect was seen with morning dosing.2 The clinical importance of this is uncertain.

3. Indometacin. Diazepam 10 to 15 mg impaired the performance of a number of psychomotor tests (digit symbol substitution, letter cancellation, tracking and flicker fusion) in 119 healthy medical students. It also caused subjective drowsiness, mental slowness and clumsiness. When indometacin 50 or 100 mg was given the effects were little different from diazepam alone, except that the feeling of dizziness (common to both drugs) was increased and caused subjective clumsiness.3

4. Naproxen. A double-blind, crossover study failed to find any clinically important changes in mood or attention in healthy subjects given naproxen and diazepam.4 A single-dose study in 10 healthy subjects found that peak serum concentrations of naproxen 500 mg were reduced by 23%, the time to peak concentration was increased (1.36 to 2 hours) and the absorption rate constant was decreased (4.07 to 2.42 hr⁻¹) by diazepam 10 mg. Other pharmacokinetic parameters were not affected.3 No special precautions appear to be necessary.

(b) Midazolam

A clinical study found that diclofenac 75 mg given intravenously to 10 patients reduced the dose of intravenous midazolam needed to produce sedation and hypnosis by 35%, when compared with 10 control subjects not given diclofenac.6 The clinical importance of this is uncertain.

For the interactions of parecoxib with midazolam see ‘NSAIDs; Parecoxib + Miscellaneous’, p.160.

(c) Zaleplon

A randomised, single-dose study in 17 healthy subjects found that ibuprofen 600 mg had no effect on the pharmacokinetics of zaleplon 10 mg.7

**Benzodiazepines + Paracetamol (Acetaminophen)**

Paracetamol reduces the urinary excretion of diazepam but diazepam plasma levels are little affected.

Clinical evidence, mechanism, importance and management

The 96-hour urinary excretion of a single 10-mg oral dose of diazepam and its metabolite, nordiazepam, were reduced from 44% to 12% and from 27% to 8%, respectively, in 2 female subjects, and from 11% to 4.5%, respectively, in a male subject, by a single 500-mg dose of paracetamol. The reasons are not understood. Plasma levels of diazepam and its metabolite were not significantly affected.1 There would seem to be no reason for avoiding concurrent use. There seems to be no information about other benzodiazepines.

**Benzodiazepines + Probenecid**

Probenecid reduces the clearance of adinazolam, lorazepam and nitrazepam. Increased effects (e.g. sedation) may be expected. Probenecid does not appear to interact with temazepam.

Clinical evidence

(a) Adinazolam

In a single-dose study in 16 healthy subjects, probenecid 2 g increased the psychomotor effects of sustained-release adinazolam 60 mg. The tests used were symbol-digit substitution, digit span forwards and continuous performance tasks.1 The peak serum levels of adinazolam and its active metabolite, N-desmethyladinazolam, were increased by 37% and 49%, respectively, and the clearances were reduced by 16% and 53%, respectively, by probenecid. Both drugs have uricosuric actions, but when used together the effects appear not to be additive.1

(b) Lorazepam

Probenecid 500 mg every 6 hours approximately halved the clearance of a single 2-mg intravenous dose of lorazepam in 9 healthy subjects. The elimination half-life was more than doubled, from 14.3 hours to 33 hours.2

(c) Nitrazepam

Probenecid 500 mg daily for 7 days reduced the clearance of nitrazepam by 25% in healthy subjects.3

(d) Temazepam

Probenecid 500 mg daily for 7 days but did not significantly affect the clearance of temazepam in healthy subjects.3

Mechanism

Probenecid inhibits the renal tubular clearance of many drugs and their metabolites, including some of the benzodiazepines. It also inhibits the glucuronidation of nitrazepam and lorazepam by the liver.2,3 The overall result is that these benzodiazepines accumulate and their effects are increased. Temazepam, which also undergoes glucuronidation, was not affected, possibly as increased sulfation compensated.3

Importance and management

Established interactions but of uncertain clinical importance. Be alert for increases in the effects (sedation, antegrade amnesia) of adinazolam, lorazepam and possibly nitrazepam. Reduce the dosage as necessary. Note that adinazolam is no longer available. There seems to be no direct information about other benzodiazepines, but those that are metabolised like lorazepam and nitrazepam (e.g. oxazepam) may also interact. Temazepam does not appear to interact with probenecid.

**Benzodiazepines and related drugs + Protease inhibitors**

A study and a case report show that saquinavir markedly decreases midazolam metabolism, resulting in a significant increase in sedation. Ritonavir similarly affects triazolam and, to a lesser extent, alprazolam, but appears not to affect zolpidem levels.

Clinical evidence, mechanism, importance and management

A. Benzodiazepines

(a) Alprazolam

A crossover study in 10 healthy subjects found that ritonavir 200 mg for 4 doses decreased the clearance of a single 1-mg dose of alprazolam by 59%. The half-life of alprazolam was increased from 13.3 to 29.6 hours and the subjects experienced increased and prolonged sedation.1

(b) Midazolam

A randomised study in 12 healthy subjects found that saquinavir (soft-gel formulation) 1.2 g three times daily increased the bioavailability of oral midazolam from 41 to 90% and increased the AUC fivefold. Psychomotor tests showed impaired skills and greater sedation in the presence of saquinavir.2 When intravenous midazolam was given, the sedative effects were only marginally altered.3 However, a 32-year-old with advanced HIV, taking zidovudine, lamivudine, co-trimoxazole and saquinavir 600 mg three times daily, did not wake spontaneously from a 5 mg intravenous dose of midazolam. He was given 300 micrograms of intravenous flumazenil to revert the prolonged sedation, but he was not free from sedation until 5 hours later. On a previous occasion, in the absence of saquinavir, he woke spontaneously 2 hours after the dose of midazolam.3 The manufacturers of saquinavir note that in 16 healthy subjects, saquinavir/ritonavir 1000/100 mg twice daily for 2 weeks increased the maximum levels and AUC of a single 7.5-mg oral dose of midazolam by 4.3-fold and 12.4-fold, respectively.4

(c) Triazolam

In a crossover study in 6 healthy subjects ritonavir 200 mg for 4 doses reduced the clearance of triazolam 125 micrograms to less than 4% of control values and increased the half-life from 3 to 41 hours, which resulted in increased and prolonged sedation.5 A very brief case report also describes prolonged sedation in a patient given ritonavir and triazolam.6

B. Non-benzodiazepine hypnotics

A crossover study in 6 healthy subjects found that ritonavir 200 mg twice daily for 4 doses resulted in only a small and clinically unimportant reduction in the clearance of a single 5-mg dose of zolpidem.5

Mechanism

Alprazolam, midazolam and triazolam are metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited, to varying degrees, by the protease inhibitors. Benzodiazepine levels and effects are therefore increased by saquinavir and ritonavir. Zolpidem metabolism depends on several isoenzymes so inhibition of CYP3A4 alone may not produce clinically significant changes in its clearance.

Importance and management
