**Clinical evidence, mechanism, importance and management**

A patient taking lovastatin developed rhabdomyolysis, which was attributed to the addition of nicotinic acid 2.5 g daily. A similar reaction occurred in another patient taking the same combination as well as in a further patient taking ciclosporin, nicotinic acid and lovastatin (see also ‘Statins + Ciclosporin’, p.1097). Myopathy has also been briefly reported in a patient taking lovastatin and nicotinic acid. These adverse reports are isolated and it is by no means certain that nicotinic acid contributed to what happened. Myopathy does occur with lovastatin alone, with a reported incidence of 0.1%. A combined preparation of lovastatin/nicotinic acid is marketed (Advicor, USA), and in a 52-week study investigating efficiency and tolerability, none of the 814 patients experienced drug-induced myopathy, although 7 patients were withdrawn from the study due to elevated creatine kinase levels. Similarly, a review of the use of extended-release niacin with lovastatin found that myopathy, which was reported in 3% of patients, tended to be associated with higher initial doses of statins. There do not appear to be any published reports of myopathy occurring with nicotinic acid and any other statins. However, in a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, nicotinic acid was identified as a potentially interacting drug in 2 of 215 cases for simvastatin, 1 of 71 cases for pravastatin, and 1 of 40 cases for lovastatin. Nicotinic acid was not identified as an interacting drug in any reports for atorvastatin or fluvastatin.

Nicotinic acid does not alter the bioavailability of fluvastatin or pravastatin.

Although these cases are isolated, some caution is certainly warranted. The US manufacturers of lovastatin recommend a maximum dose of 20 mg in patients taking nicotinic acid in doses of 1 g or more daily. Similarly the UK manufacturers of simvastatin recommend a maximum dose of 10 mg in patients taking nicotinic acid in doses of 1 g or more daily. To be on the safe side, if the decision is made to use nicotinic acid with any statin the outcome should be very well monitored. Patients should be told to report otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

**References**

**Statins + NNRTIs**

Delavirdine is expected to raise the levels of atorvastatin, simvastatin and lovastatin. This expectation is supported by a case of rhabdomyolysis, which developed in a patient taking atorvastatin and delavirdine. Efavirenz (and possibly nevirapine) lower the levels of atorvastatin, simvastatin, and pravastatin.
Clinical evidence, mechanism, importance and management

(a) Delavirdine

An isolated case report describes a 63-year-old HIV-positive man, who had been taking atorvastatin 20 mg daily with indinavir, lamivudine and stavudine, and who was admitted to hospital 2 months after indinavir was replaced with delavirdine. He had a one-month history of malaise, muscle pain, vomiting, and dark urine. Laboratory tests confirmed a diagnosis of rhabdomyolysis, and he was found to have acute renal failure. All drugs were withheld, and he gradually recovered over the following month. It was suggested that delavirdine inhibited the metabolism of atorvastatin.1 Although the possible interaction between simvastatin and delavirdine does not appear to have been studied it would be expected to be similar, if not in greater in magnitude, to that seen with atorvastatin. One of the manufacturers of simvastatin contraindicates concurrent use,2 and the US manufacturer of delavirdine advises against the use of either simvastatin or lovastatin. They also advise caution with atorvastatin, due to the risk of rhabdomyolysis.3 See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

(b) Efavirenz

In an open-label study 42 healthy subjects were given efavirenz 600 mg daily for 11 days, with atorvastatin 10 mg daily, simvastatin 40 mg daily, or pravastatin 40 mg daily for the last 2 days. Efavirenz reduced the AUC of simvastatin and its active metabolites by about 45 to 55%, reduced the AUC of atorvastatin and its active metabolites by 35 to 45% and reduced the AUC of pravastatin by about 40%. The pharmacokinetics of efavirenz were not changed. Decreases in LDL-cholesterol were at-tended when efavirenz was given with simvastatin.4 The changes with atorvastatin and simvastatin were expected, as efavirenz induces the cytochrome P450 3A4 enzyme and, in combination, with certain other drugs. The changes with atorvastatin and simvastatin were unexpected, and atorvastatin induced the cytochrome P450 3A4 enzyme. The reasons for the reduction in the pravastatin AUC are less clear, as it is not metabolised by CYP3A4.4 It would seem prudent to monitor the lipid-profile of patients taking efavirenz and any of these drugs, although bear in mind that NNRTIs are often used with ‘protease inhibitors’, (p.1108), for further guidance.

Statins + Orlistat

No clinically relevant interaction has been seen between orlistat and atorvastatin, pravastatin or simvastatin.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a randomised study, 32 healthy subjects were given atorvastatin 20 mg daily for 6 days, with or without orlistat 120 mg three times daily for 6 days. Orlistat had no significant effect on the pharmacokinetics of atorvastatin.1

(b) Pravastatin

In a placebo-controlled, crossover study in 24 subjects with mild hypercholesterolaemia, orlistat 120 mg three times daily was reported to have no effect on the pharmacokinetics, or lipid-lowering effects, of pravastatin 40 mg daily, when both drugs were given for 6 days.4 A review includes brief details of a comparative study in two groups of healthy subjects given pravastatin, either with orlistat or placebo. After 10 days there was no significant difference in the pravastatin AUC between the groups, but the maximum serum concentration did show a ten-dency to be higher in the orlistat group.3

(c) Simvastatin

In a placebo-controlled, randomised study in 29 healthy subjects orlistat 120 mg three times daily had no effect on the pharmacokinetics of simvastatin 40 mg daily.4

Statins + Phenytoin

In an isolated case, phenytoin reduced the cholesterol-lowering effect of simvastatin, fluvastatin and atorvastatin. The concurrent use of phenytoin and fluvastatin modestly raises the levels of both drugs.

Clinical evidence, mechanism, importance and management

A 50-year-old woman taking simvastatin 10 mg daily had her antiepilep-tic medication changed from sodium valproate to phenytoin 325 mg daily. Over the following 3 months her total cholesterol rose from 9.4 to 15.99 mmol/L. The dose of simvastatin was gradually increased to 40 mg daily without significant effect on her cholesterol levels. Despite further changes (to fluvastatin 40 mg daily, then to atorvastatin 80 mg daily) her cholesterol level remained above 10 mmol/L. Finally phenytoin was discontinued and her cholesterol dropped to 6.24 mmol/L with atorvas-tatin 80 mg daily.1 The reasons are not known, but it is possible that phenytoin induced the metabolism of the statins, so that they were cleared from the body more quickly and were therefore less effective. The concurrent use of phenytoin 300 mg and fluvastatin 40 mg increased the maximum levels and AUC of fluvastatin by 27% and 40%, respectively, and increased the maximum levels and AUC of phenytoin by 5% and 20%, respectively.2 These changes are relatively modest and probably occur because both drugs are metabolised by the cytochrome P450 3A4 enzyme.

Evidence of an interaction currently appears to be limited to these two reports and the clinical significance remains unclear. The change in phenytoin levels seems unlikely to be clinically significant. There is a small risk that the concurrent use of fluvastatin and phenytoin could result in myopathy. Patients should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Phosphodiesterase type-5 inhibitors

A man taking simvastatin developed symptoms of rhabdomyoly-sis after taking a single dose of sildenafil. The pharmacokinetics of atorvastatin and sildenafil do not appear to be altered by concurrent use, and tadalafil does not alter lovastatin pharmacoki-netics.

Clinical evidence

(a) Sildenafil

A 76-year-old man who had been taking simvastatin 10 mg daily for 3 years, presented at a clinic with a 3-day history of severe and unexplained muscle aches, particularly in the lower part of his legs and feet. The problem had started within 10 hours of taking a single 50-mg dose of sildenafil. When examined he showed no muscle tenderness or swelling but his creatine phosphokinase level was slightly raised (406 units/L). There was also a mild elevation of blood urea nitrogen and an increase in creatinine and potassium levels. A tentative diagnosis of rhabdomyolysis...
was made, there being no other obvious identifiable cause for the myalgia. Both simvastatin and sildenafil were stopped, and he made a full recovery. A study in 24 healthy subjects found that the pharmacokinetics of sildenafil (single 100-mg dose) and atorvastatin (10 mg daily for 7 days) were unchanged by concurrent use.

(b) Tadalafil
In a study in 16 healthy subjects, tadalafil 20 mg daily for 14 days did not affect the pharmacokinetics of a 40-mg dose of lovastatin.

Mechanism, importance and management

The reasons for this possible interaction are not known. This is as yet an isolated case, and no broad generalisations can be based on such slim evidence. Based on the current evidence no further precautions currently seem necessary.

Statins + Protease inhibitors

The levels of atorvastatin and simvastatin are markedly increased by lopinavir and saquinavir (with ritonavir), nelfinavir, and ritonavir alone. Pravastatin seems only moderately affected. Several cases of rhabdomyolysis have been attributed to this interaction.

Clinical evidence

(a) Indinavir
In a non-randomised study patients receiving HAART were given pravastatin or atorvastatin. Neither of the statins altered the pharmacokinetics of indinavir, the combination was well tolerated, and no increase in adverse events was seen.

(b) Lopinavir/Ritonavir
Either atorvastatin 20 mg daily or pravastatin 20 mg daily were given to 24 healthy subjects for 4 days during a 14-day course of lopinavir/ritonavir 400/100 mg twice daily. The maximum serum levels and AUC of atorvastatin were increased by between 4.7- and 5.9-fold and the maximum serum levels and AUC of pravastatin were only increased by about 30%. Atorvastatin and pravastatin had no effect on the pharmacokinetics of lopinavir or ritonavir.

(c) Nelfinavir
In an open label study, 31 healthy subjects were given either atorvastatin 10 mg daily or simvastatin 20 mg daily for 28 days, with nelfinavir 1.25 g twice daily for the last 14 days. Nelfinavir increased the maximum serum levels and AUC of atorvastatin approximately twofold and the maximum serum levels and AUC of simvastatin approximately sixfold. No significant adverse effects, or any signs of rhabdomyolysis were noted throughout the study.

One study found that nelfinavir 750 mg three times daily increased the maximum serum levels and AUC of pravastatin 40 mg daily by 29% and 35%, respectively, and increased the maximum serum levels and AUC of atorvastatin 40 mg daily by 32% and 209%, respectively. A further study, in which 14 healthy subjects took nelfinavir 1.25 g twice daily for 12 days, with pravastatin 40 mg daily for the final 4 days, found that the AUC of pravastatin ranged from a decrease of 65% to an increase of 11%, and the maximum serum levels ranged from a decrease of 77% to an increase of 154%.

In another study, 14 healthy subjects were given nelfinavir 1.25 g twice daily for 18 days, with pravastatin 40 mg daily for the last 4 days. No significant change was noted in the pharmacokinetics of nelfinavir, nor of its major metabolite.

A case report describes a 70-year-old HIV-positive man taking nelfinavir who developed rhabdomyolysis and died, about 3 weeks after being given simvastatin 80 mg daily. He had previously tolerated both pravastatin 40 mg daily and simvastatin 10 mg daily.

(d) Ritonavir
A 51-year-old woman was admitted to hospital with a 4-day history of muscular aches and weakness. Among other drugs, she had been taking zidovudine, lamivudine, indinavir, and simvastatin for 2 years. Ritonavir 100 mg twice daily had been added to her usual regimen 2 weeks previously. The rhabdomyolysis was therefore attributed to an interaction between ritonavir and simvastatin. Another similar case has also been reported. See also (b) above and (c) below for interactions of ritonavir combined with other protease inhibitors.

(e) Saquinavir/Ritonavir
Ritonavir 300 mg twice daily and saquinavir 400 mg twice daily were given to healthy subjects for 3 days, after which the dose was increased to ritonavir 400 mg twice daily and saquinavir 400 mg twice daily for a further 11 days. On the last 4 days atorvastatin, pravastatin, or simvastatin (all 40 mg daily) were also given. The mean pravastatin AUC was approximately halved (13 subjects), the mean atorvastatin AUC was increased approximately fourfold (14 subjects) and the mean simvastatin acid AUC was increased approximately 32-fold (14 subjects). No cases of rhabdomyolysis were noted.

Mechanism

The protease inhibitors, especially ritonavir, are known to be strong inhibitors of the cytochrome P450 isoenzyme 3A4. The levels of statins metabolised by this isoenzyme (notably simvastatin, and to some extent atorvastatin) are therefore increased. See ‘Lipid regulating drugs’, (p.1086), for information on the metabolism of the individual statins.

Importance and management

The interactions of the protease inhibitors and atorvastatin or simvastatin appear to be established by the pharmacokinetic studies cited here, and supported by a few case reports. It is generally recommended that simvastatin and lovastatin, which is similarly metabolised, should be avoided in patients taking protease inhibitors, and several manufacturers of simvastatin contraindicate concurrent use.

Atorvastatin should be used in low doses (i.e.10 mg) with care. See also ‘muscle toxicity’, (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Pravastatin and fluvastatin can probably be used without dose adjustments, but monitoring is needed to confirm this as one study with nelfinavir and pravastatin suggested a trend towards reduced pravastatin efficacy.

Statins + Rifampicin (Rifampin)

Rifampicin lowers the serum levels of atorvastatin, fluvastatin, pravastatin, and simvastatin.
Clinical evidence, mechanism, importance and management

It was briefly mentioned in a review by the manufacturer of fluvastatin that rifampicin reduced the AUC and the maximum serum levels of fluvastatin by 51% and 59%, respectively. No further study details were given. In a randomised, crossover study in 10 healthy subjects, 5 days pre-treatment with rifampicin 600 mg daily reduced the AUCs of simvastatin and simvastatin acid by 87% and 93%, respectively. A study of the same design with a 40-mg dose of atorvastatin found that rifampicin decreased the AUC of atorvastatin by 80% and decreased the AUCs of its two active metabolites by 43% and 81%, respectively. There was considerable intersubject variation in these values. In a further study by the same authors, this time with pravastatin 40 mg, it was found that rifampicin reduced the AUC of pravastatin by 31%, but again there were large interindividual differences in the results, with some subjects having an increase in AUC. It might therefore be necessary to increase the dosage of atorvastatin, fluvastatin, simvastatin, and possibly pravastatin in some subjects, if rifampicin is given concurrently, but this needs confirmation.

Statins + St John’s wort (Hypericum perforatum)

St John’s wort modestly decreases the plasma level of simvastatin, but not pravastatin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 16 healthy subjects took St John’s wort 300 mg three times daily for 14 days. On day 14 simvastatin 10 mg was given to 8 subjects and pravastatin 20 mg was given to the other 8 subjects. St John’s wort did not affect the plasma concentration of pravastatin, but it tended to reduce the simvastatin AUC and significantly reduced the AUC of its active metabolite, simvastatin acid, by 62%. The reason for this interaction is unknown, but St John’s wort may reduce the levels of simvastatin and its metabolite by inhibiting the cytochrome P450 isoenzyme CYP3A4 or by having some effect on P-glycoprotein. The clinical significance of these reductions is unclear, but it may be prudent to consider an interaction if lipid-lowering targets are not met.

Statins + Tacrolimus

An isolated case of rhabdomyolysis occurred in a patient taking tacrolimus with simvastatin. Tacrolimus does not appear to affect atorvastatin pharmacokinetics.

Clinical evidence, mechanism, importance and management

A 51-year-old woman, who was taking tacrolimus after a kidney transplant, started taking simvastatin 10 mg daily following a stroke. After 5 months, the dose was increased to 20 mg daily, and fusidic acid was started for osteomyelitis. Muscle pain developed 2 weeks later, and after a further 3 weeks she was admitted to hospital, when her creatinine kinase level was found to be 24 000 units/mL (reported range 10 to 70 units/mL) and she had renal impairment. The simvastatin and fusidic acid were immediately stopped and the patient recovered over the following 2 weeks. She was later treated with a combination of fluvastatin, tacrolimus and fusidic acid without incident, leading the authors to suspect that the rhabdomyolysis was caused by an interaction between simvastatin and tacrolimus. However, note that ‘fusidic acid’, (p.1102), has been implicated in cases of rhabdomyolysis with simvastatin. The clinical significance of this case report is therefore unclear.

Statins; Atorvastatin + Sirolimus

A pharmacokinetic study in 13 healthy subjects found that the short-term use of tacrolimus (2 doses 12 hours apart) did not affect the pharmacokinetics of atorvastatin.

Statins; Lovastatin + Fibre or Pectin

Pectin and oat bran can reduce the cholesterol-lowering effects of lovastatin.

Clinical evidence, mechanism, importance and management

The serum LDL-cholesterol levels of 3 patients taking lovastatin 80 mg daily showed a marked rise from 4.48 to 6.36 mmol/L when they were also given pectin 15 g daily. One patient had a 59% rise in LDL-cholesterol. Two other patients taking lovastatin had a rise in LDL-cholesterol from 5.03 to 6.54 mmol/L when they were also given 50 to 100 g of oat bran daily. One patient had a 41% rise in LDL-cholesterol. When the pectin and oat bran were stopped, the serum levels of the LDL-cholesterol fell. It is presumed that both pectin and oat bran reduced the absorption of lovastatin from the gut. Evidence is still very limited but if patients are adding these fibres to their diets it would seem prudent to separate the ingestion of lovastatin by as much as possible.

Statins; Pravastatin + Aspirin

Aspirin 324 mg did not significantly affect the pharmacokinetics of a single 20-mg dose of pravastatin.

Statins; Pravastatin + Mianserin

An isolated report describes rhabdomyolysis attributed to the long-term concurrent use of pravastatin and mianserin, triggered by a cold.
Clinical evidence, mechanism, importance and management

An isolated report describes a 72-year-old woman taking pravastatin 20 mg daily and mianserin 10 mg daily for 2 years, who was hospitalised because of weakness in her legs that began 2 days previously, shortly after she developed a cold. She could stand, but was unable to walk unaided. Laboratory data revealed evidence of increased serum enzymes, all of which suggested rhabdomyolysis. Within a week of stopping the pravastatin the leg weakness had disappeared and all of the laboratory results had returned to normal. The authors of the report attributed the toxicity to the long-term use of both drugs, ageing and the development of a cold. However, what part these factors and/or the presence of mianserin actually played in the development of this toxicity is not known. It seems unlikely that this case is of general significance.

Probucol 500 mg did not cause any clinically significant changes in the bioavailability of a single 20-mg dose of pravastatin in a study in 20 healthy subjects.1

Bosentan modestly reduces the AUC of simvastatin and its active metabolite, which could lead to a reduction in simvastatin efficacy.

Statins; Pravastatin + Probucol

Statins; Simvastatin + Fish oils

In a three-way, crossover study, 9 healthy subjects were given either bosentan 125 mg twice daily for 5.5 days, simvastatin 40 mg daily for 6 days, or both treatments together. Simvastatin had no effect on the pharmacokinetics of bosentan, but bosentan reduced the AUC of simvastatin and its β-hydroxyacid metabolite by 34% and 46%, respectively.1

Mechanism

Bosentan is known to be a mild inducer of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of simvastatin. Induction of simvastatin metabolism may have led to the reduced levels seen. See ‘Lipid regulating drugs’, (p.1086) for more information on the metabolism of all the statins.

Importance and management

A 40% reduction in the AUC of simvastatin is potentially clinically significant. If bosentan and simvastatin are used concurrently it would seem prudent to monitor the outcome to ensure that simvastatin is effective.

In a randomised, crossover study in 23 subjects, omega-3-acid ethyl esters (Omacor) 4 g daily did not significantly affect the pharmacokinetics of simvastatin 80 mg daily when both drugs were given together for 14 days. The combination was also well tolerated.1 No additional precautions would appear to be necessary on concurrent use.

Lithium is used in the management of mania, bipolar disorder (formerly manic depression) and recurrent depressive illnesses. The dosage of lithium is adjusted to give therapeutic serum concentrations of 0.4 to 1 mmol/L, although it should be noted that this is the range used in the UK, and other ranges have been quoted.

Lithium is given under close supervision with regular monitoring of serum concentrations because there is a narrow margin between therapeutic concentrations and those that are toxic. Initially weekly monitoring is advised, dropping to every 3 months for those on stable regimens. It is usual to take serum-lithium samples about 10 to 12 hours after the last oral dose. Adverse effects that are not usually considered serious include nausea, weakness, fine tremor, mild polydipsia and polyuria. If serum concentrations rise into the 1.5 to 2 mmol/L range, toxicity usually occurs, and may present as lethargy, drowsiness, coarse hand tremor, lack of coordination, muscular weakness, increased nausea and vomiting, or diarrhoea. Higher levels result in neurotoxicity, which manifests as ataxia, giddiness, tinnitus, confusion, dysarthria, muscle twitching, nystagmus, and even coma or seizures. Cardiovascular symptoms may also develop and include ECG changes and circulatory problems, and there may be a worsening of polyuria. Lithium levels of over 2 mmol/L can be extremely dangerous and therefore require urgent attention. Chronic lithium toxicity has been reported to have a 9% mortality, whilst acute toxicity has a 25% mortality. However, patients with chronic lithium toxicity are more likely to experience severe symptoms at lower serum-lithium levels. Concurrent medications, older age and prior neurological illness may increase the susceptibility to lithium toxicity.

In addition to the effects described above, lithium can induce diabetes insipidus and hypothyroidism in some patients, and is contraindicated in those with renal or cardiac insufficiency. Just how lithium exerts its beneficial effects is not known, but it may compete with sodium ions in various parts of the body, and it alters the electrolyte composition of body fluids.

Many of the interactions involving lithium occur because of altered serum-lithium concentrations. Lithium is mainly excreted by the kidney; it undergoes glomerular filtration and then tubular reabsorption competitively with sodium. Therefore, drugs that affect renal excretion (e.g. ‘thiazide diuretics’, (p.1123)) or electrolyte balance (e.g. ‘sodium compounds’, (p.1128)) are likely to interact. Drug interactions may be an important cause of lithium neurotoxicity occurring when serum-lithium levels are within the therapeutic range. This tends to occur with centrally active drugs e.g. ‘antipsychotics’, (p.710), ‘carbamazepine’, (p.1118), ‘SSRIs’, (p.1115), and ‘tricyclic antidepressants’, (p.1117). Most of the interactions involving lithium are discussed in this section but a few are found elsewhere in this publication. Virtually all of the reports are concerned with the carbonate, but sometimes lithium is given as the acetate, aspartate, chloride, citrate, gluconate, orotate or sulphate instead. There is no reason to believe that these lithium compounds will interact any differently to lithium carbonate.

**Lithium + ACE inhibitors**

ACE inhibitors can raise lithium levels, and in some individuals two to fourfold increases have been recorded. Cases of lithium toxicity have been reported in patients when given captopril, enalapril or lisinopril (and possibly perindopril). One analysis found an increased relative risk of 7.6 for lithium toxicity requiring hospitalisation in elderly patients newly started on an ACE inhibitor. Risk factors for this interaction seem to be poor renal function, heart failure, volume depletion, and increased age.

**Clinical evidence**

An analysis of 10,615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any ACE inhibitor (not specifically named) were compared between these 413 hospitalised patients and 1651 control patients. For any use of ACE inhibitor (63 cases and 110 controls) there was an increased relative risk of hospitalisation for lithium toxicity of 1.6. When patients who had started taking an ACE inhibitor within the last month were evaluated (14 cases and 5 controls), a dramatically increased risk of lithium toxicity was found (relative risk 7.6). Studies and case reports of the interaction between lithium and specific named ACE inhibitors are outlined in the subsections below.

(a) Captopril

A patient taking lithium carbonate developed a serum-lithium level of 2.35 mmol/L and toxicity (tremor, dysarthria, digestive problems) within 10 days of starting to take captopril 50 mg daily. He was rehospitalised on half his previous dose of lithium. A retrospective study also reports a case of increased lithium levels with captopril (see under (c) Lisinopril, below).

(b) Enalapril

A woman taking lithium carbonate developed signs of lithium toxicity (ataxia, dysarthria, tremor, confusion) within 2 to 3 weeks of starting to take enalapril 20 mg daily. After 5 weeks her plasma-lithium levels had risen from 0.88 to 3.3 mmol/L, and moderate renal impairment was noted. No toxicity occurred when the enalapril was later replaced by nifedipine. Lithium toxicity following the use of enalapril, and associated in some cases with a decrease in renal function, has been seen in another 5 patients, and a reduced lithium dosage was found adequate in another patient. Enalapril 5 mg daily for 9 days had no effect on the mean serum-lithium levels of 9 healthy male subjects. However, one subject had a 31% increase in lithium levels.

A retrospective study also reports several cases of increased lithium levels with enalapril (see under (c) Lisinopril, below).

(c) Lisinopril

A retrospective study of patient records identified 20 patients who were stabilised on lithium and then started on an ACE inhibitor (13 given lisinopril, 6 enalapril and one captopril). Their serum-lithium levels rose by an average of 35% (from 0.64 to 0.86 mmol/L) and there was a 26% decrease in lithium clearance. Signs and symptoms suggestive of toxicity (increased tremor, confusion, ataxia), necessitating a dosage reduction or lithium withdrawal, developed in four (20%) of these patients. Three patients the development of the interaction was delayed for several weeks. A woman taking lithium developed toxicity and a trough-serum level of 3 mmol/L within 3 weeks of stopping clonidine and starting lisinopril 20 mg daily. Other reports similarly describe acute lithium toxicity in 4 patients when they were given lisinopril. One of them was also taking verapamil, which has also been shown to interact with lithium, but not usually to raise lithium levels (see ‘Lithium + Calcium-channel blockers’, p.1121).

(d) Perindopril

A patient taking lithium developed toxicity 3 months after starting to take perindopril and bendroflumethiazide, which may also interact, see ‘Lithium + Diuretics; Thiazide and related’, p.1123.

(e) Ramipril

Ramipril has been shown to decrease renal lithium excretion in rats.

**Mechanism**

Not fully understood. It has been suggested that as both ACE inhibitors and lithium cause sodium to be lost in the urine, and also ACE inhibitors reduce thirst stimulation, fluid depletion can occur. The normal compensatory reaction for fluid depletion is constriction of the efferent renal arterioles to maintain the glomerular filtration rate, but this mechanism is blocked by the ACE inhibitor. In addition, lithium and sodium ions are competitively reabsorbed, mainly in the proximal tubule, and with less sodium available, more lithium is retained. Consequently the renal excretion of lithium falls and toxicity develops.

**Importance and management**

The interaction between lithium and the ACE inhibitors is established and of clinical importance, although its incidence is probably small. One manufacturer has suggested that the concurrent use of ACE inhibitors and lithium carbonate should generally be avoided. However, although lithium levels can rise, this is not always of clinical importance. The risk of lithium toxicity increases when other risk factors are also present (see below).

If any ACE inhibitor is added to established lithium treatment, monitor well for symptoms of lithium toxicity (see ‘Lithium’, p.1111) and consider measuring lithium levels more frequently. Be alert for the need to reduce the lithium dosage (possibly by between one-third to one-half), and the development of the interaction may be delayed, so monitoring lithium levels every week or every two weeks has been advised.

**Risk factors for increased lithium toxicity**

Include advanced age, congestive heart failure, renal insufficiency, and volume depletion. Some consider these to be contraindications to the use of lithium.

**Lithium + Acetazolamide**

There is some evidence that the excretion of lithium can be increased by the short-term use of acetazolamide. However, lithium toxicity has been seen in one patient given the combination for a month.

**Clinical evidence, mechanism, importance and management**

A single-dose study in 6 subjects given lithium 600 mg ten hours before acetazolamide 500 or 750 mg found a 31% increase in the urinary excretion of lithium. A woman was successfully treated for a lithium overdose...
with acetazolamide, intravenous fluids, sodium bicarbonate, potassium chloride and mannitol.2

Paradoxically, lithium toxicity occurred in another patient after a month of treatment with acetazolamide. Lithium levels rose from 0.8 to 5 mmol/L, although it should be noted that the later measurement was taken 8 hours post-dose.3 See ‘Lithium’, (p.1111) for details of lithium monitoring.

Lithium + Aciclovir

An isolated case report describes lithium toxicity caused by high-dose intravenous aciclovir.

Clinical evidence, mechanism, importance and management

A 42-year-old woman, taking lithium carbonate 450 mg twice daily, developed signs of lithium toxicity 6 days after starting treatment with intravenous aciclovir 10 mg/kg, which was given every 8 hours for a severe herpes zoster infection following chemotherapy. Her serum-lithium levels had risen over fourfold to 3.4 mmol/L. The reasons for this interaction are unknown but the authors of the report postulate that aciclovir may have inhibited the renal excretion of lithium.1

This appears to be the first and only report of this interaction, but it would now be prudent to monitor for symptoms of lithium toxicity (see ‘Lithium’, (p.1111)) and consider monitoring lithium levels if high-dose intravenous aciclovir is given to any patient. The report recommends measuring lithium levels every second or third day.1 Oral aciclovir is predicted not to interact because of its low bioavailability, and no interaction would be expected with topical aciclovir as the plasma levels achieved by this route are minimal.

Lithium + Angiotensin II receptor antagonists

Case reports describe lithium toxicity in patients given candesartan, losartan, valsartan, and possibly irbesartan. Other angiotensin II receptor antagonists would be expected to interact similarly.

Clinical evidence

(a) Candesartan

A 58-year-old woman taking long-term lithium for depression (stable serum-lithium levels between 0.6 and 0.7 mmol/L), and unnamed calcium antagonists for hypertension, was additionally given candesartan 16 mg daily. She was hospitalised 8 weeks later with a 10-day history of ataxia, increasing confusion, disorientation and agitation, and was found to have a serum-lithium level of 3.25 mmol/L. She recovered completely when all the drugs were stopped. She was later restabilised on her original lithium dosage with a change to urapidil for her hypertension.1

(b) Irbesartan

A report describes a 74-year-old woman with increased lithium levels of 2.3 mmol/L and symptoms of lithium toxicity, which were associated with several drugs including irbesartan, linsinopril, escitalopram, levmepromazine, furosemide and spiranolactone. It was suggested that these drugs could have delayed lithium excretion or worsened neurotoxic effects. An increase in the linsinopril dose and the addition of irbesartan several weeks before admission may have contributed to the lithium toxicity.2

(c) Losartan

An elderly woman taking lithium carbonate developed lithium toxicity (ataxia, dysarthria, and confusion) after starting to take losartan 50 mg daily. Her serum-lithium levels rose from 0.63 to 2 mmol/L over 5 weeks. The lithium and losartan were stopped and her symptoms had disappeared 2 days later. When lithium therapy was restarted and the losartan was re-placed by nicardipine, her lithium levels were restabilised at 0.77 mmol/L within 2 weeks.3

(d) Valsartan

A woman with a long history of bipolar disorder was treated with lithium carbonate (serum levels consistently at 0.9 mmol/L) and a number of other drugs (L-tryptophan, lorazepam, glibenclamide, conjugated oestrogens and ciprofloxacin). Two weeks before being hospitalised for a manic relapse she was additionally started on valsartan 80 mg daily. While in hospital the ciprofloxacin was stopped, lorazepam was replaced by zopiclone, and quetiapine was added. On day 3 of her hospitalisation her serum-lithium levels were 1.1 mmol/L and she became increasingly delirious, confused and ataxic over the next week. By day 11 her serum-lithium levels had risen to 1.4 mmol/L. When an interaction was suspected, the valsartan was replaced by diltiazem. She later recovered and was stabilised on her original lithium carbonate dosage with lithium levels of 0.8 mmol/L.4

Mechanism

Not fully understood. It could be that, as with the ACE inhibitors, angiotensin II receptor antagonists inhibit aldosterone secretion, resulting in increased sodium loss by the kidney tubules. This causes lithium retention and thus an increase in lithium levels. However, angiotensin II receptor antagonists have less effect on aldosterone than the ACE inhibitors, making a clinically significant interaction less likely. Animal studies show that ramipril,5 but not losartan,6 decreases the excretion of lithium by the kidney, which would support this idea.

Importance and management

Direct information about interactions between lithium and angiotensin II receptor antagonists seems to be limited to these reports, although the interaction has been predicted to occur with all drugs of this class. Such sparse evidence is not enough to recommend contraindicating the concurrent use of angiotensin II receptor antagonists with lithium, although the UK manufacturers of irbesartan7 and olmesartan8 do not recommend the combination. Several manufacturers (including the UK manufacturers of eprosartan and telmisartan)9,10 advise careful monitoring of serum-lithium levels, and this seems a sensible precaution, even though the risk of an interaction is probably fairly low. One report suggests weekly monitoring for the first month of concurrent use,4 but any rise in serum-lithium levels may be gradual so that toxicity might take as long as 3 to 7 weeks to develop fully. Be mindful that the lithium dosage may need to be decreased.11

Patients on lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given angiotensin II receptor antagonists. As with ‘ACE inhibitors’, (p.1112), the risk of lithium toxicity would be expected to increase when risk factors such as advanced age, renal insufficiency, heart failure and volume depletion are also present.

Lithium + Antibacterials

A retrospective study of patients receiving long-term lithium therapy found that concurrent medication, especially antibiotics, tended to be associated with a higher risk of elevated serum-lithium levels. However, the underlying infection and poor fluid intake might have contributed.

Lithium + Antibacterials; Co-trimoxazole or Trimethoprim

Two reports describe lithium toxicity in three patients given co-trimoxazole; in two of these patients toxicity was paradoxically accompanied by a fall in serum-lithium levels. A further report describes lithium toxicity accompanied by an increase in serum-lithium levels in a patient given trimethoprim.

Clinical evidence, mechanism, importance and management

Two patients stabilised on lithium carbonate (serum level 0.75 mmol/L) showed signs of lithium toxicity (tremor, fasciculations, muscular weakness, dysarthria, apathy) within a few days of being given co-trimoxazole [dose not stated], yet their serum-lithium levels were found to have fallen to about 0.4 mmol/L. Within 48 hours of withdrawing the co-trimoxazole, the signs of toxicity had gone, and their serum-lithium concentrations had returned to their former levels. Another report very briefly states that ataxia, tremor and diarrhoea developed in a patient on lithium and timolol when co-trimoxazole was given. A 40-year-old woman taking lithium 1.2 g daily, experienced nausea, diarrhoea, malaise, difficulty concentrating, trembling, an uncertain gait and muscle spasms after trimethoprim 300 mg daily was started; her serum-lithium levels appeared to be elevated. She made a good recovery following rehydration.

The reasons for this interaction are not understood, although trimethoprim may affect the renal excretion of lithium. The general importance of this interaction is uncertain. If concurrent use is undertaken it would clearly be prudent to monitor the clinical response, as it would appear that in this situation serum level monitoring might not always be a reliable guide to toxicity. Consider also ‘Lithium + Antibacterials’, p.1113.

Lithium + Antibacterials; Tetracyclines

The lithium levels of three patients rose, to toxic levels in two cases, after they took metronidazole. Renal impairment was also reported in two of these patients.

Clinical evidence, mechanism, importance and management

A 40-year-old woman taking lithium carbonate 1.8 g daily, levothyroxine 150 micrograms daily and propranolol 60 mg daily developed signs of lithium toxicity (ataxia, rigidity, poor cognitive function, impaired co-ordination) after completing a one-week course of metronidazole 500 mg twice daily. Her serum-lithium levels had risen by 46% (from 1.3 to 1.9 mmol/L). Another report describes 2 patients whose serum-lithium levels rose by about 20 and 125%, 3 to 12 days, respectively, after they finished a one-week course of metronidazole (750 mg or 1 g daily in divided doses). A degree of renal impairment occurred during concurrent treatment and was still present 5 and 6 months later. In contrast, one other patient is said to have taken both drugs together uneventfully. There seems to be no reason for avoiding concurrent use, but the outcome should be well monitored. Some have recommended that a reduction in the lithium dose should be considered, especially in patients maintained at relatively high serum-lithium levels. Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given metronidazole. The authors of one of the reports also recommend frequent analysis of creatinine and electrolyte levels and urine osmolality in order to detect any renal problems in patients on this combination.

Consider also ‘Lithium + Antibacterials’, p.1113.
cline, and the other in a man taking doxycycline. An isolated case of pseudotumor cerebri occurred in one patient taking lithium and minocycline.

Clinical evidence

(a) Doxycycline

A man on long-term treatment with lithium carbonate became confused within a day of starting to take doxycycline 100 mg twice daily. By the end of a week he had developed symptoms of lithium toxicity (ataxia, dysarthria, worsened tremor, fatigue, etc.). His serum-lithium levels had risen from a range of 0.8 to 1.1 mmol/L up to 1.8 mmol/L; his renal function remained normal. He recovered when the doxycycline was withdrawn. 1

(b) Minocycline

A case report describes pseudotumor cerebri in an obese 15-year-old girl taking lithium, 4 months after she started taking minocycline 75 mg twice daily for acne.2

(c) Tetracycline

An isolated report describes a woman, who had been taking lithium for 3 years, with serum levels within the range of 0.5 to 0.84 mmol/L. Within 2 days of starting to take a sustained-release form of tetracycline (Tetrabid) her serum-lithium levels had risen to 1.7 mmol/L, and 2 days later they had further risen to 2.74 mmol/L. By then she showed clear symptoms of lithium toxicity (slight drowsiness, slurring of the speech, fine tremor and thirst).3

In contrast, 13 healthy subjects taking lithium carbonate 450 mg twice daily or 900 mg once daily had a small reduction in serum-lithium levels (from 0.51 to 0.47 mmol/L) when they were given tetracycline 500 mg twice daily for 7 days.4 The incidence of adverse reactions remained largely unchanged, except for a slight increase in CNS and gastrointestinal adverse effects.

Mechanism

Not understood. One suggested reason for increased serum-lithium levels is that tetracycline (known to have nephrotoxic potential) may have adversely affected the renal clearance of lithium.3

Importance and management

These adverse interaction reports are isolated and unexplained. Two reports make the point that these drugs are commonly used for acne caused by lithium,5,6 so any common interaction resulting in raised lithium levels would be expected to have come to light by now. The case of pseudotumor cerebri also appears rare, but note that the female gender and obesity are risk factors for its development and so greater caution may be warranted in this type of patient.2 The authors advise frequent enquiry about headaches and visual changes.

There would seem to be no reason for avoiding the concurrent use of lithium and tetracycline, doxycycline or minocycline, but be aware of the potential for a rare interaction. Consider also ‘Lithium + Antibacterials’, p.1113.

No pharmacokinetic or pharmacodynamic changes, as studied by psychometric testing, were identified.1

Lithium + Antidepressants; Nefazodone

No pharmacokinetic interaction occurs between lithium and nefazodone.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, nefazodone 200 mg twice daily was given alone for 5 days. After a washout period, lithium was given for 11 days, in escalating doses from 250 mg twice daily to 500 mg twice daily. When therapeutic steady-state lithium levels were achieved nefazodone 200 mg twice daily was added for 5 days. The pharmacokinetics of both nefazodone and lithium were unaltered by concurrent use, although there were some small changes in the pharmacokinetics of the nefazodone metabolites. However, since the combination was well tolerated, no dosage adjustments were considered necessary on concurrent use.1

Lithium + Antidepressants; SSRIs

The concurrent use of lithium and SSRIs can be advantageous and uneventful, but various kinds of neurotoxicities have occurred in some patients. Isolated reports describe the development of symptoms similar to those of the serotonin syndrome in patients taking lithium and fluoxetine, fluvoxamine, paroxetine and possibly citalopram. In addition, increases and decreases in serum-lithium levels have been seen with fluoxetine.

Clinical evidence

(a) Citalopram

No pharmacokinetic changes were seen in one study in 8 healthy subjects when lithium 30 mmol/day (as lithium sulfate 1.98 g daily) was added to citalopram 40 mg daily.1 Another study, in 24 patients who had previously not responded to citalopram alone, found that the concurrent use of citalopram 40 or 60 mg and lithium carbonate 800 mg daily was effective and did not increase adverse effects.2 Even so, the manufacturers of citalopram suggest that concurrent use should be undertaken with caution, as they are aware of reports of enhanced serotonergic effects when lithium and SSRIs are used together.3,4

For a report of the serotonin syndrome in a patient with bipolar affective disorder treated with lithium, citalopram and olanzapine, see ‘Olanzapine + Lithium’, p.756.

(b) Fluoxetine

A woman with bipolar affective disorder, successfully maintained for 20 years on lithium carbonate 1.2 g daily, developed stiffness of her arms and legs, dizziness, unsteadiness in walking and speech difficulties within a few days of starting fluoxetine 20 mg daily. Her serum-lithium levels had fallen from a range of 0.75 to 1.15 mmol/L up to 1.7 mmol/L. The lithium dosage was reduced to 900 mg daily and the fluoxetine withdrawn. Within 7 days, the toxic symptoms had disappeared and the lithium levels had fallen to 0.9 mmol/L.3 Two other patients had increases in serum-lithium levels of about 45 and 70% (but no lithium toxicity) about a month after starting fluoxetine 20 or 40 mg daily, respectively. The problem resolved when the lithium dosage was reduced by 40 and 30%, respectively, and in the second case, the fluoxetine was withdrawn. Both patients also developed mania, either after readjustment of the lithium dose or during the combined treatment.4 The US manufacturer of fluoxetine7 says that concurrent use of these two drugs has resulted in both increased and decreased serum-lithium concentrations.

Toxicity (confusion, ataxia, coarse tremor, incoordination, movement disorders, fever) was seen in a patient when lithium was added to fluoxetine treatment, although the serum-lithium levels remained within the therapeutic range.3 A woman maintained on clonazepam and then started on fluoxetine 20 mg then 40 mg daily, developed tremor and ataxia 6 days af-
ter lithium carbonate 100 mg increased to 400 mg daily was added. The problems resolved when the lithium and fluoxetine were withdrawn.9 Extra-pyramidal effects and ataxia were seen in one patient on lithium and fluoxetine, and dysoria in another patient who was also taking carbamazepine, citalopram and trimipramine.10 The development of the serotonin syndrome is also reported to have occurred in 2 patients on lithium and fluoxetine.11,12 However, this is a man on lithium developed a stroke. The effect on fluoxetine, attributed to synergistic impairment of his temperature regulatory system by the two drugs,13 Absence seizures occurred in another patient given both drugs.14

(c) Fluvoxamine

A woman taking fluvoxamine became somnolent within a day of starting lithium. The lithium level 20 hours after the last dose was 0.2 mmol/L. She recovered when both drugs were stopped and she was discharged on lithium alone. The excessive somnolence was considered to have been possibly caused by increased serotonin levels caused by this drug combination.15 A woman on long-term lithium treatment was started on fluvoxamine 50 mg daily, increased to 200 mg daily over 10 days. She gradually developed tremor, difficulties in making fine hand movements, impaired motor co-ordination and hyperreflexia. Serum lithium levels remained therapeutic throughout. The reaction was interpreted as a mild form of the serotonin syndrome.16

The Committee on Safety of Medicines in the UK had received 19 reports of adverse reactions when fluvoxamine was given with lithium (5 reports of convulsions and one of hyperpyrexia) by 1989.17 In contrast to these reports, a study in 6 patients found that lithium (dosed to achieve plasma levels of 0.3 to 0.65 mmol/L) and fluvoxamine 100 to 150 mg daily (for between 3 and 23 weeks) was safe and effective, and no adverse interaction of any kind occurred.18 Another study in 6 depressed patients found that lithium did not affect the pharmacokinetics of fluvoxamine 100 mg daily and combined use was more effective than fluvoxamine alone.19 It would seem therefore that concurrent use can be valuable, but there is a clear need to monitor the outcome so that any problems can be quickly identified.20

(d) Paroxetine

A study in 14 patients taking lithium found that tremor increased significantly when paroxetine 20 to 40 mg daily was added. The greatest increase occurred approximately 3 weeks after combined treatment was started, but tremor activity was still significantly greater than baseline after 6 weeks. No patient discontinued treatment because of the increase in tremor.21

A 59-year-old woman with a long-standing bipolar disorder who had taken paroxetine 10 mg increased to 30 mg daily for 3 weeks, developed symptoms suggestive of the serotonin syndrome (shivering, tremor of her arms and legs, flushed face, agitation, and some impairment of mental focusing) after lithium 400 mg daily was added.22 Her serum lithium and paroxetine levels were found to be 0.63 mmol/L and 690 nanograms/mL respectively (the latter being sixfold higher than the upper levels seen in other patients). The paroxetine dosage was reduced to 10 mg daily, which decreased the serum levels to 390 nanograms/mL, whereupon she became symptom-free and her depression was relieved. It is not clear whether this reaction was due to an interaction or not as she never took the higher dose of paroxetine in the absence of lithium.

There is a report of seizures, unsteadiness and blurred speech in a patient with bipolar disorder and cystic fibrosis taking lithium and paroxetine; both drugs were discontinued. However, this patient was abusing oxycodeone and clonazepam and was also on a variety of anti-asthma medications (salbutamol, salmeterol, budesonide, montelukast and cromoglicate), so the exact cause of the seizures is unclear.23

(e) Sertraline

In a randomised, placebo-controlled study, 16 healthy subjects were given lithium 600 mg twice daily for 9 days. On day 8, half of the subjects received two 100-mg doses of sertraline 8 hours apart, while the other half received placebo. Sertraline caused a statistically insignificant fall of 1.4% in steady-state lithium levels, and a statistically insignificant rise in renal lithium excretion. However, there was a high incidence of adverse effects (mainly tremor and nausea) with the combined treatment: tremor occurred in 7 out of the 8 taking sertraline, whereas no adverse effects were reported in the placebo group.24

Severe priapism occurred in a patient taking lithium carbonate 600 mg daily within 2 weeks of having the dosage of sertraline increased from 50 to 100 mg daily. It was not clear whether this was purely a reaction to the increased sertraline dosage, although it was suggested that the effect may have been due to the serotonergic effects of both drugs.25 The UK manufacturer of sertraline suggests that reports of increased tremor indicate a possible pharmacodynamic interaction, and therefore they advise caution if both drugs are used.26

Mechanism

Not fully understood although it seems likely that many of the symptoms could be due to the effects of both lithium and SSRIs on serotonin.

Importance and management

Concurrent use can be uneventful. A review of the safety of the combined use of lithium and the SSRIs identified 503 subjects who had received the combination without any evidence of serious adverse events.26 However, occasionally and unpredictably adverse reactions develop, but the precise incidence is not known. Most manufacturers of the SSRIs, and the US manufacturers of lithium,27 suggest that the combination of lithium and the SSRIs should be used with caution, and patients should be monitored closely. The UK manufacturers of lithium say that the combination may precipitate a serotonergic syndrome,28,29 which justifies immediate discontinuation of treatment.28

If lithium is used in conjunction with an SSRI be alert for any evidence of toxicity. The symptoms may include tremor, dystarthisia, ataxia, confusion, and many other symptoms of the serotonin syndrome. Heat stroke has also been seen and the serum-lithium levels may rise. It would clearly be prudent to monitor concurrent use carefully. For more information on the serotonin syndrome, see ‘Additive or synergistic interactions’, (p.9).

Lithium + Antidepressants; Tricyclic and related

The concurrent use of a tricyclic antidepressant and lithium can be successful in some patients, but others may develop adverse effects, a few of them severe. Cases of neurotoxicity, the serotonin syndrome and the neuroleptic malignant syndrome have been reported.

Clinical evidence

A study in 14 treatment-resistant depressed patients aged between 61 and 82 found that 7 showed complete improvement and 3 showed partial improvement, 3 to 21 days after lithium was added to treatment with the tricyclic or related antidepressants. Lithium adverse effects occurred in 6 patients; 4 of whom stopped lithium as a result. One of them was successfully restarted at a lower dose. Tremor was the most frequent adverse effect, and reversible neurotoxicity with a stroke-like syndrome was the most severe. The antidepressants used were amitriptyline, doxepin, maprotiline and trazodone.1 A meta-analysis of 9 studies on the acute treatment of unipolar or bipolar depression indicated that the combined use of a mood stabiliser (lithium in 6 studies) and a tricyclic antidepressant was associated with an increased risk of switches into hypomania, when compared with a mood stabiliser alone. It was suggested that monotherapy with a mood stabiliser should be tried to see if it is effective, before adding an antidepressant. Tricyclics were considered to be second-line antidepressants, with SSRIs the preferred choice.2

Reports relating to specific tricyclics are outlined below.

(a) Amitriptyline

A study in 17 lithium-maintained patients found that tremor increased significantly when amitriptyline 75 to 150 mg daily was added. The greatest increments occurred within approximately 3 weeks of starting the combined treatment, but tremor activity was still significantly greater than baseline after 6 weeks. No patient discontinued treatment because of the increase in tremor.3 Seizures occurred in a patient on amitriptyline 300 mg daily, 13 days after lithium carbonate 300 mg three times daily was started. After recovery, combined therapy was resumed, but further seizures occurred 10 days later. Her lithium levels were 0.9 mmol/L three days before this second episode. She later took amitriptyline 500 mg daily without adverse effect.4 Another patient developed neuroleptic malignant syndrome after one week of treatment with lithium carbonate 300 mg and amitriptyline 25 mg, both three times daily. The patient had also received chlorpromazine for one week, just before the lithium-antidepressant therapy was started.5 No pharmacokinetic interaction was found in 10 therapy-resistant patients with major depression who were given amitriptyline and lithium for 4 weeks.6

(b) Clomipramine

A depressed man taking clomipramine 175 mg, levomepromazine 25 mg and flunitrazepam 2 mg daily, was started on lithium 600 mg daily. About one week later, after his dosage of lithium was raised to 1 g daily and he developed the serotonin syndrome (myoclonus, shivering, tremors, inco-ordination). Due to this reaction, and because his serum-lithium level was 1.6 mmol/L, the lithium was stopped. The serotonin syndrome then abated. The clomipramine dosage was reduced, but some mild symptoms remained until the clomipramine was stopped. He responded well to lithium 600 mg daily alone, without developing the serotonin syndrome.7

(c) Doxepin

A 64-year-old man developed periods of confusion and disorientation within 2 weeks of starting to take lithium 300 mg twice daily with doxepin 100 mg at bedtime. He was admitted to hospital because of urinary retention, and he was also lethargic and became confused, but despite the withdrawal of both drugs he developed a condition similar to the neuroleptic malignant syndrome (fever, muscle rigidity, changes in consciousness, autonomic dysfunction), which was successfully treated with dantrolene.8

(d) Nortriptyline

A 65-year-old woman developed tremor, memory difficulties, disorganised thinking and auditory hallucinations when given lithium carbonate 300 mg twice daily (lithium level 0.82 mmol/L) and nortriptyline 50 mg daily. However, because she only ever received lithium with nortriptyline, the possibility that this was an effect of lithium alone cannot be excluded.9

Mechanism

Not fully understood. Tremor is a relatively frequent adverse effect of both lithium and antidepressants with serotonergic properties. It might be expected that combinations of lithium (which is itself serotonergic) with such antidepressants will enhance not only efficacy, but also increase the incidence of adverse effects.3 For more information about the serotonin syndrome, see ‘Additive or synergistic interactions’.

Importance and management

The concurrent use of lithium and tricyclics can be valuable, but the reports cited here clearly show the need to monitor the outcome closely so that any problems can be dealt with quickly. The incidence of these serious reactions is not known.

3. Zannelli R, Bauer M, Jobert M, Müller-Oerlinghausen B. Changes in quantitatively assessed adverse effects, a few of them severe. Cases of neurotoxicity, the serotonin syndrome and the neuroleptic malignant syndrome have been reported.

Lithium + Antidepressants; Venlafaxine

Symptoms similar to those of the serotonin syndrome have developed in a few patients taking lithium with venlafaxine. No clinically significant pharmacokinetic interaction appears to occur between these two drugs.

Clinical evidence, mechanism, importance and management

In an open study of 13 major depressive patients who did not respond to a 4-week course of venlafaxine 300 mg daily, lithium was added and continued for 4 weeks. After 12 days of combined treatment, 2 patients experienced symptoms of hypomania, marked nausea and trembling (considered to be a moderate form of the serotonin syndrome), and had to stop lithium treatment. Their lithium-plasma levels were within the therapeutic range (0.83 and 0.77 mmol/L on day 7). Lithium was well tolerated by most of the other patients, with trembling being the most frequent adverse effect (4 out of 11).1

A case report describes a 50-year-old woman who developed the serotonin syndrome 45 days after starting to take lithium and venlafaxine (and within 10 days of the most recent dose increase of venlafaxine). Both drugs were immediately stopped and she recovered over the next 4 to 5 days. Plasma levels of venlafaxine, its metabolite O-desmethylvenlafaxine (ODV), and lithium had remained within the normal therapeutic range throughout. As she had previously experienced profound adverse effects with two different SSRIs, the authors concluded that the patient was unusually sensitive to serotonergic medication.2

In a pharmacokinetic study, 12 healthy subjects were given a single 600-mg dose of lithium carbonate on day 1 and day 8, with venlafaxine 50 mg every 8 hours for 7 days from day 4. The renal clearance of venlafaxine was reduced by about 50% and that of its active metabolite ODV was reduced by 15%. Neither of these changes was considered clinically relevant, as the total clearance was not affected. The maximum serum levels of the lithium were increased by about 10%, and the time to reach this was reduced by about 30 minutes, but these changes met the criteria for bioequivalence, and the other pharmacokinetic parameters of lithium were unchanged.3 The general picture that emerged was that no clinically important pharmacokinetic interaction normally occurs if these two drugs are used together.

There seems to be no good reason for avoiding concurrent use, but be aware that an interaction is possible and monitor the outcome carefully. For more information about the serotonin syndrome, see ‘Additive or synergistic interactions’, (p.9).

Lithium + Antiepileptics; Carbamazepine

Although the combined use of lithium and carbamazepine is beneficial in many patients, it may increase the risk of neurotoxicity. Sinus node dysfunction has also occurred in a few patients. An isolated report describes a patient who had a marked rise in lithium levels and lithium toxicity, which was apparently caused by carbamazepine-induced renal impairment.

Clinical evidence

(a) Neurotoxicity with normal drug levels

A patient taking lithium 1.8 g daily developed severe neurotoxicity (ataxia, truncal tremors, nystagmus, limb hyperreflexia, muscle fasciculation) within 3 days of starting to take carbamazepine 600 mg daily. Blood levels of both drugs remained within the therapeutic range. The symptoms resolved when each drug was withdrawn in turn, and re-occurred within 3 days of restarting concurrent treatment.1 Five patients with rapid-cycling bipolar disorder developed similar neurotoxic symptoms (confusion, drowsiness, generalised weakness, lethargy, coarse tremor, hyperreflexia, cerebellar signs) when they were given lithium carbonate with carbamazepine [doses not stated]. Plasma levels of both drugs remained within the accepted range.2 Other reports describe adverse neurological effects during the concurrent use of lithium and carbamazepine, which were also not accompanied by significant changes in lithium levels.3,7 although in one patient raised serum levels of both drugs were seen.8 A systematic search through the Medline database, for reports of neurotoxic adverse effects in patients taking lithium at low therapeutic concentrations, found a total of 41 cases over approximately 30 years from 1966. Carbamazepine had been taken concurrently in 22% of these cases, in some instances with other potentially interacting drugs.9 Another retrospective study of 46 type I bipolar patients found significant benefits of long-term combined lithium and carbamazepine therapy compared with monotherapy with lithium (31 patients) or carbamazepine (15). However, rates of adverse effects increased 2.5-fold compared with monotherapy, and there were particular excesses of tremor and drowsiness.10 In other patients the combined use of lithium and carbamazepine was said to be well tolerated and beneficial,1,12,13 but one report suggests that the dosages may need to be carefully titrated to avoid adverse effects.14

(b) Sinus node dysfunction

A 9-year study in a psychiatric hospital found that, of 5 patients on lithium who developed sinus node dysfunction, 4 were also on carbamazepine.14

(c) Toxic lithium levels

An isolated case report describes carbamazepine-induced acute renal failure, which resulted in a 3.5-fold rise in lithium levels and lithium toxicity 3 weeks after carbamazepine was started.13

Mechanism

Not understood. A paper that plotted the serum levels of lithium and carbamazepine on a 3-dimensional graph failed to find any evidence of synergistic toxicity.16 Sinus node dysfunction can be caused by either lithium or carbamazepine, but this is rare. However, the effects may possibly be additive.

Importance and management

The neurotoxic interaction is established, but its incidence is not known. The incidence of severe neurotoxicity may be quite small, but increased mild adverse events such as tremor and drowsiness seem to be fairly common.10 The authors of one paper suggest that the risk factors appear to be a history of neurotoxicity with lithium, and compromised medical or neurological function.2 If concurrent use is undertaken, the outcome should be closely monitored. This is particularly important because neurotoxicity can develop even though the levels remain within the accepted therapeutic range. If severe neurotoxicity develops the lithium treatment should be discontinued promptly, whatever the lithium level.2

Lithium + Antiepileptics; Gabapentin

Gabapentin did not alter the pharmacokinetics of single-dose lithium in patients with normal renal function.

Clinical evidence, mechanism, importance and management

In a double-blind study, 13 patients with normal renal function were given a single 600-mg dose of lithium either with or without gabapentin at steady state. Gabapentin did not significantly alter the pharmacokinetics of the lithium, and no increase in adverse effects was noted. More long-term studies will be needed to confirm this lack of interaction, especially in patients with impaired renal function as both drugs are eliminated by renal excretion.1

Lithium + Antiepileptics; Lamotrigine

Lamotrigine does not appear to cause a clinically significant alteration in lithium levels. Cognitive adverse effects have been reported in one patient taking the combination.

Clinical evidence, mechanism, importance and management

In an open, randomised, two-period, crossover study, 20 healthy men were given 2 g of anhydrous lithium gluconate (9.8 mmol of lithium) every 12 hours for 11 doses, either with or without lamotrigine 100 mg daily. It was found that the serum-lithium levels were decreased by about 8% by lamotrigine, but these small changes were not considered to be clinically relevant.1

A 2002 review of the few published reports on the use of lithium with lamotrigine suggested that the combination appears to be well tolerated.2 However, one woman taking lithium who had been treated with lamotrigine 50 mg for 4 weeks, experienced delirium when the dose of lamotrigine was increased to 150 mg daily. The symptoms disappeared when the lamotrigine dose was reduced to 100 mg daily.3 It is not clear whether these effects were directly caused by the combination of lithium and lamotrigine. However, the authors of the review considered that if cognitive ad-
verse effects occur, it might be worth considering a reduction in the dose of either or both drugs. More study is needed.

Lithium + Antiepileptics; Phenytoin

Symptoms of lithium toxicity (sometimes with unchanged lithium levels) have been seen in a few patients concurrently treated with phenytoin, although the interaction has not been clearly demonstrated.

Clinical evidence, mechanism, importance and management

A patient with a history of depression and convulsions was treated with increasing doses of lithium carbonate and phenytoin over a period of almost 4 years. Although the serum levels of both drugs remained within the therapeutic range, he eventually began to develop symptoms of lithium toxicity (thirst, polyuria, polydipsia and tremor) that disappeared when the lithium was stopped. Later, when lithium was restarted, the symptoms returned, this time abating when the phenytoin was replaced by carbamazepine. The patient then claimed that he felt normal for the first time in years. Another report describes symptoms of lithium toxicity in a patient with lithium levels within the normal range. This patient was also taking phenytoin.

In another case, a man taking phenytoin became ataxic within 3 days of starting to take lithium. He had no other toxic symptoms and his serum-lithium level was 2 mmol/L. However, as he only ever took lithium in the presence of phenytoin, it is not possible to say whether the effects were as a result of an interaction, or whether toxic levels would have occurred with the lithium alone. Another similar case has also been reported.

Information seems to be limited to these reports and none of them presents a clear picture of the role of phenytoin in the reactions described. The interaction is not well established. Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given phenytoin. Increased serum lithium monitoring does not appear to be of value in this situation as the interaction occurred in patients with lithium levels within the normally accepted range.

Lithium + Antiepileptics; Topiramate

Two isolated reports describe elevated serum-lithium levels and evidence of toxicity in patients also taking topiramate. No important pharmacokinetic interaction has been seen in healthy subjects.

Clinical evidence, mechanism, importance and management

A 42-year-old woman with type II bipolar disorder was started on lithium carbonate 1.5 g and topiramate 500 mg daily, resulting in a steady-state trough serum-lithium level of 0.5 mmol/L after 10 days. She was also started on citalopram 10 mg daily. The patient raised the topiramate dose to 800 mg daily in an attempt to lose weight, and 5 weeks later began to complain of severe anorexia, nausea, fatigue and impaired concentration. She had managed to lose 35 lb (almost 16 kg) of weight she had gained whilst on a previous drug combination. When examined she was lethargic, with tremors, nystagmus, bradycardia and memory loss. Her trough serum-lithium level had risen by 180% to 1.4 mmol/L. The symptoms disappeared over 4 days when the lithium was stopped. Two months later she was stabilised once again on lithium carbonate 1.2 g and topiramate 500 mg daily, with a steady-state serum-lithium level of 0.5 mmol/L. Another report describes a case of increased lithium levels and toxicity (worsening concentration, confusion, lethargy) after topiramate was added to lithium therapy. The lithium was stopped and then restarted at half the original dose, which produced therapeutic lithium levels of 0.67 mmol/L. In addition, while maintaining the dose of lithium at 450 mg daily, further increases in the topiramate dose from 75 to 125 mg daily over 4 weeks resulted in parallel elevations of lithium levels (from 0.67 to 0.92 mmol/L).

However, a review of the pharmacokinetic interactions of topiramate reported a study that had found that there was little pharmacokinetic interaction with lithium when topiramate (50 mg twice daily titrated to 100 mg twice daily) was given to 12 healthy subjects receiving lithium carbonate 300 mg three times daily. The AUC of lithium was about 18% lower and the clearance 21.7% higher. When compared with historical data, the clearance of topiramate appeared to be lower.

The reasons for these reactions are not known, but topiramate is mainly eliminated by renal excretion and high doses of topiramate may competitively interfere with lithium excretion. Similarly, lithium may affect topiramate clearance. Some of the toxicity could have been due to the adverse effects of either drug, with the weight loss in the first case possibly disturbing the sodium excretion, which could have affected the loss of lithium in the urine.

These cases highlight the possible risk of elevated serum-lithium levels especially if high doses of topiramate are used. Patients on lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given topiramate. Consider monitoring lithium levels in patients newly started on this combination and carefully adjusting the dose of topiramate and/or lithium to minimise adverse effects.

Lithium + Antiepileptics; Valproate

No clinically relevant adverse interaction appears to occur between lithium carbonate and valproate.

Clinical evidence, mechanism, importance and management

In a crossover study, 16 healthy subjects were given valproate (as valproate semisodium) or a placebo twice daily for 12 days, to which lithium carbonate 300 mg three times daily was added on days 6 to 10. The valproate-serum levels and AUC rose slightly, while the serum-lithium levels were unaffected. Adverse effects did not change significantly. It was concluded that the concurrent use of these drugs is safe. A review on the efficacy of lithium/anticonvulsant combinations in bipolar disorder lists several studies in which the combination of valproate (as valproate semisodium) and lithium was used. On the whole the combination was considered safe and well tolerated, although a few patients discontinued treatment due to adverse effects, which included gastrointestinal symptoms and raised liver transaminases. It was, however, difficult to know if these adverse effects were due to the individual drugs or the result of an interaction. Other adverse effects that have been reported with the combined treatment include tremor, cognitive impairment and alopecia.

Lithium + Aspirin or other Salicylates

No clinically significant pharmacokinetic interaction appears to occur between aspirin, lysine aspirin and sodium salicylate and lithium.

Clinical evidence, mechanism, importance and management

In a steady-state study 10 healthy women with average plasma-lithium levels of 0.63 mmol/L had a slight 6% rise in their renal excretion of lith-
Lithium when they were given aspirin 1 g four times daily for 7 days. However, no statistically significant alteration in lithium levels was found.  

No change in serum lithium levels was seen in 7 patients taking lithium when they were given aspirin 975 mg four times daily for 6 days. Another report states that aspirin 600 mg four times daily had no effect on the absorption or renal excretion of single doses of lithium carbonate given to 6 healthy subjects. Further reports describe no change in serum lithium levels with 

It showed no major changes in their mental state or movement disorders in 6 healthy subjects. 3 Further reports describe no change in serum lithium sorption or renal excretion of single doses of lithium carbonate given to 6 patients. A retrospective study of patient records revealed 5 patients with bipolar affective disorder, treated with lithium carbonate 900 mg to 2.4 g daily, who had developed a reversible neurotoxic syndrome with ataxia, dysarthria, drowsiness and confusion when they were given clonazepam 2 to 16 mg daily. In one case the clonazepam was added to their antipsychotics (chlorpromazine, perphenazine, haloperidol) and in 4 cases the clonazepam replaced the antipsychotic treatment. In all cases the lithium levels rose, and in two of these cases they reached toxic levels. The authors of the report suggest that the neurotoxicity was caused either by the increase in lithium levels, or by synergistic toxicity, however, the use of antipsychotics may also have increased CNS sensitivity. It was recommended that lithium levels should be measured more frequently if clonazepam is added, and the effects of concurrent use well monitored.  

(a) Alprazolam  

Alprazolam 2 mg daily for 4 days slightly increased the steady-state AUC of lithium by about 8% and reduced its urinary recovery from 93.6% to 78.2% in 10 healthy subjects taking lithium 900 mg to 1.5 g daily. It was suggested that these changes were unlikely to be clinically significant, but confirmation of this is needed.  

(b) Clonazepam  

A retrospective study of patient records revealed 5 patients with bipolar affective disorder, treated with lithium carbonate 900 mg to 2.4 g daily, who had developed a reversible neurotoxic syndrome with ataxia, dysarthria, 

No change in serum lithium levels was seen in 7 patients taking lithium who were also regularly given coffee (4 to 8 cups daily containing 70 to 120 mg of caffeine per cup) found that when the coffee was withdrawn, their serum-lithium levels rose by an average of 24%, although the levels of 3 patients did not change. These findings are consistent with another report of 2 patients with lithium-induced tremors that were aggravated when caffeine was withdrawn. 

Lithium + Benzodiazepines  

Neurotoxicity and increased serum-lithium levels were reported in five patients when clonazepam was added to treatment with lithium. An isolated case of serious hypothermia has been reported during the concurrent use of lithium and diazepam. Alprazolam seems unlikely to cause a clinically important rise in serum-lithium levels.  

Lithium + Baclofen  

The hyperkinetic symptoms of two patients with Huntington’s chorea were aggravated within a few days of starting concurrent lithium and baclofen. One patient took lithium first, the other baclofen.  

Lithium + Caffeine  

The heavy consumption of caffeine-containing drinks may cause a small to moderate reduction in serum-lithium levels.  

Clinical evidence, mechanism, importance and management  

A study in 11 psychiatric patients taking lithium 600 mg to 1.2 g daily who were also regular coffee drinkers (4 to 8 cups daily containing 70 to 120 mg of caffeine per cup) found that when the coffee was withdrawn, their serum-lithium levels rose by an average of 24%, although the levels of 3 patients did not change. These findings are consistent with another report of 2 patients with lithium-induced tremors that were aggravated when they stopped drinking large amounts of coffee. One of the patients had a 50% rise in lithium levels, and required a reduction in lithium dose from 1.5 g daily to 1.2 g daily. 

It is not clear exactly how caffeine affects the excretion of lithium by the renal tubules, but other xanthines have a similar effect (see ‘Lithium + Theophylline’, p.1129). The weight of evidence cited here suggests that although there is no need for those on lithium to avoid caffeine (coffee, tea, cola drinks etc.), in cases where a reduction in caffeine intake is desirable, it should be withdrawn cautiously. This is particularly important in those whose serum-lithium levels are already high, because of the risk of toxicity. When caffeine is withdrawn it may be necessary to reduce the dose of lithium. In addition, remember that there is a caffeine-withdrawal syndrome (headache and fatigue being the major symptoms) that might worsen some of the major psychiatric disorders (such as affective and schizophrenic disorders).  

Clinical evidence

Prompted by the occasional observation of decreased serum-lithium levels in outpatients receiving calcitonin, a study was undertaken in 4 bipolar depressive women. The patients, who had been stable on lithium for 10 years, were additionally given salmon calcitonin (salcatonin) 100 units subcutaneously for 3 consecutive days for postmenopausal osteoporosis. It was found that their serum-lithium levels fell, on average, from 0.73 to 0.59 mmol/L. The clearance of lithium in the urine was tested in 2 of the patients, and both showed increases (9.8 and 16.2%).

Mechanism

Not known. Increased renal excretion and possibly some reduced intestinal absorption of the lithium have been suggested by the authors of the report.

Importance and management

Information seems to be limited to this study, which only lasted for 3 days. The study found only a small fall in serum-lithium levels, and did not assess the effect on the control of depression. It seems unlikely that this interaction will be clinically important in most patients, but as some patients may be affected, monitor the outcome of concurrent use, and consider monitoring lithium levels.

Lithium + Calcium-channel blockers

The concurrent use of lithium and verapamil can be uneventful, but neurotoxicity (ataxia, movement disorders, tremors) with unchanged lithium levels has been reported in a few patients. Reduced daily increased lithium levels have also occurred with verapamil. An acute parkinsonian syndrome and marked psychosis has been seen in at least one patient taking lithium and diltiazem. Reduced lithium clearance, and one possible case of increased lithium levels have been reported with nifedipine.

Clinical evidence

(a) Diltiazem

A woman stable on lithium for several years developed marked psychosis and parkinsonism within a week of starting to take diltiazem 30 mg three times daily. An acute parkinsonism syndrome developed in a 58-year-old man within 4 days of adding 30 mg of diltiazem three times daily to his treatment with lithium and tiotixene. However, this report has been questioned as the symptoms may have been attributable to an adverse effect of the tiotixene, and, even if the lithium toxicity was genuine, it is thought to have been more likely due to recent increases in the lithium dose, or the patient’s diuretic therapy than diltiazem.

(b) Nifedipine

In a study of patients with essential hypertension, two doses of nifedipine 20 mg did not affect single-dose lithium clearance, but nifedipine 40 to 80 mg daily for 6 and 12 weeks was found to decrease single-dose lithium clearance by 30%. A man, on lithium carbonate 1.5 g daily with a level of 0.8 mmol/L, developed ataxia and dysarthria 7 days after starting nifedipine 30 mg daily for 48 hours, then 60 mg daily. His lithium dose was reduced by 40%, but his serum-lithium level first increased to 1.1 mmol/L (about 2 weeks after starting the nifedipine), before restabilising at 0.9 mmol/L. In contrast, a patient taking lithium, who developed dysarthria and ataxia after verapamil was added to her treatment (see (c) below), was subsequently well controlled on lithium and nifedipine 40 mg daily.

(c) Verapamil

A 42-year-old woman taking lithium carbonate 900 mg daily developed toxicity (nausea, vomiting, muscular weakness, ataxia and tinnitus) within 9 days of starting to take verapamil 80 mg three times daily. Her bipolar depressive disorder improved even though her serum-lithium levels remained unchanged at 1.1 mmol/L. The toxicity disappeared within 48 hours of stopping the verapamil, but her disorder worsened. The same pattern was repeated when verapamil was re-started and then withdrawn. Another 3 cases of movement disorders (including ataxia, tremors and choreoathetosis) resulting from the concurrent use of lithium and verapamil have also been reported, and two of which had documented unchanged serum-lithium levels. In one case the patient was restabilised by halving the dose of lithium.

Conversely, a patient stable on lithium 900 mg to 1.2 g daily for over 8 years had a marked fall in his serum-lithium levels from about 1.04 to 0.5 mmol/L when he was given verapamil 80 mg four times daily. He was restabilised on double the dose of lithium. Another patient had an increased lithium clearance when given verapamil for 3 days, and a fall in serum-lithium levels from 0.61 to 0.53 mmol/L.

In addition to unchanged or decreased lithium levels with verapamil, one manufacturer notes that increased lithium levels have occurred.

Mechanism

Not understood. However, it has been suggested that calcium-channel blockers and lithium affect neurotransmitter production, (several pathways have been described), which results in CNS sensitivity. This produces movement disorders, which are said to mimic lithium toxicity. In most of the cases mentioned above, symptoms of toxicity were present at therapeutic lithium levels, which would support this suggested mechanism.

Importance and management

The neurotoxic adverse reactions cited above for lithium and verapamil contrast with two other case reports describing uneventful concurrent use. Variable reports of altered serum-lithium levels have also occurred. This unpredictability emphasises the need to monitor the effects closely where it is thought appropriate to give lithium and verapamil. Only a couple of isolated reports of neurotoxicity have been reported with lithium and diltiazem, and their general relevance is uncertain, but bear them in mind in the event of an unexpected response to treatment. Some limited data suggest that nifedipine may slightly reduce lithium clearance, and the clinical relevance of this is again uncertain.

Lithium + Cisplatin

Isolated case reports describe either a fall or no alteration in serum-lithium levels in patients given cisplatin. However, note that cisplatin-induced renal impairment may cause an increase in lithium levels.

Clinical evidence, mechanism, importance and management

The serum-lithium levels of a woman taking lithium carbonate 300 mg four times daily fell, over a period of 2 days, from 1 to 0.3 mmol/L, and from 0.8 to 0.5 mmol/L, on two occasions when given cisplatin (100 mg/m² intravenously over 2 hours). To prevent cisplatin-induced renal toxicity, she was also given a fluid load over a total of 24 hours, which included one litre of sodium chloride 0.9% over 4 hours, one litre of mannitol 20% over 4 hours, and one litre of dextrose 5% in sodium chloride 0.9%. Serum-lithium levels returned to normal at the end of 2 days. No change in the control of the psychotic symptoms was seen.
A man had a transient 64% decrease in serum-lithium levels, without perceptible clinical consequences, during the first four courses of cisplatin, bleomycin, and etoposide. The effect became less pronounced during the subsequent courses. It is not clear whether the fall in serum-lithium levels in these cases was due to increased renal clearance caused by the cisplatin or the sodium load, dilution from the fluid load, or a combination of all three factors.

In contrast, one patient had no clinically significant changes in her serum-lithium levels when treated with cisplatin, but 2 months later her deteriorating renal function resulted in a rise in her serum-lithium levels.

None of these interactions was of great clinical importance, but the authors of the first report pointed out that some regimens of cisplatin involve the use of higher doses (40 mg/m² daily) with a sodium chloride 0.9% fluid load over 5 days, and under these circumstances it would be prudent to monitor the serum-lithium levels carefully. Concurrent use should be monitored in all patients.

Monitor the serum-lithium levels carefully. Concurrent use should be avoided, but other manufacturers do not appear to mention this potential interaction. An early study in rats reported increased lithium clearance with methylprednisolone. The available evidence is insufficient to recommend routine monitoring. However, it may be prudent to consider monitoring lithium effects in patients with renal impairment, or other conditions pre-disposing to lithium toxicity, taking levels if early symptoms suggest a potential problem.

The concurrent use of lithium carbonate and furosemide can be safe and uneventful, but serious lithium toxicity has been described. Bumetanide interacts similarly. The risk of lithium toxicity with a loop diuretic is greatly increased during the first month of concurrent use.

**Clinical evidence**

A patient with systemic lupus erythematosus suffering from steroid-induced depression and moderate renal impairment was given lithium 600 mg daily and her depression improved. However, serum-lithium levels increased from 0.4 to 0.8 mmol/L within one week and the lithium treatment caused an exacerbation of a finger tremor. The lithium was discontinued and then restarted at 400 mg daily, resulting in serum levels of 0.4 mmol/L, which improved her depression and was associated with only a fine finger tremor. Three other patients with steroid-induced depression were also successfully treated with lithium.

One UK manufacturer warns that drugs affecting electrolyte balance, such as corticosteroids, may alter lithium excretion and should therefore be avoided, but other manufacturers do not appear to mention this potential interaction. An early study in rats reported increased lithium clearance with methylprednisolone. The available evidence is insufficient to recommend routine monitoring. However, it may be prudent to consider monitoring lithium effects in patients with renal impairment, or other conditions pre-disposing to lithium toxicity, taking levels if early symptoms suggest a potential problem.

**Corticosteroids may disturb electrolyte balance, which in theory could affect serum-lithium levels, but there do not appear to be any reports of significant interactions.**

**Clinical evidence, mechanism, importance and management**

A patient with systemic lupus erythematosus suffering from steroid-induced depression and moderate renal impairment was given lithium 600 mg daily and her depression improved. However, serum-lithium levels increased from 0.4 to 0.8 mmol/L within one week and the lithium treatment caused an exacerbation of a finger tremor. The lithium was discontinued and then restarted at 400 mg daily, resulting in serum levels of 0.4 mmol/L, which improved her depression and was associated with only a fine finger tremor. Three other patients with steroid-induced depression were also successfully treated with lithium.

One UK manufacturer warns that drugs affecting electrolyte balance, such as corticosteroids, may alter lithium excretion and should therefore be avoided, but other manufacturers do not appear to mention this potential interaction. An early study in rats reported increased lithium clearance with methylprednisolone. The available evidence is insufficient to recommend routine monitoring. However, it may be prudent to consider monitoring lithium effects in patients with renal impairment, or other conditions pre-disposing to lithium toxicity, taking levels if early symptoms suggest a potential problem.

**Bumetanide**

Bumetanide has been responsible for the development of lithium toxicity in 2 patients, one of whom was on a salt-restricted diet. Six healthy subjects stabilised on lithium carbonate 300 mg three times daily (mean serum levels 0.43 mmol/L) were given furosemide 40 mg daily for 14 days. Five experienced some minor adverse effects, probably attributable to the furosemide, without significant changes in serum-lithium levels, but one subject experienced such a marked increase in the toxic effects of lithium that she withdrew from the study after taking both drugs for only 5 days. Her serum-lithium levels were found to have risen from 0.44 to 0.71 mmol/L.

There are another 4 case reports of individual patients who experienced serious lithium toxicity or other adverse reactions when given lithium and furosemide. One of the patients was also on a salt-restricted diet, which has also been implicated in episodes of lithium toxicity, see ‘Lithium + Sodium compounds’, p.1128. In contrast, 6 patients who had been stabilised on lithium for over 6 years had no significant changes in their serum-lithium levels over a 12-week period while taking furosemide 20 to 80 mg daily. Other studies in healthy subjects also found no significant changes in lithium levels when furosemide 40 or 80 mg daily was given.

**Mechanism**

Not fully understood. If and when a rise in serum-lithium levels occurs, it may be related to the salt depletion that can accompany the use of furosemide (for a more detailed explanation see ‘Lithium + Sodium compounds’, p.1128). As with the ‘thiazide diuretics’, such an interaction would take a few days to develop. This may explain why one study in subjects given a single dose of lithium failed to demonstrate that furosemide had any effect on the urinary excretion of lithium.

**Importance and management**

Information seems to be limited to the reports cited. The incidence of this interaction is uncertain and its development unpredictable. It would be imprudent to give furosemide or bumetanide to patients stabilised on lithium unless the effects can be well monitored because some patients may develop serious toxicity. Patients on lithium should be aware of the symptoms of lithium toxicity (see ‘Lithium’, p.1111) and told to report them immediately should they occur. Consider increased monitoring of lithium levels in patients newly started on this combination.

**Lithium + Bumetanide**

Bumetanide has been responsible for the development of lithium toxicity in 2 patients, one of whom was on a salt-restricted diet.

**Lithium + Diuretics; Loop**

The concurrent use of lithium carbonate and furosemide can be safe and uneventful, but serious lithium toxicity has been described. Bumetanide interacts similarly. The risk of lithium toxicity with a loop diuretic is greatly increased during the first month of concurrent use.

**Clinical evidence**

An analysis of 10,615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any loop diuretic (not specifically named) were compared between these 413 hospitalised patients and 1651 control patients. For any use of a loop diuretic (54 cases and 71 controls) there was an increased relative risk of hospitalisation for lithium toxicity of 1.7. When patients who were newly started on a loop diuretic were analysed (12 cases and 6 controls), a dramatically increased risk of lithium toxicity within a month of initiating treatment was found (relative risk 5.1). Reports relating to specific named loop diuretics are discussed below.

(a) **Bumetanide**

Bumetanide has been responsible for the development of lithium toxicity in 2 patients, one of whom was on a salt-restricted diet.

(b) **Furosemide**

Six healthy subjects stabilised on lithium carbonate 300 mg three times daily (mean serum levels 0.43 mmol/L) were given furosemide 40 mg daily for 14 days. Five experienced some minor adverse effects, probably attributable to the furosemide, without significant changes in serum-lithium levels, but one subject experienced such a marked increase in the toxic effects of lithium that she withdrew from the study after taking both drugs for only 5 days. Her serum-lithium levels were found to have risen from 0.44 to 0.71 mmol/L.

There are another 4 case reports of individual patients who experienced serious lithium toxicity or other adverse reactions when given lithium and furosemide. One of the patients was also on a salt-restricted diet, which has also been implicated in episodes of lithium toxicity, see ‘Lithium + Sodium compounds’, p.1128. In contrast, 6 patients who had been stabilised on lithium for over 6 years had no significant changes in their serum-lithium levels over a 12-week period while taking furosemide 20 to 80 mg daily. Other studies in healthy subjects also found no significant changes in lithium levels when furosemide 40 or 80 mg daily was given.

**Mechanism**

Not fully understood. If and when a rise in serum-lithium levels occurs, it may be related to the salt depletion that can accompany the use of furosemide (for a more detailed explanation see ‘Lithium + Sodium compounds’, p.1128). As with the ‘thiazide diuretics’, such an interaction would take a few days to develop. This may explain why one study in subjects given a single dose of lithium failed to demonstrate that furosemide had any effect on the urinary excretion of lithium.

**Importance and management**

Information seems to be limited to the reports cited. The incidence of this interaction is uncertain and its development unpredictable. It would be imprudent to give furosemide or bumetanide to patients stabilised on lithium unless the effects can be well monitored because some patients may develop serious toxicity. Patients on lithium should be aware of the symptoms of lithium toxicity (see ‘Lithium’, p.1111) and told to report them immediately should they occur. Consider increased monitoring of lithium levels in patients newly started on this combination.
Clinical evidence and mechanism

(a) Amlorilide

Amlorilide has been found to have no significant effect on serum-lithium levels when used in the treatment of lithium-induced polyuria. One review briefly mentions a case report in which amlorilide was successfully used as a replacement for bendroflumethiazide, which had caused lithium toxicity. However, some manufacturers suggest that, as a diuretic, amlorilide reduces the renal clearance of lithium, thereby increasing the risk of lithium toxicity. There appears to be no evidence to confirm this alleged interaction.

(b) Spironolactone

One study found that spironolactone had no statistically significant effect on the excretion of lithium. Whereas, in another report, the use of spironolactone 100 mg daily was accompanied by a rise in serum-lithium levels from 0.63 to 0.9 mmol/L. The levels continued to rise for several days after the spironolactone was stopped.

(c) Triamterene

Triamterene, given to a patient taking lithium while on a salt-restricted diet, is said to have led to a strong lithium diuresis. Similarly, triamterene increased lithium excretion in 8 healthy subjects.

Importance and management

These diuretics have been available for a very considerable time and it might have been expected that by now any serious adverse interactions with lithium would have emerged, but information is very sparse. None of the reports available gives a clear indication of the outcome of concurrent use, but some monitoring would be a prudent precaution. Patients on lithium should be aware of the symptoms of lithium toxicity (see ‘Lithium’, (p.1111)) and told to report them immediately should they occur.

References

Thiazide and related diuretics can cause a rapid rise in serum-lithium levels, leading to toxicity unless the lithium dosage is reduced appropriately. This interaction has been seen with bendroflumethiazide, chlorothiazide, chlortalidone, hydrochlorothiazide and indapamide, and potentially occurs with hydroflumethiazide. Other thiazides and related diuretics are expected to behave similarly.

Clinical evidence

A retrospective analysis of 10 615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for toxicity during a 10-year study period. The prescriptions for a thiazide-type diuretic were compared between these 413 hospitalised patients and 1651 control patients. For any use of a thiazide diuretic (16 cases and 37 controls) there was a non-significant increased relative risk of 1.3 for hospitalisation due to lithium toxicity. When treatment for patients who were newly started on a thiazide diuretic was analysed (5 cases and 6 controls), the increased relative risk of toxicity was also non-significant (1.3). The authors considered that these findings suggest that the use of thiazide diuretics and lithium may not be as hazardous as previously thought. However, the authors also suggest that another explanation is that clinicians were aware of the potential interaction and so adjusted doses or observed patients more closely in the outpatient setting, thereby avoiding any hospitalisations for toxicity.

Case reports and studies for named thiazide diuretics are outlined below.

(a) Bendroflumethiazide

A study in 22 patients, who had been treated with either bendroflumethiazide 2.5 mg or hydroflumethiazide 25 mg daily for at least 2 months, found that these diuretics caused a 24% reduction in the urinary clearance of a single 600-mg dose of lithium carbonate. There is also a case report of a roughly twofold increase in serum-lithium levels, and a case of lithium toxicity with a roughly threefold increase in serum-lithium levels mentioned in a review article, both following the addition of bendroflumethiazide to treatment with lithium. In a further case, lithium toxicity, with serum-lithium levels of 4.28 mmol/L was detected 3 months after the addition of bendroflumethiazide. However, this case was complicated by the presence of perindopril, which might also raise lithium levels, as has occurred with other ‘ACE inhibitors’, (p.1112).

In contrast to these reports, one single-dose study found that bendroflumethiazide 7.5 mg given 10 hours after lithium carbonate 600 mg had no effect on lithium clearance. However, it seems unlikely that single-dose studies will detect an interaction (see Mechanism below).

(b) Chlorothiazide

A single 300-mg dose of lithium carbonate was given to 4 healthy subjects alone and following 7 days of treatment with chlorothiazide 500 mg daily. Lithium-plasma levels were increased and lithium clearance was decreased by about 26% following chlorothiazide treatment.

Lithium toxicity developed in a patient taking lithium after she was given chlorothiazide, spironolactone and amlorilide. The lithium levels rose from 0.6 to 2.2 mmol/L.

A 54-year-old patient developed nephrogenic diabetes insipidus when she was treated with lithium carbonate. The addition of chlorothiazide reduced her polyuria, but resulted in an elevation in her lithium level from 1.3 to more than 2 mmol/L, with accompanying signs of toxicity. The patient was later successfully treated with chlorothiazide and a reduced dose of lithium.

(c) Chlortalidone

A 58-year-old woman developed lithium toxicity within 10 days of starting chlortalidone [dose unknown]. Her lithium levels rose from 0.8 to 3.7 mmol/L.

(d) Hydrochlorothiazide

In a placebo-controlled study, the serum-lithium levels of 13 healthy subjects taking lithium 300 mg twice daily rose by 23% (from 0.3 to 0.37 mmol/L), when they were given hydrochlorothiazide 25 mg twice daily for 5 days. Similar results were found in another small study.

In addition to these studies at least 6 cases of lithium toxicity have been seen when hydrochlorothiazide was given to patients taking lithium.

Hydrochlorothiazide was either given with amlorilide, or spironolactone or triamterene. See also ‘Lithium + Diuretics; Potassium-sparing’, p.1122.

(e) Hydroflumethiazide

A study in 22 patients who had been treated with either bendroflumethiazide 2.5 mg or hydroflumethiazide 25 mg daily for at least 2 months found that these diuretics caused a 24% reduction in the urinary clearance of a single 600-mg dose of lithium carbonate.

(f) Indapamide

A 64-year-old man developed lithium toxicity one week after starting to take indapamide 5 mg daily. His serum-lithium level was 3.93 mmol/L.

Mechanism

Not fully understood. The interaction occurs even though the thiazides and related diuretics exert their major actions in the distal part of the kidney tubule whereas lithium is mainly reabsorbed in the proximal part. However, thiazide diuresis is accompanied by sodium loss which, within a few days, is compensated by retention of sodium, this time in the proximal part of the tubule. Since both sodium and lithium ions are raised similarly, the increased reabsorption of sodium would include lithium as well, hence a significant and measurable reduction in its excretion.
Importance and management

Established, well-documented and potentially serious interactions. The rise in serum-lithium levels and the accompanying toxicity develops most commonly within about a week to 10 days, although it has apparently been seen after 19 days and even 3 months. Not every patient necessarily develops a clinically important interaction, but it is not possible to predict which patients will be affected. The lack of serious cases of toxicity in the case-control study either suggests the interaction is rare, or that appropriate precautions are used when the combination is prescribed.

Although the diuretics named above have been implicated in this interaction, it seems likely that all thiazides and related diuretics will interact similarly. None of the thiazide or related diuretics should be given to patients on lithium unless the serum-lithium levels can be closely monitored and appropriate downward dosage adjustments made. The US manufacturers also say that caution should be used and serum-lithium levels monitored closely with adjustment of the dosage. One UK manufacturer says that if a thiazide diuretic has to be prescribed for a patient treated with lithium, then the lithium dosage should first be reduced, and the patient then stabilised by frequent monitoring of lithium levels. Similar precautions should be exercised on diuretic withdrawal. However, this does not seem to be in line with most other recommendations. Patients on lithium should be aware of the symptoms of lithium toxicity (see “Lithium”, p.1111)) and told to report them immediately should they occur.

Concurrent use under controlled conditions has been advocated for certain psychiatric conditions and for the control of lithium-induced nephrogenic diabetes insipidus. A successful case is described above. It has been suggested that a 40 to 70% reduction in the lithium dose would be needed with doses of 0.5 to 1 g of chlorothiazide, but it would seem sensible to base any dose adjustments on individual lithium levels.

Clinical evidence, mechanism, importance and management

(a) Herbal diuretics

A 26-year-old woman who had been taking lithium 900 mg twice daily for 5 months, with hydroxyzine, lorazepam, propranolol, risperidone and sertraline, came to an emergency clinic complaining of nausea, diarrhoea, unsteady gait, tremor, nystagmus and drowsiness, (all symptoms of lithium toxicity). Her lithium level, which had previously been stable at 1.1 mmol/L was found to be 4.5 mmol/L. For the past 2 to 3 weeks she had been taking a non-prescription herbal diuretic containing corn silk, Equisetum hyemale, juniper, ovate buchu, parsley and uva ursi, all of which are believed to have diuretic actions. The other ingredients were bromelain, paprika, potassium and vitamin B6.

The most likely explanation for what happened is that the herbal diuretic caused the lithium toxicity. It is impossible to know which herb or combination of herbs actually caused the toxicity, or how, but this case once again emphasises that herbal remedies are not risk-free just because they are natural. It also underscores the need for patients to avoid self-medication without first seeking informed advice and supervision if they are taking potentially hazardous drugs like lithium.

(b) St John’s Wort (Hypericum perforatum)

A search of Health Canada’s database of spontaneous adverse reactions identified one case in which St John’s wort was suspected of inducing mania in a patient also taking lithium. No further details were given of this case.

Lithium + Iodides

The hypothyroid and goitrogenic effects of lithium carbonate and iodides may be additive if given concurrently. Other factors such as geographical location, age and gender may also be important.

Clinical evidence

A man with normal thyroid function showed evidence of hypothyroidism after 3 weeks of treatment with lithium carbonate 750 mg to 1.5 g daily. After 2 further weeks, during which he was also treated with potassium iodide, the hypothyroidism became even more marked, but resolved completely within 2 weeks of the withdrawal of both drugs. This patient was studied before the potential risk of hypothyroidism with iodine was well-recognised.

In another study of the possible effects of iodide intake on thyroid function in 10 patients on lithium therapy, 3 to 5 weeks of potassium iodide caused hypothyroidism in 2 patients and hyperthyroidism in one. Little effect on thyroid function was seen in 5 control patients given potassium iodide without lithium. A case of hypothyroidism involving lithium and a product containing isoproamide iodide plus haloperidol (Vesalium) has also been reported.

Mechanism

Lithium accumulates in the thyroid gland and blocks the release of the thyroid hormones by thyroid-stimulating hormone, and can therefore cause clinical hypothyroidism. The prevalence of hypothyroidism may be higher in women, in middle-age, and in countries with a higher level of nutritional iodine. Potassium iodide temporarily prevents the production of thyroid hormones but, as time goes on, synthesis recommences. Thus, both lithium and iodide ions can depress the production or release of the hormones and therefore have additive hypothyroid effects.

Importance and management

The pharmacological interaction of altered thyroid function with lithium and iodides would appear to be established. However, the clinical use of iodides is now very limited (mostly to the pre-operative treatment of thyrotoxicosis). It is therefore unlikely that iodides will be used in patients on lithium. Where countries are adopting iodization programmes to prevent iodine deficiency, there may be an increased risk of clinical hypothyroidism.
Lithium in patients taking lithium. Lithium-induced hypothyroidism can be treated with thyroxine replacement.

Lithium + Ispaghula (Psyllium)

In an isolated case, the withdrawal of ispaghula husk resulted in an increase in lithium levels. Psyllium slightly reduced the absorption of lithium in a study in healthy subjects.

Clinical evidence

A 47-year-old woman recently started on lithium was found to have blood-lithium levels of 0.4 mmol/L five days after an increment in her lithium dose and whilst also taking one teaspoonful of ispaghula husk twice daily. The ispaghula husk was stopped 3 days later and lithium levels measured 4 days later were found to be 0.76 mmol/L.

A study in 6 healthy subjects similarly showed that the absorption of lithium (as measured by the urinary excretion) was reduced by about 14% by psyllium.

Mechanism

Not understood. One idea is that the absorption of the lithium from the gut is reduced.

Importance and management

Information is very limited and the general importance of this interaction is uncertain, but it would now seem prudent to bear this interaction in mind in variants given ispaghula or psyllium preparations. If an interaction is suspected consider monitoring lithium levels and separating the administration of the two drugs by at least an hour, or use an alternative laxative.

Lithium + Mazindol

An isolated report describes a case of lithium toxicity, which was attributed to the concurrent use of mazindol.

Clinical evidence, mechanism, importance and management

A bipolar depressive woman, stabilised on lithium carbonate, showed signs of lithium toxicity (sluggishness, ataxia) within 3 days of starting to take mazindol 2 mg daily. After 9 days she developed twitching, limb rigidity and muscle fasciculation, and was both dehydrated and stuporous. Her serum-lithium levels were found to have risen from a range of 0.4 to 1.3 mmol/L up to 3.2 mmol/L. The mazindol was stopped, and she recovered over the next 48 hours whilst being rehydrated. It is not known whether this was a direct interaction between the two drugs, but the authors suggest that the anorectic effect of mazindol led to this toxicity [i.e. the reduced intake of sodium and water caused a reduction in the renal excretion of lithium]. There seem to be no other reports of interactions between lithium and other anorectic drugs confirming this possibility.

This is an isolated case and its general importance is uncertain, but bear it in mind in the case of an unexpected response to treatment. Note that stimulants such as mazindol are no longer generally recommended as appetite suppressants.

Lithium + Methyldopa

Symptoms of lithium toxicity, not always associated with raised lithium levels, have been described in four patients and four healthy subjects when they were also given methyldopa.

Clinical evidence

A manic-depressive woman, taking lithium carbonate 900 mg daily was hospitalised for signs of manic compensation and her lithium dose was increased to 1.8 g daily. When she was also given methyldopa 1 g daily for hypertension, she developed signs of lithium toxicity (blurred vision, hand tremors, mild diarrhoea, confusion, and slurred speech), even though her serum-lithium levels were within the range of 0.5 to 0.7 mmol/L. The methyldopa was then stopped and the lithium carbonate dose reduced to 1.5 g daily. Ten days later the lithium level was 1.4 mmol/L, and the lithium dose was decreased to 900 mg daily. Later the author of this report demonstrated this interaction on himself. He took lithium carbonate 150 mg four times daily for a week (lithium level 0.5 mmol/L), and then added methyldopa 250 mg every 8 hours. Within 2 days, signs of lithium toxicity had clearly developed, and the following day his lithium level had increased to 0.8 mmol/L. He then stopped the methyldopa, and about 36 hours later his lithium level was 0.7 mmol/L.

There are 3 other cases of patients who took methyldopa with lithium, and developed symptoms of lithium toxicity. In one of these cases the patient had lithium levels within the normal therapeutic range, but in the other two the lithium levels increased to 1.5 and 1.87 mmol/L. A small study in 3 healthy subjects also found that the combination of lithium and methyldopa resulted in increased confusion, sedation and dysphoria.

Mechanism

Not understood. Both a central effect and an effect on renal excretion have been proposed.

Importance and management

Information appears to be limited to the reports cited, but the interaction would seem to be established. Avoid concurrent use whenever possible, but if this is not workable then the effects should be closely monitored. Serum-lithium measurements may be unreliable because symptoms of toxicity can occur even though the levels remain within the normally accepted therapeutic range.

Lithium + NSAIDs

NSAIDs may increase serum-lithium levels leading to toxicity, but there is great variability between different NSAIDs and also between individuals taking the same NSAID. For example, studies have found that celecoxib causes a modest 17% increase in lithium levels, yet case reports describe increases of up to 344%. Similar effects occur with other NSAIDs, and it seems likely that all NSAIDs will interact similarly. However, note that sulindac seems unique in that it is the only NSAID that has also been reported to cause a decrease in lithium levels.
Clinical evidence

A retrospective analysis of 10,615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any NSAID were compared between these 413 hospitalised patients and 1651 control patients. For any use of an NSAID (63 cases and 187 controls) there was no increased relative risk of hospitalisation for lithium toxicity (relative risk 1.1). Similarly, when patients who were newly started on an NSAID were analysed (4 cases and 17 controls), there was still no increased risk (relative risk 0.6). The authors considered that these findings suggest that the use of NSAIDs and lithium may not be as hazardous as previously thought, although they do suggest that another explanation could be that clinicians were aware of the potential interaction, and so adjusted doses or observed patients more closely in the outpatient setting, thereby avoiding any hospitalisations for toxicity.1

Case reports and studies about individual, named NSAIDs are outlined in the following subsections, and ‘Table 31.1’, (p.1127) summarises the effects of NSAIDs on lithium concentrations.

(a) Celecoxib

A 58-year-old woman, with a stable serum-lithium level of between 0.5 and 0.9 mmol/L, developed renal impairment associated with severe lithium toxicity, within 5 days of starting to take celecoxib 400 mg twice daily. Her lithium level was 4 mmol/L. Of note, and a possible contributory factor, was the presence of ibuprofen, which she had taken with her lithium for several years without incident.2

In addition to 3 of the cases in ‘Table 31.1’, (p.1127), a review of the FDA’s Adverse Event Reporting System database in January 2003 found 2 cases of increased lithium levels and symptoms of lithium toxicity in patients who also took celecoxib.3

(b) Ibuprofen

Three patients stabilised on lithium, with plasma levels of 0.7 to 0.9 mmol/L, were given ibuprofen 1.2 or 2.4 g daily for 7 days. The serum-lithium levels of one patient rose from 0.8 to 1 mmol/L and he experienced nausea and drowsiness. The 2 other patients, including the one on the 1.2-g ibuprofen dose, did not show this interaction.4

(c) Indometacin

A case report describes lithium toxicity in a man given indometacin 50 mg every 6 hours. Three days after he started the indometacin his serum creatinine was raised, and 9 days later he had symptoms of lithium toxicity and was found to have a lithium level of 3.5 mmol/L. It was suggested that the indometacin caused renal impairment, which led to lithium retention and toxicity.5

(d) Ketorolac

An 80-year-old man taking haloperidol, procyclidine, clonazepam, aspirin, digoxin and lithium (serum levels between 0.5 and 0.7 mmol/L) was additionally given indometacin 100 mg daily for arthritis, which was replaced, after 13 days, by ketorolac 30 mg daily. The next day his serum-lithium level was 0.9 mmol/L and 6 days later 1.1 mmol/L. Subsequently the patient developed severe nausea and vomiting, and both drugs were stopped.6

(e) Mefenamic acid

Acute lithium toxicity, accompanied by a sharp deterioration in renal function, was seen in a patient taking lithium carbonate with mefenamic acid 500 mg three times daily for 2 weeks. Withdrawal of the drugs and subsequent rechallenge confirmed this interaction.7 Another case of toxicity was seen in a patient on lithium given mefenamic acid. Her renal function was impaired when the lithium was started, but it had been stable for about 6 months before the NSAID was added.8 A brief report also mentions another case of this interaction.9

(f) Niflumic acid

An isolated report describes lithium toxicity in a woman who took niflumic acid (said to be three capsules daily) for 7 days with the addition of aspirin 1.5 g daily after 5 days. Her serum-lithium levels rose from 0.8 to 1.6 mmol/L.10

(g) Nimesulide

A 42-year old woman taking lithium was given nimesulide 100 mg and ciprofloxacin 250 mg, both twice daily, for flank pain and dysuria. After 72 hours, she developed symptoms of lithium toxicity and the dose of lithium was reduced. After 98 hours she had vomiting, ataxia, and oliguria, and lithium levels were found to be 3.23 mmol/L (previous level 1.08 mmol/L) and her serum creatinine was raised.11

(h) Oxyphenbutazone

In an apparently isolated case, a 49-year-old woman is reported to have developed nausea and vomiting associated with a rise in lithium levels following the addition of oxyphenbutazone suppositories 500 mg daily. She responded well to a reduction in the lithium dosage.12

(i) Parecoxib

The manufacturers of parecoxib say that valdecoxib, the main active metabolite of parecoxib, has been shown to cause decreases in the clearance of lithium (serum clearance reduced by 25%, renal clearance reduced by 30%), resulting in a 34% increase in its serum levels. Valdecoxib pharmacokinetics were unchanged by lithium.13

(j) Piroxicam

A 56-year-old woman, stabilised for over 9 years on lithium, with levels usually between 0.8 and 1 mmol/L, experienced lithium toxicity (unsteadiness, trembling, confusion) and was admitted to hospital on three occasions after taking piroxicam. Her serum levels on two occasions had risen to 2.7 and 1.6 mmol/L, although in the latter instance the lithium had been withdrawn the day before the levels were taken. In a subsequent study her serum-lithium levels rose from 1 to 1.5 mmol/L after she took piroxicam 20 mg daily.14 Two other case reports describe lithium toxicity, which occurred 4 weeks and 4 months after piroxicam was started.15,16

(k) Rofecoxib

A 73-year-old man, with lithium levels of between 0.6 and 0.9 mmol/L for the past 13 years, developed symptoms of lithium toxicity (serum-lithium level 1.5 mmol/L) within 9 days of starting to take rofecoxib 12.5 mg daily. An interaction was strongly suspected. However, it should be noted that the patient had required his lithium dose to be successively decreased over the 13 years to maintain his lithium levels within the desired range. Captopril 6.25 mg daily had also been started during this time,17 although it is unclear whether it had a part to play either in the lithium dose reduction or the development of an interaction.

In addition to 6 of the cases in ‘Table 31.1’, (p.1127), a review of the FDA’s Adverse Event Reporting System database in January 2003 found 7 cases of increased serum-lithium concentrations after the addition of rofecoxib.18

(l) Sulindac

1. Lithium levels reduced. A patient stabilised on lithium had a marked fall in serum-lithium levels from 0.65 to 0.39 mmol/L after 2 weeks of concurrent treatment with sulindac 100 mg twice daily. Her serum-lithium levels gradually climbed over the next 6 weeks to 0.71 mmol/L and restabilised without any change in the dosage of either lithium or sulindac. She needed amitriptyline for depression while the lithium levels were low, but bouts of depression had not been uncommon, even when lithium levels were stable.19 The serum-lithium levels of another patient were approximately halved a week after his dosage of sulindac was doubled to 200 mg twice daily. He remained on both drugs, but a higher dose of lithium was needed.20

2. Lithium levels unaffected. Two small studies (in a total of 10 patients)21,22 and a case report23 found that serum-lithium levels were unaffected by the use of sulindac.

3. Lithium levels increased. Two patients developed increased serum-lithium levels apparently due to the use of sulindac.24 In one case the lithium levels rose from 1 to 2 mmol/L after 19 days of treatment with sulindac 150 mg twice daily, and symptoms of toxicity were seen. The levels fell to 0.8 mmol/L within 5 days of stopping the sulindac. The other patient had a rise from 0.9 to 1.7 mmol/L within a week of adding sulindac 150 mg twice daily. The sulindac was continued and the lithium dosage was reduced from 1.8 to 1.5 g daily. The serum-lithium levels fell and were 1.2 mmol/L at 37 days and 1 mmol/L at 70 days. No symptoms of lithium toxicity occurred.25

(m) Tiaprofenic acid

A 79-year-old woman on lithium (as well as fosinopril, nifedipine, oxazepam and haloperidol) had a rise in her trough serum-lithium levels during a 10-year study period. The prescriptions for any NSAID were compared between these 413 hospitalised patients and 1651 control patients. For any use of an NSAID (63 cases and 187 controls) there was no increased relative risk of hospitalisation for lithium toxicity (relative risk 1.1). Similarly, when patients who were newly started on an NSAID were analysed (4 cases and 17 controls), there was still no increased risk (relative risk 0.6). The authors considered that these findings suggest that the use of NSAIDs and lithium may not be as hazardous as previously thought, although they do suggest that another explanation could be that clinicians were aware of the potential interaction, and so adjusted doses or observed patients more closely in the outpatient setting, thereby avoiding any hospitalisations for toxicity.1

Mechanism
Not understood. It has been suggested that the interacting NSAIDs inhibit the synthesis of the renal prostaglandins (PGE$_2$) so that the renal blood flow is reduced, thereby reducing the renal excretion of the lithium. In addition, reduced renal PGE$_2$ levels may be associated with increased reabsorption of sodium and lithium. However, this fails to explain why aspirin, which blocks renal prostaglandin synthesis by 65 to 70%, does not usually affect serum-lithium levels, see ‘Lithium + Aspirin or other Salicylates’, p.1119.

Importance and management
The interaction between NSAIDs and lithium is well established, although the incidence is unknown. The increase in serum-lithium levels appears to vary between the different NSAIDs and also between individuals taking the same NSAID (see ‘Table 31.1.’, p.1127). Factors such as advanced age, impaired renal function, decreased sodium intake, volume depletion, renal artery stenosis, and heart failure increase the risk.

The documentation of these interactions is variable and limited, and although only some NSAIDs have been shown to interact, it seems likely that they will all interact to a greater or lesser extent. What is known indicates that most NSAIDs should be avoided, especially if other risk factors are present, unless serum-lithium levels can be very well monitored (initially every few days) and the dosage reduced appropriately. The effects of sulindac appear to be unpredictable (serum levels raised, lowered or temporarily every few days) and the dosage reduced appropriately. The effects of ibuprofen appear to be unpredictable (serum levels lowered, lowered or unchanged) so that good monitoring is still necessary.

Patients on lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given a NSAID.

Lithium + Paracetamol (Acetaminophen)

Paracetamol appears not to alter lithium levels.

Clinical evidence, mechanism, importance and management
A study in 9 healthy subjects given lithium carbonate 300 mg every 12 hours to achieve steady state, followed by the addition of 650 mg of paracetamol every 6 hours for 5 days, found no evidence that paracetamol increased serum-lithium levels. Six subjects had no change in serum levels, one subject had a 0.1 mmol/L decrease, and two had a 0.1 mmol/L increase.1 One patient whose serum lithium level doubled while taking rofecoxib was later given paracetamol without any problems.2

No precautions seem necessary on concurrent use.

Lithium + Propranolol

One study suggests that propranolol may decrease the clearance of lithium, but the significance of this is unclear. An isolated report describes a patient taking lithium who developed marked bradycardia after he took propranolol 30 mg daily.

Clinical evidence, mechanism, importance and management
A study in lithium-treated manic-depressive patients found that the clearance of lithium was about 20% lower in 23 patients also taking propranolol than in 292 similar patients on lithium alone.1 However, the clinical effects of this difference were not evaluated, so the significance of this finding is unclear. A 70-year-old man who had been stable on lithium for 16 years was additionally started on propranolol 30 mg daily for lithium-induced tremor. Six weeks later he was hospitalised because of vomiting, dizziness, headache and a fainting episode. His pulse rate was 35 to 40 bpm and his serum-lithium level was 0.3 mmol/L. When later discharged on lithium without propranolol his pulse rate had risen to a range of 64 to 80 bpm.2

The authors attribute the bradycardia to an interaction with lithium as the low dose of propranolol was considered unlikely to cause bradycardia alone. They also point out that both drugs affect the movement of calcium across cell membranes, which could account for the decreased contraction rate of the heart muscle, and thus bradycardia in this patient. They suggest careful monitoring in elderly patients with atherosclerotic cardiovascular problems.

The general importance of this interaction, if it is such, is uncertain, but it seems possible with all beta blockers because they can all cause bradycardia. However, as beta blockers are used to treat lithium-induced tremor, any serious problem would be expected to have come to light by now.

Lithium + Sodium compounds

The ingestion of marked amounts of sodium can prevent the establishment or maintenance of adequate serum-lithium levels. Conversely, dietary salt restriction can cause serum-lithium levels to rise to toxic concentrations if the lithium dosage is not reduced appropriately.

Clinical evidence
(a) Lithium reduction caused by the ingestion of sodium
A 35-year-old man, started on lithium carbonate 250 mg four times a day, had a serum-lithium level of 0.5 mmol/L by the following morning. When the dosage frequency was progressively increased to five, and later six times a day, his serum-lithium levels did not exceed 0.6 mmol/L because, unknown to his doctor, he was also taking sodium bicarbonate.
The patient’s wife said he had been taking “Soda Bic” for years but since he started on lithium he had been “shovelling it in.” When the sodium bicarbonate was stopped, relatively stable serum-lithium levels of 0.8 mmol/L were achieved on the initial dosage of lithium carbonate. An investigation to find out why a number of inpatients failed either to reach or maintain adequate therapeutic serum-lithium levels over a period of 2 months, revealed that a clinic nurse had been giving the patients Efferdex, a product containing about 50% sodium bicarbonate, because the patients complained of nausea. The reduction in the expected serum-lithium levels was as much as 40% in some cases. Other studies confirm that the serum-lithium levels can fall, and the effectiveness of treatment can lessen, if the intake of sodium is increased.

Lithium response increased by sodium restriction

The serum-lithium levels of 4 patients rose more rapidly and achieved a higher peak when salt was restricted to less than 10 mmol of sodium per day compared with the situation when the patients took a dietary salt supplement.

Mechanism

The situation is complex and not fully established, but the mechanism can be broadly described in simplistic terms. Sodium balance is controlled by the kidney; if the serum sodium is low the kidney can reabsorb more sodium to maintain the balance. The kidney excretes and reabsorbs both lithium and sodium, but it does not appear to clearly distinguish between lithium and sodium ions. Therefore, if a patient taking lithium restricts sodium intake, the kidney may reabsorb both sodium and lithium, causing a rise in serum-lithium levels. A corresponding decrease in lithium levels can occur when sodium intake is supplemented.

Importance and management

Well established and clinically important interactions. The establishment and maintenance of therapeutic serum-lithium levels can be jeopardised if the intake of sodium is altered. Warn patients not to take non-prescription antacids or urinary alkalinisers without first seeking informed advice. Sodium balance is controlled by the kidney; if the serum sodium is low the kidney can reabsorb more sodium to maintain the balance. The kidney excretes and reabsorbs both lithium and sodium, but it does not appear to clearly distinguish between lithium and sodium ions. Therefore, if a patient taking lithium restricts sodium intake, the kidney may reabsorb both sodium and lithium, causing a rise in serum-lithium levels. A corresponding decrease in lithium levels can occur when sodium intake is supplemented.

Lithium + Theophylline

Serum-lithium levels are moderately reduced by 20 to 30% by the concurrent use of theophylline, which may cause patients to relapse.

Clinical evidence

The serum-lithium levels of 10 healthy subjects taking lithium carbonate 900 mg daily fell by 20 to 30%, and the urinary clearance increased by 30%, when they were given theophylline (Theo-dur). Steady-state theophylline levels of 5.4 to 12.7 micrograms/mL were achieved, and it was noted that higher theophylline levels were strongly correlated with increased lithium clearance. This study has been reported in brief elsewhere.

A man taking theophylline was diagnosed with a bipolar disorder and started on lithium while in hospital for an exacerbation of COPD. When the dose of theophylline was raised, because of a worsening in his condition, his lithium dose also had to be increased to control the emergence of manic symptoms. He received a maximum theophylline dose of 1.5 g daily, during which time he needed 2.7 g of lithium daily. When the theophylline was stopped, he only needed around 1.5 g of lithium daily to control his manic symptoms. Two studies support the evidence from these cases with the finding that lithium excretion is increased by about 50% by amnophylline or theophylline.

Mechanism

Uncertain. Theophylline has an effect on the renal clearance of lithium.

Importance and management

Information is very limited but the interaction appears to be established. Depressive and manic relapses may occur if the dosage of lithium is not raised appropriately when theophylline is given. Serum-lithium levels should be monitored if theophylline or aminophylline is stopped, started, or if the dosage is altered.

Other xanthines e.g. caffeine appear to have a similar effect, see ‘Lithium + Caffeine’, p.1120.

Lithium + Triptans

In two cases patients on lithium developed symptoms suggestive of the serotonin syndrome after taking sumatriptan.

Clinical evidence, mechanism, importance and management

A comprehensive literature search published in 1998 identified several cases of adverse events reported with sumatriptan and lithium, although in most cases other medications were also being taken. Two patients taking sumatriptan and lithium concurrently were identified with symptoms suggestive of the serotonin syndrome, but these were mild to moderate and self-limiting. The number of patients taking lithium and sumatriptan was not stated, so the incidence is unknown. The conclusion was reached that sumatriptan can be used cautiously in patients receiving lithium. The manufacturers of sumatriptan and other triptans (e.g. almotriptan) do not appear to have studied the effects of these drugs on lithium and there seem to be no other reports of problems with lithium and triptans. More study is needed.

The intended target of the MAOIs (monoamine oxidase inhibitors) is MAO within the brain, but MAO is also found in other parts of the body. Particularly high concentrations occur in the gut and liver, where it acts as a protective detoxifying enzyme against tyramine and possibly other potentially hazardous amines, which exist in foods that have undergone bacterial degradation. There are at least two forms of MAO: MAO-A metabolises (deaminates) noradrenaline (norepinephrine) and serotonin (5-HT), while MAO-B metabolises phenylethylamine. Substances like tyramine and dopamine are metabolised by both forms of MAO.

The older MAOIs (see ‘Table 32.1’, (below)) are non-selective or non-specific, and inhibit both isoenzymes A and B. They are irreversible and long-acting, because the return of MAO activity depends upon the regeneration of new enzymes. As a result their effects (both beneficial and adverse) can last for 2 to 3 weeks after they have been withdrawn. Tranylcypromine differs in being a more reversible inhibitor of MAO, so the onset and disappearance of its actions are quicker than the other non-selective MAOIs. However, its effects still last for a number of weeks after withdrawal (e.g. see ‘MAOIs or RIMAs + Tyramine-rich foods’, (p.1153)), so it is still effectively an irreversible inhibitor, and is usually classified as such. These non-selective MAOIs cause serious and potentially life-threatening hypertensive interactions with the sympathomimetics found in some proprietary ‘cough and cold remedies’, (p.1147), and with ‘tyramine-rich foods’, (p.1153), and ‘drinks’, (p.1151).

Some of the newer and more recently developed drugs with MAO inhibitory activity (see ‘Table 32.1’, (below)) interact to a lesser extent than the older MAOIs. This is because they are largely selective. One group of these selective inhibitors targets MAO-A, and are relatively rapidly reversible; inhibition of this enzyme is responsible for the antidepressant effect. These selective MAO-A inhibitors (moclobemide, toloxatone) have been given the acronym RIMAs (Reversible Inhibitors of Monoamine oxidase A). They leave MAO-B largely uninhibited so that there is still a metabolic pathway available for the breakdown of amines, such as tyramine, that can cause a rise in blood pressure. In practical terms this means that the amount of tyramine needed to cause a hypertensive crisis is about tenfold greater than with the non-selective MAOIs (see ‘tyramine-rich foods’, (p.1153)).

The other newer selective MAOIs that specifically inhibit MAO-B are ineffective for the treatment of depression and are mainly used for Parkinson’s disease, and so are covered elsewhere, see ‘Antiparkinsonian and related drugs’, (p.672). In low doses they inhibit MAO-B, leaving MAO-A largely uninhibited. However, selegiline loses some of its selectivity at doses of more than 10 mg daily and will therefore be subject to the same interactions as the non-selective MAOIs. Rasagiline is another irreversible selective inhibitor of MAO-B used for Parkinson’s disease.

Some other drugs covered elsewhere also have MAOI activity. Furazolidone is an antiprotozoal with MAOI activity. Linezolid is an oxazolidinone antibacterial with reversible nonsselective MAOI activity. Interactions typical of MAOI inhibitors might therefore occur with furazolidone and linezolid.

If you look at the product information issued by manufacturers, you will frequently see warnings about real and alleged interactions with MAOIs. Blackwell,\(^1\) who has done much work on the interactions of the MAOIs, has rightly pointed out that the MAOIs have developed such a sinister reputation that manufacturers often issue a reflexive admonition to avoid co-administration with new drugs. This means that many of the warnings about potential interactions with the MAOIs may lack a sound scientific basis. However, equally this does not mean that the proven serious life-threatening interactions that are associated with the MAOIs should be dismissed, and it should be noted that any drug with indirectly-acting sympathomimetic activity is likely to interact.

*MAO-B inhibitors are used in Parkinson’s disease, so are covered elsewhere.
MAOIs + Antihistamines

The alleged interaction between the MAOIs and antihistamines appears to be based on a single animal study, and is probably more theoretical than real. The exception seems to be cyproheptadine, which can reduce the effect of MAOIs because of its serotonin antagonist effect, see ‘MAOIs or RIMAs + Antihistamines; Cyproheptadine’, below.

Clinical evidence, mechanism, importance and management

A number of lists, charts and books about adverse interactions suggest that potentially serious interactions can occur between the MAOIs and the antihistamines. This appears to be based on a study in rabbits from 1972, which showed that some antihistamines (notably alkyamine antihistamines such as chlorphenamine, brompheniramine, and also diphenhydramine) produced a fatal hypotension, thought to be due to serotonin potentiation, when given intravenously to phentolamine pretreated rabbits. This reaction was considered to be similar to that seen with ‘pethidine’, (p.1140), or the ‘tricyclics’, (p.1149). However, in over 20 years since the publication of this data, the manufacturers of various antihistamines did not identify any clinical reports of adverse interactions attributed to the use of any antihistamine with an MAOI.”

MAOIs or RIMAs + Antihistamines; Cyproheptadine

Isolated reports describe delayed hallucinations in a patient on phenelzine and cyproheptadine, and the rapid re-emergence of depression in two other patients on brofaromine or phenelzine when given cyproheptadine.

Clinical evidence

A woman who had responded well to brofaromine rapidly became depressed again when she took cyproheptadine. She had to be hospitalised due to suicidal ideation, but eventually she responded to treatment and she then took brofaromine and cyproheptadine for 6 months. A man whose depression responded well to phenelzine 75 mg daily was given cyproheptadine 4 mg to treat associated sexual dysfunction and anorgasmia. Within 3 days of adding the cyproheptadine his depression returned, but the anorgasmia did not improve. When the cyproheptadine was stopped his depression was relieved. Hallucinations developed in a woman taking phenelzine 2 months after cyproheptadine was started.

Mechanism

Cyproheptadine is a serotonin antagonist. The reversal of the effects of the brofaromine was therefore attributed by the authors of one report to the blockade of 5-HT (serotonin) receptors by cyproheptadine (brofaromine has both MAO-A inhibitory and 5-HT uptake inhibitory properties).

Cyproheptadine has also been observed to block the activity of serotonin reuptake inhibitors (see ‘SSRIs + Cyproheptadine’, p.1216).

Importance and management

Information seems to be limited to these reports but it would now be prudent to be alert for a reduction in efficacy or an adverse response if cyproheptadine is given with any MAOI or RIMA. The manufacturer of cyproheptadine actually contraindicates concurrent used with MAOIs. However, there appears to be no reason why cyproheptadine cannot be used to treat the serotonin syndrome occurring in a patient on an MAOI. As with other sedative antihistamines (see ‘MAOIs + Antihistamines’, above), the UK manufacturers of cyproheptadine also say that MAOIs prolong and intensify the antimuscarinic effects of antihistamines, but there seems to be no clinical data to support this.

1. Katz RJ, Rosenthal M. Adverse interaction of cyproheptadine with serotoninergic antidepres-

No adverse interactions between the MAOIs and antimuscarinics have been reported, although the possibility has been suggested.

Clinical evidence, mechanism, importance and management

A hyperthermic reaction has been reported in some animals given translycypromine or nialamide with procyclidine or benzatropine. It considered that this might be due to an exaggerated dopamine response. However, there do not appear to be any reports of such an interaction occurring clinically. Nevertheless, some manufacturers of irreversible non-selective MAOIs and antimuscarinics issue cautions about the possibility of increased effects of antimuscarinics when given with MAOIs. This is presumably because, in theory, inhibition of drug-metabolising enzymes by MAOIs may possibly enhance the effects of antimuscarinics.

Although the MAOIs can enhance and prolong the activity of barbiturates in animals, only a few isolated cases of adverse responses attributed to an interaction have been described.

Clinical evidence

One reviewer briefly mentions that on three or four occasions patients taking an MAOI continued, without the prescriber’s knowledge, to take their usual barbiturate hypnotic and thereby “...unknowingly raised their dose of barbiturate by five to ten times, and as a consequence normally managed to stagger through the day.” No details are given, so it is not known whether the serum barbiturate levels of these patients were measured, or whether the raised levels are only a surmise. A patient taking translycypromine 10 mg three times daily was inadvertently given intramuscular amobarbital sodium 250 mg for sedation. Within an hour she became ataxic, and fell to the floor, repeatedly hitting her head. After complaining of nausea and dizziness the patient became semicomatose and remained in that state for a further 36 hours. To what extent the head trauma played a part is uncertain. A man taking amobarbital sodium 195 mg at night suffered severe headache, and became confused after also taking phenelzine 15 mg three times daily for 4 weeks. On admission to hospital he was comatose, and he had a temperature of 40°C, blood pressure of 150/90 mmHg, tachycardia, stertorous respiration, fixed dilated pupils, exaggerated tendon reflexes and extensor plantar responses. His condition deteriorated and he died 2 hours after admission. Pathology suggested a rise in intracranial pressure was responsible. The authors attribute this response to the drugs, but do not rule out a possible contribution of alcohol.

Mechanism

Not known. Animal studies show that MAOIs prolong the activity of barbiturates, and that this is possibly because they inhibit the metabolism of barbiturates by a mechanism independent of MAO inhibition. Whether this occurs in man as well is uncertain.

Importance and management

The evidence for these interactions seem to be confined to a few unconfirmed anecdotal reports. There is no well-documented evidence showing that concurrent use should be avoided, although some caution is clearly appropriate. For mention of successful anaesthesia including the use of thiopental in patients on MAOIs, see ‘Anaesthetics, general + MAOIs’, p.100.

Isolated cases of adverse reactions (chorea, severe headache, fasciculation, massive oedema, and prolonged coma) attributed to interactions between phenelzine and chlor Diazoxide, clonazepam or nitrazepam, and between isocarboxazid and chlor Diazoxide have been described. Evidence from clinical trials suggests that there is no interaction between moclobemide and benzodiazepines, although one study found a slight progressive worsening in driving performance.

Clinical evidence and mechanism

(a) MAOIs (non-selective, irreversible)

A patient who had been taking phenelzine 45 mg daily for 9 years developed a severe occipital headache after taking 500 micrograms of clonazepam. A similar but milder headache occurred the next night when she took the same dose. No blood pressure measurements were taken. Another report describes facial flushing in a patient taking clonazepam, which occurred after phenelzine was started, and which responded to a reduction in the clonazepam dose.

A patient with depression responded well when given phenelzine 15 mg and chlor Diazoxide 10 mg three times a day, but 4 to 5 months later developed choreiform movements of moderate severity, and slight dysarthria. These symptoms subsided when both drugs were withdrawn.

Two patients taking chlor Diazoxide and either phenelzine or isocarboxazid developed severe oedema, which was attributed to the use of the combination.

A patient became unconscious and hyperreflexic, with a low blood pressure (100/60 mmHg), increased heart rate (100 bpm), and increased temperature (38.4°C) about 29 hours after taking an overdose of phenelzine and chlor Diazoxide. Another report briefly mentions a case of prolonged coma lasting 3 days in a patient who overdosed with phenelzine and chlor Diazoxide.

A patient taking phenelzine 30 mg twice daily was started on nitrazepam 5 mg at night and the dose was gradually increased to 15 mg at night over 2 months. He developed MAOI toxicity (excessive sweating, postural hypotension) within 10 days of increasing his dose of nitrazepam to 15 mg daily. Both drugs were stopped and he recovered after 3 days. The phenelzine was restarted 2 weeks later without problems. It was suggested that since the patient was a slow acetylator, metabolism of nitrazepam by N-acetyl transferase would have been decreased, which may have affected the metabolism of phenelzine, thereby increasing its levels.

(b) RIMAs

A meta-analysis of 879 patients taking moclobemide is reported to have found that insomnia, restlessness, agitation and anxiety occurred twice as often in the 467 patients taking one or more benzodiazepines than in those not taking concurrent benzodiazepines. However, these adverse events were often already present when moclobemide was started, so it is suggested that the patient groups were probably different. Apart from this difference between the patient groups, there was no evidence of any relevant pharmacokinetic or pharmacodynamic interaction. Another review briefly reported that no clinically relevant interaction was noted between moclobemide and benzodiazepines in clinical studies.

Driving performance gradually worsened over 6 weeks in a double-blind study in depressed patients given moclobemide (22 subjects) or fluoxetine (19 subjects). Thirty-one patients were taking long-term benzodiazepines, and at the start of the study their driving was no different to the patients not taking benzodiazepines. In an attempt to suggest a possible reason for the worsening performance, various variables were assessed in a regression analysis. It was found that patients taking moclobemide who were also taking a benzodiazepine with nordiazepam among its metabolites (clorazepate, prazepam, diazepam, clorazolam, clotiazepam) ex-
perceived a progressive worsening in their driving, whereas patients on other benzodiazepines (bromazepam, alprazolam, oxazepam, lorazepam) tended to have no change in driving ability. It was tentatively suggested that moclobemide may have inhibited the metabolism of nordiazepam by the cytochrome P450 isozyme CYP2C19, so increasing the effect of the benzodiazepine, and worsening driving performance.11

Importance and management

The case reports of adverse interactions cited here appear to be isolated, and it is by no means certain that all the responses were in fact due to drug interactions. However, bear them in mind in the event of unexpected responses to treatment. No special precautions would normally be required during concurrent use, although a reminder that benzodiazepines may affect the performance of skilled tasks, such as driving, may be appropriate when a patient’s medication is changed. Note that the manufacturer of moclobemide says that if depressed patients with excitation or agitation are first treated with moclobemide, a sedative such as a benzodiazepine should also be given for up to 2 to 3 weeks.12 Further study is required to find out if there are any clinically important pharmacokinetic interactions between moclobemide and any of the benzodiazepines.

MAOIs or RIMAs + Buspirone

Elevated blood pressure has been reported in four patients taking buspirone and either phenelzine or tranylcypromine. Buspirone may have contributed to a case of the serotonin syndrome in a patient who overdosed on moclobemide and clomipramine.

Clinical evidence, mechanism, importance and management

(a) MAOIs

Four cases of significant blood pressure elevation, which occurred during the use of buspirone and either phenelzine or tranylcypromine, have been reported to the FDA’s Spontaneous Reporting System. One patient was a 75-year-old woman and the other 3 patients were men aged between 30 and 42 years. The report does not say how much the blood pressure rose, or how quickly, and no other details are given.1 On the basis of this rather sparse information the manufacturers of buspirone2,3 recommend that it should not be used concurrently with an MAOI.

(b) RIMAs

A severe case4 of the serotonin syndrome (including hyperthermia and muscle rigidity requiring mechanical ventilation) has been reported in a patient who took an overdose of moclobemide, clomipramine and buspirone,5 (p.1149). Concurrent use of more than one serotoninergic drug is thought to be a risk factor for the development of ‘the serotonin syndrome’, (p.9).

MAOIs + Caffeine or Choline theophyllinate

Isolated reports suggest that the CNS stimulant effects of caffeine may possibly be increased by the MAOIs. Another isolated report describes the development of tachycardia and apprehension in a patient taking phenelzine after she also took a cough syrup, containing choline theophyllinate.

Clinical evidence

(a) Caffeine

One reviewer briefly mentions that a patient who normally drank 10 or 12 cups of coffee daily, without adverse effects, experienced extreme jitteriness during treatment with an MAOI, which subsided when the coffee consumption was reduced to 2 or 3 cups a day. The same reaction was also said to have occurred in other patients taking MAOIs who drank tea or some of the ‘Cola drinks’ which contain caffeine.1 This reviewer also mentions another patient taking an MAOI who claimed that a single cup of coffee taken in the morning kept him jittery all day and up the entire night as well, a reaction that occurred on three separate occasions.1 In another report, a woman taking phenelzine experienced a severe headache with a slight blood pressure rise on two occasions after drinking cola containing 55 to 55 mg of caffeine.2 Similarly, a brief mention is made of 2 patients taking phenelzine who experienced extreme restlessness, agitation, tremor, and insomnia after starting to drink large quantities of diet cola.3 This was attributed to an interaction between phenelzine and aspartame,4 but could equally well be attributed to an interaction with caffeine, or indeed a reaction to caffeine alone. Caffeine and theophylline may have contributed to the serious reaction that occurred in a woman the day after discontinuing phenelzine, who took a Do-Do tablet (containing ephedrine, caffeine, theophylline),5 see also ‘MAOIs or RIMAs + Symptom-mimetics; Indirectly-acting’ , p.1147.

(b) Choline theophyllinate

A woman with agoraphobia, being treated with phenelzine 45 mg daily, developed tachycardia, palpitations and apprehension lasting for about 4 hours after she had taken a cough syrup containing choline theophyllinate and guaifenesin. The symptoms recurred when she was again given the cough syrup, and yet again when given choline theophyllinate alone, but not when given guaifenesin alone.6

Mechanism

Unknown. Caffeine alone can cause headache, tachycardia, and jitteriness, and individuals vary in their susceptibility to these effects. The effects of caffeine, theophylline, and theobromine in rats were enhanced by MAOIs.8

Importance and management

Apart from these few reports, the literature appears to be otherwise silent about an interaction between the MAOIs and xanthines. Whether this reflects their mildness and unimportance, or their rarity, is not clear. There would seem to be no need for any special precautions in patients taking MAOIs who are given xanthine bronchodilators or consuming caffeine-containing beverages or pharmaceuticals, but bear these adverse reports in mind in the event of any unexpected response. Nevertheless, some manufacturers of MAOIs recommend the avoidance of excessive amounts of tea and coffee, or caffeine in any form.8–10

MAOIs + Cloral hydrate

A case of fatal hyperpyrexia and another case of serious hypertension have been linked to interactions between cloral hydrate and phenelzine, but in both cases there are other plausible explanations for the reactions seen.

Clinical evidence, mechanism, importance and management

A woman taking phenelzine 15 mg three times daily was found in bed deeply comatose with marked muscular rigidity, twitching down one side and a temperature of 41°C. She died without regaining consciousness. A postmortem failed to establish the cause of death, but it subsequently came to light that she had started drinking whisky, and she had access to cloral hydrate of which she may have taken a fatal dose.1 Another patient, also taking phenelzine 15 mg three times daily and cloral hydrate to aid sleep, developed an excruciating headache followed by nausea, photophobia and a substantial rise in blood pressure.2 This latter reaction is similar to the ‘cheese reaction’, see ‘tyramine-rich foods’, (p.1153), but at the time the authors of the report were unaware of this type of reaction so that they failed to find out if any tyramine-rich foods had been eaten on the day of the attack.2

There is no clear evidence that either of these adverse reactions was due to an interaction between phenelzine and cloral hydrate, and there do not seem to be any other reports to suggest that an interaction between these drugs is likely.

MAOIs + Cocaine

Some reports suggest that patients on MAOIs may experience a severe headache if they abuse cocaine. Two isolated reports describe the delayed development of hyperpyrexia, and other symptoms including coma, agitation, muscle tremors and rigidity after patients taking phenelzine or iproniazid were given a cocaine spray during surgery.

Clinical evidence, mechanism, importance and management

The use of cocaine is generally contraindicated in patients taking MAOIs because it is expected to interact like ‘indirectly-acting sympathomimetics’. (p.1147). This is supported by a report of hypertensive reactions in 2 patients taking phenelzine who became drunk and used cocaine. Both experienced frightening reactions including headache, a rise in blood pressure, palpitations, and chest tightness. One required no treatment, and the other was treated with propranolol and diazepam.3 Because this reaction was not considered as dangerous as expected, phenelzine has been tried as a deterrent to the abuse of cocaine: one uncontrolled study reports its use in 26 patients without mentioning any adverse reactions.4 Another report mentions one man given phenelzine for cocaine abuse who experienced no reaction to the use of cocaine. He was then given tranylcypromine, and after 10 weeks risked sniffing cocaine, which did produce a severe occipital headache and nausea. However, after abstaining for another 10 weeks he again used cocaine, this time without any reaction.5

A man taking phenelzine 15 mg twice daily underwent vocal chord surgery. He was anaesthetised with thiopental, and later nitrous oxide and isoflurane 0.5% in oxygen. Muscle paralysis was produced with suxamethonium and gallamine. During the operation his vocal chords were sprayed with 1 mL of a 10% cocaine spray. He regained consciousness 30 minutes after the surgery and was returned to the ward, but a further 30 minutes later he was found unconscious, with generalised coarse tremors and marked muscle rigidity. His rectal temperature was 41.5°C. He was initially thought to have malignant hyperpyrexia and was treated accordingly with wet blankets, as well as with intravenous fluids and oxygen, and he largely recovered within 7 hours. However, later it seemed more likely that the reaction had been due to an adverse interaction between the phenelzine and cocaine, because he had been similarly and uneventfully treated with cocaine in the absence of phenelzine on two previous occasions.6 A similar case was described in a woman taking iproniazid who had her trachea sprayed with 1 mL of 10% cocaine before intubation during surgery. She was also given pethidine 20 mg, and shortly after surgery became pyrexial, flushed, agitated and sweated profusely. She was treated with intravenous chlorpromazine.7 In this case, the reaction could have been due to the pethidine alone (see MAOIs or RIMAs + Opoids; Pethidine (Meperidine), p.1140), or both the cocaine and the pethidine. The reasons for these adverse reactions are not understood, but a delayed excitatory reaction due to increased 5-HT (serotonin) concentrations has been suggested.8 The general importance of these cases is not known, but bear them in mind if cocaine is used in a patient on an MAOI.

MAOIs or RIMAs + Dextromethorphan

Two fatal cases of hyperpyrexia and coma (symptoms similar to the serotonin syndrome) have occurred in patients taking phenelzine with dextromethorphan (in overdose in one case). Three other serious but non-fatal reactions occurred in patients taking dextromethorphan with isocarboxazid or phenelzine. MAOIs should not be used with dextromethorphan. Moclobemide inhibits the metabolism of dextromethorphan, and isolated cases of severe CNS reactions have occurred with the combination, which is also contraindicated.

Clinical evidence

(a) MAOIs

A woman taking phenelzine 15 mg four times daily complained of nausea and dizziness before collapsing, 30 minutes after drinking about 55 mL of a cough mixture containing dextromethorphan. She remained hyperpyrexial (42°C), hypotensive (systolic blood pressure below 70 mmHg) and unconscious for 4 hours, before dying after a cardiac arrest.1

A 15-year-old girl taking phenelzine 15 mg three times daily (as well as thoridazine, procyclidine and metronidazole) took 13 capsules of Romilar CF (containing dextromethorphan hydrobromide 15 mg, phenidamine tartrate 6.25 mg, phenylephrine hydrochloride 5 mg and paracetamol (acetaminophen) 120 mg in each capsule). She became comatose, hyperpyrexial (103°F), had a blood pressure of 100/60 mmHg, a pulse of 160 bpm and later died of a cardiac arrest.2 This case is complicated by the overdose and multiplicity of drugs present, particularly the phenylephrine. See ‘MAOIs or RIMAs + Sympathomimetics; Phenylephrine’, p.1148.

A 28-year-old woman developed severe myoclonus and rigidity, and became largely unresponsive after taking phenelzine and Robitussin DM (dextromethorphan hydrobromide 15 mg with guaifenesin 100 mg).3 Yet another patient taking phenelzine developed muscular rigidity, uncontrollable shaking, generalised hyperreflexia and sweating when given Robitussin DM. Within 2 hours he had responded to 10 mg of intravenous diazepam and oral activated charcoal.4

The US manufacturer of tranylcypromine notes that the concurrent use of MAOIs and dextromethorphan has resulted in brief episodes of psychosis or bizarre behaviour.5 Similarly, the US manufacturer of phenelzine mentions one case of drowsiness and bizarre behaviour when dextromethorphan lozenges were used by a patient taking phenelzine. They also note that concurrent use of dextromethorphan may cause a reaction similar to
that seen with pethidine (meperidine), as described in some of the cases above.

(b) RIMAs

Moclobemide 300 mg twice daily for 9 days markedly reduced the O-demethylation of dextromethorphan (seven 20-mg doses given every 4 hours over 2 days), in 4 healthy subjects. The manufacturer notes that isolated cases of severe CNS adverse reactions have been seen with the combination. Concurrent use of dextromethorphan may have contributed to a fatal reaction involving the illicit use of moclobemide and ‘ecstasy’, (p.1144).

Mechanism

(a) The authors of three of the reports3-5 suggest that these effects may have been due to an increase in serotonin activity in the CNS ‘the serotonin syndrome’, (p.9). Symptoms similar to the serotonin syndrome (hyperpyrexia, dilated pupils, hyperexcitability and motor restlessness) have been seen in rabbits treated with dextromethorphan and nialamide, phenelzine or pargyline, and also with MAOIs and ‘pethidine’, (p.1140).

(b) Moclobemide appears to inhibit the metabolism of dextromethorphan by the cytochrome P450 isoenzyme CYP2D6, and the combination may also cause adverse CNS effects.

Importance and management

Despite the very limited information available, the severity of the reactions indicates that patients taking MAOIs should avoid taking dextromethorphan. The manufacturer of moclobemide also contraindicates the concurrent use of dextromethorphan. Patients should be warned that many cough preparations contain dextromethorphan.

MAOIs + D Congressional

An isolated report describes delirium in a man taking lithium and disulfiram when the moclobemide he was also taking was replaced by tranylcypromine.

Clinical evidence, mechanism, importance and management

A man with disulfiram implants taking long-term lithium had his MAO changed from moclobemide [dosage not stated] to tranylcypromine 10 mg twice daily. Within 2 days he became acutely delirious (agitated, disoriented, incoherent, visual hallucinations) and later comatose, with nystagmus and a downward gaze. He was successfully treated with haloperidol and promethazine, and recovered within 24 hours. No alcohol was detected in his blood, and serum tranylcypromine levels were below 50 micrograms/L, which was considered normal.

The authors of this report attribute the reaction to an interaction between tranylcypromine and disulfiram. However, there would seem to be other possible explanations for this reaction. MAOIs have rarely been seen to interact adversely with lithium, (p.1136), and there also seems potential for an interaction between the two ‘MAOIs’, (p.1137).

This seems to be the only report of an adverse reaction between disulfiram and an MAO, so it is possible that this is just an idiosyncratic reaction. However, warnings about this drug combination, based on theoretical considerations and studies in animals, have previously been given, and tranylcypromine was considered to be the MAOI that presented the greatest risk. Consequently, the US manufacturers of tranylcypromine and isocarboxazid recommend caution with the concurrent use of disulfiram. It seems that this particular patient had no problems while taking moclobemide, which is a RIMA.

2. Ciraulo DA. Can disulfiram (Antabuse) be safely co-administered with the monoamine oxidase inhibitor (MAOI) antidepressants? J Clin Psychopharmacol (1989) 9, 315–16.

MAOIs + Dopa-rich foods

A few reports describe a rapid, serious and potentially life-threatening hypertensive reaction in patients taking MAOIs if they eat young broad bean pods, which contain dopa. No serious hypertensive reaction is likely to occur with moclobemide.

Clinical evidence

A 65-year-old hypertensive man taking pargyline had a severe headache after eating “whole, cooked, broad beans” (young broad bean pods). A controlled study in this man found that he had a rise in systolic blood pressure from 165 to 262 mmHg about 20 minutes after eating whole broad bean pods. The pods alone had the same effect, but the beans on their own had little effect. This rise in blood pressure was also seen in two other patients on pargyline, and was reversed by intravenous phentolamine. Two normotensive subjects taking pargyline 50 mg daily also had an increase in blood pressure (over 70 mmHg systolic in one subject) following the ingestion of bean pods. Another case report describes a man taking phenelzine 15 mg three times daily who had a very severe headache after eating a meal including fresh, young, sliced, broad bean pods from his garden. One other case has been briefly mentioned, although it was not known whether the broad beans were eaten with or without the pods.

Mechanism

Broad bean (Vicia faba) pods contain dopa, which is enzymatically converted in the body, firstly to dopamine and then to noradrenaline, both of which are normally broken down by monoamine oxidase. In the presence of an MAOI this breakdown is suppressed, which means that the total levels of dopamine and noradrenaline are increased. Precisely how this then leads to a sharp rise in blood pressure is not clear, but either dopamine or noradrenaline, or both, directly or indirectly stimulate the alpha-receptors of the cardiovascular system.

Importance and management

Although there are only a few cases of the interaction between the non-selective MAOIs (listed in ‘Table 32.1’, (p.1130)) and broad bean pods, the interaction would appear to be established and is serious and potentially life-threatening. Patients should not eat young broad bean pods during treatment with any of these MAOIs, nor for a period of 2 to 3 weeks after their withdrawal. It should be noted that this prohibition does not apply to ‘mature’ broad beans (the seeds) removed from their pods, which is the more common way of eating broad beans.

MAOIs + Dopa

No adverse interactions have been reported between the MAOIs and doxapram, although animal studies suggest that an increased pressor effect is theoretically possible.

Clinical evidence, mechanism, importance and management

The manufacturers note that animal studies have shown that the actions of doxapram may be potentiated by pretreatment with an MAOI, and that
the pressor effects of MAOIs and doxapram may be additive. Based on this, they advise that concurrent use should be undertaken with great care.

To date, there appear to be no clinical reports of this interaction.

MAOIs + Erythromycin

An isolated case report describes severe hypotension and fainting in a woman taking phenelzine, which occurred shortly after she started a course of erythromycin.

Clinical evidence, mechanism, importance and management

A woman taking phenelzine 15 mg daily experienced three syncopal episodes 4 days after starting to take erythromycin 250 mg four times daily for pneumonia. When admitted to hospital her supine systolic blood pressure was only 70 mmHg. When she sat up, it was unrecordable. Although she was not dehydrated, she was given 4 litres of sodium chloride 0.9%, without any effect on her blood pressure. Within 24 hours of stopping the phenelzine her blood pressure had returned to normal. The reasons for this severe hypotensive reaction are not known, but it was suggested that the erythromycin may have caused rapid gastric emptying, which resulted in a very rapid absorption of the phenelzine (described by the author as rapid dumping into the blood stream), which resulted in the adverse effect of hypotension. This seems to be the first and only report of this interaction, and so its general importance is uncertain.

MAOIs + Ginseng

Isolated reports describe two patients taking phenelzine who developed adverse effects (including headache and insomnia) after taking ginseng.

Clinical evidence, mechanism, importance and management

A 64-year-old woman taking phenelzine developed headache, insomnia, and tremulousness on two occasions after taking ginseng. Three years later, she experienced the same symptoms and an increase in depression 72 hours after starting to take ginseng capsules. Another depressed woman taking ginseng and bee pollen experienced a relief of her depression and became active and extremely optimistic when she was started on the ginseng and the MAOI were somehow additive. Ginseng has stimulant effects, but its adverse effects include insomnia, nervousness, hypertension and euphoria. These two cases once again illustrate that herbal medicines are not necessarily problem-free if combined with orthodox drugs.

MAOIs or RIMAs + Levodopa

A rapid, serious and potentially life-threatening hypertensive reaction can occur in patients taking MAOIs if they are also given levodopa. An interaction with levodopa given with carbidopa or benserazide is unlikely. No serious hypertensive reaction has been reported to occur with moclobemide. See also ‘MAOIs + Doparich foods’. p.1135.

Clinical evidence

(a) MAOIs

A patient who had been taking phenelzine daily for 10 days was given 50 mg of oral levodopa. In just over an hour his blood pressure had risen from 135/90 mmHg to about 190/130 mmHg, and despite a 5 mg intravenous injection of phentolamine it continued to rise over the next 10 minutes to 200/135 mmHg, before falling after a further 4 mg injection of phentolamine. The following day the experiment was repeated with levodopa 25 mg, but no blood pressure changes were seen. Three weeks after withdrawal of the phenelzine even 500 mg of levodopa had no hypertensive effect.

Similar cases of severe, acute hypertension, accompanied in most instances by flushing, throbbing and pounding in the head, neck and chest, and light-headedness have been described in other case reports and studies involving the concurrent use of levodopa with pargyline, nialamide, tranylcypromine, phenelzine and isocarboxazid.

(b) RIMAs

A study in 12 healthy subjects given a single dose of levodopa/benserazide with moclobemide 200 mg twice daily found that nausea, vomiting and dizziness were increased, but no significant hypertensive reaction was seen.

Mechanism

Not fully understood. Levodopa is enzymatically converted in the body, firstly to dopamine and then to noradrenaline, both of which are normally broken down by monoamine oxidase. But in the presence of an MAOI this breakdown is suppressed, which means that the total levels of dopamine and noradrenaline are increased. Precisely how this then leads to a sharp rise in blood pressure is not clear, but either dopamine or noradrenaline, or both, directly or indirectly stimulate the alpha-receptors of the cardiovascular system.

Importance and management

The interaction between the non-selective MAOIs (listed in ‘Table 32.1’, p.1130) and levodopa on its own is well documented, serious and potentially life-threatening. Patients should not be given levodopa on its own during treatment with any of these MAOIs, nor for a period of 2 to 3 weeks after their withdrawal. Note that this interaction is inhibited by the presence of dopa-decarboxylase inhibitors such as carbidopa and benserazide (as in Sinemet and Madopar) so that a serious interaction is unlikely to occur with these preparations. Even so, the manufacturers continue to list the MAOIs among their contraindications.

No important acute adverse interaction appears to occur between levodopa/benserazide and moclobemide, but some adverse effects can apparently occur.

MAOIs or RIMAs + Lithium

Two cases of tardive dyskinesia have been described following the long-term use of tranylcypromine and lithium, which did not resolve when the MAOI was stopped. Limited evidence suggests that no problems occur when moclobemide is given with lithium.
Clinical evidence, mechanism, importance and management

(a) MAOIs

One report describes 2 patients with bipolar affective disorder who developed a buccolingual-masticatory syndrome after taking tranylcypromine 30 or 40 mg daily and lithium carbonate 900 or 1200 mg daily for 1.5 or 3 years. These symptoms did not resolve when the tranylcypromine was stopped. This reaction was attributed to dopamine receptor hypersensitivity.1

There appear to be no other reports suggesting that the combination of MAOIs and lithium is unsafe. However, there are a few reports of patients taking MAOIs and lithium who developed hyperpyrexia when given ‘tryptophan’, (p.1151). The role (if any) of lithium in these cases is unknown. Note that lithium has been used to augment antidepressants although most of the data relate to tricyclics or SSRIs.2 Bear these cases in mind in the event of any unexpected response to treatment with MAOIs and lithium.

(b) RIMAs

There was no evidence of any adverse interaction when moclobemide 150 to 675 mg daily was given for 3 to 52 weeks to 50 patients taking lithium.3 Similarly, lithium augmentation was used in a small uncontrolled study in patients on high-dose moclobemide without any evidence of important adverse effects.5

MAOIs + MAOIs or RIMAs

Strokes, fatal reactions (possibly including the serotonin syndrome), hypertensive reactions and CNS disturbances have been seen, either when one MAOI was abruptly replaced by another, when the two MAOIs were given together, or when there was an insufficient MAO-free interval. A case of serotonin syndrome occurred in a patient who overdosed on moclobemide and tranylcypromine.

Clinical evidence, mechanism, importance and management

(a) MAOIs + MAOIs

A patient who had been taking isocarboxazid for 3.5 weeks (starting at 10 mg daily and gradually increased to 30 mg daily) was switched to tranylcypromine 10 mg, starting the same day, followed by 10 mg three times daily on the following day. Later that night she complained of feeling ‘funny’, had difficulty in talking, developed a headache, was restless, flushed, sweating, had an elevated temperature of 39.5°C, and a pulse rate of 130 bpm. She died the following day.1 Another patient, switched without a drug-free period, from phenelzine 75 mg daily (by tapering the dose by 15 mg daily until discontinued) to tranylcypromine (starting at 10 mg daily, increasing by 10 mg daily, until a dose of 20 mg twice daily was reached), suffered a subcortical cerebral haemorrhage on the fourth day following the morning 20 mg dose of tranylcypromine, which resulted in total right-sided hemiplegia.2–4 The patient remained significantly disabled from the sequelae of her stroke.4 A third patient experienced a mild cerebral haemorrhage, without residual problems, when she took phenelzine 45 mg and tranylcypromine 20 mg at bedtime; the MAOIs were being switched by reducing the dose of phenelzine and gradually increasing the dose of tranylcypromine. Consumption of ‘soy sauce’, (p.1153), may have contributed to this reaction.7 In a fourth case, phenelzine 45 mg daily was stopped, and then after a 2-day drug-free period tranylcypromine 20 mg was given, with a further 30-mg dose the next day. The patient experienced a rise in blood pressure to 240/130 mmHg, but recovered unequivocally, and a year later was successfully switched from phenelzine to tranylcypromine with a 2-week drug-free interval.3 In another case, hypertension with severe headache, inability to walk and slurred speech, but without permanent sequelae, resulted from starting tranylcypromine 30 mg seven days after discontinuing phenelzine. Tranylcypromine 10 mg daily was restarted 3 days later (10 days after discontinuing the phenelzine) with no adverse effects, but when the dose was increased to 20 mg daily (14 days after discontinuing phenelzine) the patient experienced a milder version of the same symptoms.6

Acute CNS toxicity, hypertension, tachycardia, tremor and urinary retention occurred in a woman 48 hours after phenelzine was abruptly stopped and isocarboxazid started. In this patient, phenelzine was poorly tolerated causing hypertension and headache.7

Switching from iproniazid to tranylcypromine/trifluoperazine may have been the cause of a fatal reaction (fever, shivering, sweating, cyanosis) in a patient also given ephedrine6,9 (see also ‘MAOIs or RIMAs + Sympathomimetics; Indirectly-acting’, p.1147).

In contrast, one woman was switched directly from phenelzine 60 mg daily to tranylcypromine 20 mg daily without any obvious problems (blood pressure was on the high side, but within the usual range for this patient). She was abruptly switched directly back to phenelzine, again without any adverse effect.10,11 Similarly, a review of 8 cases of patients who were switched rapidly from tranylcypromine to phenelzine (3 cases) or vice versa (5 cases) found that 7 patients tolerated the switch well with minimal or no adverse effects. However the eighth patient experienced anxiety, nausea, hyperventilation, flushing, sense of doom, and increased insomnia, which may have been a mild form of the serotonin syndrome.12

The reasons for these reactions are not understood, but one idea is that the amphetamine-like properties of tranylcypromine may have had some part to play. Certainly there are cases of spontaneous rises in blood pressure and intracranial bleeding in patients given tranylcypromine.11 Not all patients experience adverse reactions when switched from one MAOI to another10,12 but because of the sometimes severe reactions, it would seem prudent to have a drug-free wash-out period when doing so, and to start dosing in a conservative and step-wise manner.

(b) RIMAs + MAOIs

The serotonin syndrome occurred in a patient who took an overdose of moclobemide and tranylcypromine. In this analysis of moclobemide overdoses, the risk of developing serotonin toxicity was increased 35-fold in patients who also took another serotonergic drug, of which this case with tranylcypromine was one of 11 mentioned.14

MAOIs + Mazindol

An isolated report describes a patient taking phenelzine who had a marked rise in blood pressure when given a single dose of mazindol.

Clinical evidence, mechanism, importance and management

A woman taking phenelzine 30 mg three times daily had a rise in blood pressure from 110/60 to 200/100 mmHg within 2 hours of receiving a 10-mg test dose of mazindol. The blood pressure remained elevated for another hour, but had fallen again after another 3 hours. The patient experienced no subjective symptoms.1 It is uncertain whether this hypertensive reaction was the result of an interaction, or simply a direct response to the mazindol alone (the dose was large compared with the manufacturer’s recommended dosage of 2 to 3 mg daily). The general importance is uncertain. The manufacturer advises avoiding the combination, and say that
Theoretically hypertension may occur when non-selective MAOIs are taken with methyldopa, although additive blood-pressure lowering effects are also a possibility. The concurrent use of anti-depressant MAOIs and methyldopa may not be desirable because methyldopa can sometimes cause depression.

Clinical evidence, mechanism, importance and management

Theoretically, methyldopa might cause hypertension in patients treated with non-selective MAOIs, by releasing catecholamines into the circulation. On the basis of this, the manufacturers of some MAOIs and methyldopa contraindicate concurrent use. Nevertheless, there do not appear to be any reports of hypertension occurring as a result of concurrent use. Conversely, the UK manufacturer of isocarboxazid mentions that it may potentiate the hypertensive effect of methyldopa. MAOIs alone have hypertensive effects and additional blood-pressure lowering effects have been reported in a few patients given paraglyline (an MAOI formerly used in the treatment of hypertension) with methyldopa. Note that the potential depressive adverse effects of methyldopa may make it an unsuitable drug for patients with depression.

Importance and management

No interaction between monosodium glutamate per se and MAOIs has been established, although it should be pointed out that the number of subjects studied was very small. It is quite possible that the anecdotal reports were due to the tyramine content of the foods, and not to monosodium glutamate. In Hong Kong, patients on MAOIs are not advised to avoid monosodium glutamate, but are instructed to avoid excessive soy sauce because of its possible high tyramine content.

Fentanyl has been used without problems in a few reports, but one fatal case of hyperthermia has occurred, and also a case of hypertension and tachycardia. Case reports describe the uneventful use of alfentanil, remifentanil and sufentanil in patients taking MAOIs.

Clinical evidence

(a) Alfentanil

A 54-year-old woman taking tranylcypromine with trifluoperazine underwent general anaesthesia with no problems. She received temazepam as premedication, and propofol induction. Supplementary alfentanil was given in increments of 250 micrograms to a total of 2.5 mg. Atracurium was given for neuromuscular block with 100% oxygen for ventilation. Similarly, another report describes successful anaesthesia using propofol, alfentanil 25 micrograms/kg, and succinylcholine during ECT therapy in two patients taking a variety of drugs including phenelzine.

(b) Fentanyl

A 71-year-old woman taking Parstelin (tranylcypromine with trifluoperazine) was given an intravenous test dose of fentanyl 20 micrograms and diazepam before surgery, without problems. She was then given another 20-microgram intravenous dose of fentanyl during surgery, followed by an epidural bolus infusion of fentanyl 50 micrograms 15 minutes before the end of the surgery. After surgery she was given a continuous epidural infusion of fentanyl 50 to 70 micrograms/hour for 4 days to control post-operative pain, also without problems. Similarly, another report describes 2 patients who had stopped taking phenelzine 36 hours and 10 days before undergoing uneventful cardiac surgery using fentanyl, pancuronium and 100% oxygen. Four further patients taking tranylcypromine, isocarboxazid, or paraglyline had no adverse reactions to fentanyl given during surgery (3 cases) or for postoperative pain relief (3 cases).

(c) Remifentanil

A patient taking phenelzine who received fentanyl during and after surgery developed postoperative hypertension, hyperthermia, and severe shivering followed by resistant hypotension, and finally died. Another patient taking phenelzine who underwent cardiac surgery, was anaesthetised with fentanyl and midazolam, developed hypotension and supraventricular tachycardia, which did not respond to digoxin and esmolol. About 15 minutes after stopping the fentanyl/midazolam and starting enflurane, the haemodynamics gradually improved, and analgesia was subsequently managed with ketorolac without problems.

(d) Sufentanil

A 43-year-old woman taking tranylcypromine 60 mg daily underwent general anaesthesia with sufentanil, isoflurane, and nitrous oxide without problem.

MAOIs + Methyldopa

Hypertension in patients taking MAOIs who had eaten certain foods (soy sauce, chicken nuggets) has been attributed, in anecdotal reports, to an interaction with monosodium glutamate. However, a small controlled study found no evidence to support this idea, and the reaction was probably related to 'tyramine', (p.1153).

Mechanism

Monosodium glutamate alone can cause a small rise in blood pressure, and MAOIs alone very occasionally cause hypertensive episodes. However, the reactions reported with soy sauce and chicken nuggets were probably due to a high tyramine content, as a high tyramine content has subsequently been detected in some soy sauces, (see also ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153).

MAOIs + Opioids; Fentanyl and related drugs

Fentanyl has been used without problems in a few reports, but one fatal case of hyperthermia has occurred, and also a case of hypertension and tachycardia. Case reports describe the uneventful use of alfentanil, remifentanil and sufentanil in patients taking MAOIs.
An isolated report describes ‘leg shakes’, diaphoresis and severe hypotension in a woman taking phenelzine when she was given dextropropoxyphene. Another isolated report describes a marked increase in sedation when a woman was given phenelzine and dextropropoxyphene. Animal data show moclobemide potentiates dextropropoxyphene.

Clinical evidence, mechanism, importance and management

(a) MAOIs

A woman taking phenelzine 15 mg three times daily, sodium valproate, lithium and trazodone, was given dextropropoxyphene 100 mg and paracetamol (acetaminophen) 650 mg for back pain and headache. Some 12 hours later she was admitted to hospital for leg shakes, discomortion and weakness. She was confused and anxious, and intensely diaphoretic. The next day she became severely hypotensive (systolic BP 55 to 60 mmHg) and needed large fluid volume resuscitation in intensive care. She later recovered fully. Another woman taking propranolol, oestrogen-replacement therapy and phenelzine became very sedated and groggy, causing her to have to lie down on two occasions, both within 2 hours of taking dextropropoxyphene 100 mg and paracetamol 650 mg. She had experienced no problems with either paracetamol or dextropropoxyphene or paracetamol before starting the phenelzine, and subsequently had no problem with paracetamol alone while continuing the phenelzine. The mechanisms of these interactions are not understood but some of the symptoms in the first case were not unlike those seen in the serotonin syndrome. Apart from these two isolated reports, there seems to be no other clinical evidence of adverse interactions between MAOIs and dextropropoxyphene. For reports of the serotonin syndrome seen with pethidine (meperidine), see ‘MAOIs or RIMAs + Opioids; Pethidine (Meperidine)’.

(b) RIMAs

In animals, the effects of dextropropoxyphene were increased by moclobemide. A brief mention is made of 3 patients, taking moclobemide and codeine (2 patients) or dextropropoxyphene (1 patient): one of these patients developed moderate agitation.

References

Hypotension (profound in one case) has been seen in a few patients given morphine and an MAOI. One case of hypotension and stupor has occurred with papaveretum. Single cases of the safe use of methadone and hydromorphone have also been described.

Clinical evidence

(a) Hydromorphone

No problems were encountered when a patient taking tranylcypromine was given hydromorphone via a patient-controlled device for postoperative pain. This patient also received sufentanil during surgery without problem.

(b) Methadone

A patient receiving methadone maintenance therapy (30 mg daily) was successfully and eventuantly treated for depression with tranylcypromine, initially 10 mg daily gradually increased to 30 mg daily.

(c) Morphine

A study in 15 patients who had been taking either phenelzine, isocarboxazid, iproniazid or Parstelin (tranylcypromine with trifuoperazine) for 3 to 8 weeks, had no changes in blood pressure, pulse rate or state of awareness when given a test dose of up to 4 mg of intramuscular morphine. However, note that none of these patients showed an interaction with test doses of up to 40 mg of pethidine (meperidine). One other study reported no adverse interaction in 3 patients taking isocarboxazid when they were given morphine premedication, and a further study revealed no problems in 9 patients taking tranylcypromine who were given morphine for postoperative pain relief. Another patient taking phenelzine was uneventfully treated with morphine postoperatively. Two further patients taking MAOIs, who reacted adversely to pethidine (meperidine), had not previously done so when given morphine. In an early report, intramuscular morphine was given without apparent problem to 5 patients who had developed severe headache while taking tranylcypromine. Another author briefly noted that he knew of about 10 cases where morphine had been used in patients taking MAOIs with no adverse effects except a more prolonged morphine action.

However, a patient taking tranylcypromine 40 mg and trifuoperazine 20 mg daily and undergoing a preoperative test with morphine, developed pin point pupils, became unconscious and unresponsive to stimuli, and had a systolic blood pressure fall from 160 to 40 mmHg after receiving a total of 6 mg of morphine intravenously. Within 2 minutes of being given naloxone 4 mg intravenously, the patient was awake and rational with a systolic blood pressure fully restored. A moderate fall in blood pressure (from 140/90 to 90/60 mmHg) was seen in another patient taking an MAOI given morphine, and a brief episode of hypotension treated with phenylephrine occurred in a patient taking phenelzine receiving continuous epidural morphine during surgery.

(d) Papaveretum

A 54-year-old woman taking phenelzine was given papaveretum 10 mg as premedication, and 50 minutes later she was found to be unrousing, sweating and hypotensive.

Mechanism, importance and management

This serious MAOI/pethidine interaction also casts a shadow over morphine, which probably accounts for its inclusion in a number of lists and charts of drugs said to interact with the MAOIs. However, there is some limited evidence that patients on MAOIs who had reacted adversely with pethidine did not do so when given morphine, and quite a number of reports of its safe use. The few hypotensive reactions cited here are of a different character and appear to be rare. There would therefore seem to be no good reason for avoiding morphine in patients taking MAOIs, but be alert for the rare adverse response. However, several manufacturers have contraindicated concurrent use of morphine in patients taking MAOIs or within 2 weeks of stopping an MAOI because they can cause CNS adverse effects with hyperr- or hypotension.
The current use of pethidine and MAOIs has resulted in a serious and potentially life-threatening reaction in several patients, and one possible case has been reported with moclobemide. Excitement, muscle rigidity, hyperpyrexia, flushing, sweating and unconsciousness can occur very rapidly. Respiratory depression and hypertension or hypotension have also been seen. Pethidine should not be given to patients taking any MAOI or RIMA.

Clinical evidence

(a) MAOIs

Severe, rapid and potentially fatal toxic reactions, both excitatory and depressive can occur. A woman stopped taking iproniazid 50 mg twice daily and about a day and a half later became restless and incoherent almost immediately after being given pethidine 100 mg for chest pain. She was comatose within 20 minutes. An hour after receiving the injection she was flushed, sweating and showed Cheyne-Stokes respiration. Her pupils were dilated and unreactive. Deep reflexes could not be initiated and plantar reflexes were extensor. Her pulse rate was 82 bpm and blood pressure 156/110 mmHg. She was rousable within 10 minutes of receiving an intravenous injection of prednisolone hemisuccinate 25 mg. A very similar reaction was described in another patient. A woman who, unknown to her doctor, was taking tranylcypromine, was given pethidine 100 mg. Within minutes she became unconscious, noisy and restless, having to be held down by 3 people. Her breathing was stertorous and the pulse impalpable. Generalised tonic spasm developed, with ankle clonus, extensor plantar reflexes, shallow respiration and cyanosis. On admission to hospital she had a pulse rate of 160 bpm, a blood pressure of 90/60 mmHg and was sweating profusely (temperature 38.3°C). Her condition gradually improved and 4 hours after admission she was conscious but drowsy. Recovery was complete the next day.

Other cases of this interaction have been reported in patients treated with iproniazid,1-5 pargyline,6,7 phenelzine8-11 and mebanazine.14 Fatalities have occurred. One of 8 patients taking an MAOI and given test doses of pethidine experienced a drop in systolic blood pressure of 30 mmHg and a rise in pulse rate of 20 bpm after the first 5-mg dose of pethidine. However, a study in 15 patients who had been taking either phenelzine, isocarboxazid, iproniazid or Parsetin (tranylcypromine) with trifluoperazine for 3 to 8 weeks, found no changes in blood pressure, pulse rate or state of awareness with test doses of up to 40 mg of pethidine. Similarly, no major problems were noted in a retrospective review of 45 episodes of anaesthesia in patients taking isocarboxazid who were given pethidine as part of premedication.

(b) RIMAs

One report suggests that on the basis of animal studies the combination of moclobemide and pethidine should be avoided or used with caution. A report of suspected serotonin syndrome in a 73-year-old woman, given pethidine in addition to her usual treatment with moclobemide 750 mg daily, nortriptyline 100 mg daily and lithium 750 mg daily, adds some weight to this suggestion.

Mechanism

Not understood, despite the extensive studies undertaken.20-22 The reaction may be due to an increase in levels of 5-HT within the brain, causing “the serotonin syndrome”, (p.9). Tramadol, an opioid with additional noradrenergic and serotonergic properties, has clearly caused the serotonin syndrome in some patients when used with MAOIs, see ‘tramadol’, (p.1141).

Importance and management

The interaction between pethidine and the MAOIs, which was first observed in the mid-1950s, is based on case reports. One case has been reported with RIMA moclobemide. It is serious and potentially fatal. Its incidence is unknown, but it is probably quite low, because one study that attempted to produce the interaction by giving increasing test doses of pethidine to 15 patients taking various MAOIs did not show the interaction.15 It may therefore be an idiosyncratic reaction. Nevertheless, it would be prudent to give pethidine to any patients on an MAOI or RIMA. Bear in mind that the older MAOIs are all essentially irreversible so that an interaction is possible for many days after their withdrawal (at least 2 weeks is the official advice), whereas the newer RIMAs (e.g. moclobemide) are reversible and unlikely still to interact 48 hours after they have been stopped.

Sensitivity test

A sensitivity test has been suggested,15 but given the fact that there are many alternatives to pethidine and MAOIs readily available, and given that a drop in systolic blood pressure of 30 mmHg has been reported even with the first step of the test dose (5 mg of pethidine)12 it would seem prudent to avoid the combination. Also, the test dose procedure is unlikely to be suitable when opioids are required in an emergency situation.

MAOIs or RIMAs + Opioids; Pethidine (Meperidine)
The serotonin syndrome developed in one patient on iproniazid and tramadol, and delirium in another given tramadol shortly after stopping phenelzine. A fatal case of possible serotonin syndrome has been seen with tramadol, moclobemide and clomipramine.

Clinical evidence, mechanism, importance and management

The manufacturers of tramadol contraindicated its use with the MAOIs1,2 on the basis that it is an opioid agonist, like pethidine (meperidine). This may mean the serotonin syndrome could develop (see ‘MAOIs or RIMAs + Opioids; Pethidine (Meperidine), p.1140). This prediction was confirmed by a report2 of the development of the serotonin syndrome (myoclonus, tremor, sweating, hyperreflexia, tachycardia) in a patient on iproniazid when tramadol was added to his drug regimen. When the tramadol was stopped the patient recovered within 48 hours. Another single case report describes the development of severe delirium in a patient within in 3 days of stopping long term treatment with phenelzine 45 mg daily and starting intramuscular tramadol 100 mg three times daily. The patient became anxious and confused, and developed visual hallucinations and persecutory ideation. The symptoms disappeared within 48 hours of stopping the tramadol. Another report suggests that tramadol may have contributed to the development of a fatal serotonin syndrome in a patient abusing tramadol, moclobemide and clomipramine.5

This demonstrates that there are sound practical and theoretical reasons for patients on MAOIs to avoid tramadol. Note that the serotonin syndrome has also occurred with ‘tramadol and SSRIs’, (p.1222).

MAOIs or RIMAs + Phenothiazines

The concurrent use of MAOIs and phenothiazines is usually safe and effective. However, rarely, cases of possible neuroleptic malignant syndrome or hyperpyrexia have been reported with MAOIs and chlorpromazine, levomepromazine or trifluoperazine. Some of these cases were fatal. Chlorpromazine has been successfully used for treatment of the serotonin syndrome occurring with MAOIs and other drugs. Moclobemide has been used with various phenothiazines without problem, but one case of fatal overdose is attributed to an interaction between moclobemide and perazine.

Clinical evidence

(a) MAOIs

MAOIs and phenothiazines have been safe and effective when used together in the treatment of psychiatric conditions, particularly in the form of a preparation containing both tranylcypromine and trifluoperazine.1,3 which is still marketed in some countries. There is also a report of the beneficial use of tranylcypromine with chlorpromazine.4

However, rarely, cases suggestive of the neuroleptic malignant syndrome or similar have been reported. In one case, a 70-year-old woman taking isocarboxazid 10 mg daily and chlorpromazine 25 mg three times daily, suddenly developed dyspnoea, tachycardia, pyrexia, muscular rigidity, hypotension, and became comatosed. Her condition initially improved over 24 hours, but she later died from acute renal failure as a result of rhabdomyolysis. Throughout the previous 2 years of inpatient care, the patient had received neuroleptics intermitently and had developed an unexplained toxic confusional state on 6 occasions, which suggested that the neuroleptic malignant syndrome had a milder chronic course in this patient before the full acute syndrome developed.5 In another case, a woman presented with symptoms of the neuroleptic malignant syndrome one week after starting tranylcypromine/trifluoperazine 10/1 mg and immediately after doubling the dose. She was intubated and treated with dantrolene and intravenous sodium bicarbonate, and made a full recovery.6 Interpretation of her case is complicated by the fact she had been previously taking imipramine, and was switched to tranylcypromine/trifluoperazine without a break (see also ‘MAOIs or RIMAs + Tricyclic and related antidepressants’, p.1149). One study mentions an unexplained fatality in a woman who suddenly developed hyperthermia and coma while taking levomepromazine and pargyline. Another report briefly mentions a woman who developed fatal hyperthermia while taking levomepromazine and tranylcypromine, and a fatality following the use of an unnamed MAOI/phenothiazine combination.8 Note that chlorpromazine9 has 5-HT antagonist activity, and has been successfully used in the treatment of severe serotonin syndrome occurring with ‘MAOIs and tricyclic antidepressants’, (p.1149).

One early reviewer stated that MAOIs increase the potency of phenothiazine derivatives such that their initial dose should be reduced by three-quarters. He briefly mentions a case of a patient taking long-term perphenazine who developed a Parkinson-like syndrome with extrapyramidal symptoms a few hours after starting an MAOI.10 The US manufacturers note that, based on the increased incidence of extrapyramidal effects reported with concurrent use of some MAOIs and phenothiazines, this possibility should be considered with promethazine.11

A report attributes 2 cases of fatal fulminant hepatitis to an interaction between iproniazid and prochlorperazine.12

A single report13 describes a woman taking an MAOI who developed a severe occipital headache after taking 30 mL of a paediatric cough linctus. Initially this interaction was attributed to promethazine, but it is now known that the linctus in question contained phenylpropanolamine, which is much more likely to have been the cause.14 See ‘MAOIs or RIMAs + Sympathomimetics; Indirectly-acting’, p.1147 for the interaction with phenylpropanolamine.

(b) RIMAs

Clinically relevant interactions were not noted when moclobemide was given with one or more neuroleptics (including phenothiazines such as chlorpromazine, levomepromazine, thioridazine). Adverse effects such as hypotension, tachycardia, drowsiness, tremor, and constipation were somewhat more frequent, probably due to additive effects.15 A fatal case of overdose with moclobemide and perazine was attributed to synergistic effects resulting in functional cardiovascular disorder.16

Mechanism

Neuroleptic malignant syndrome (NMS) is a rare condition associated with a reduction in dopamine activity in the brain, which has occurred with a wide variety of dopamine antagonists including the phenothiazines. It is unclear what role, if any, is played by the MAOIs in the few possible cases cited here. Note that MAOIs can cause the similar serotonin syndrome, and it is important to differentiate between the two conditions, especially since phenothiazines would aggravate NMS, but can successfully treat the serotonin syndrome.

Importance and management

No special precautions would normally seem to be necessary during the concurrent use of MAOIs and phenothiazines. However, bear in mind that serious, sometimes fatal, cases of the neuroleptic malignant syndrome or hyperpyrexia have rarely occurred with combinations of MAOIs and chlorpromazine, levomepromazine and trifluoperazine. The role of the MAOI in these cases is unclear. Chlorpromazine has been used successfully to treat the serotonin syndrome occurring with MAOIs and other serotoninergic drugs, but note that it should be avoided if neuroleptic malignant syndrome is a possible diagnosis, or if the patient is hypotensive, see ‘MAOIs or RIMAs + Tricyclic and related antidepressants’, p.1149.

**MAOIs + Rauwolfia alkaloids or Tetrabenazine**

Central excitation and possibly hypertension can occur if rauwolfia alkaloids are given to patients already taking an MAOI, but is less likely if the rauwolfia alkaloid is given first. Theoretically additive blood-pressure lowering effects are also a possibility. The use of drugs that have the potential to cause depression, such as the rauwolfia alkaloids or tetrabenazine, is generally contraindicated in patients needing treatment for depression.

**Clinical evidence**

A woman with a history of manic depression who had been in a depressed phase for 5 years was given nialamid 100 mg three times daily. Two days later, reserpine 500 micrograms three times daily was also started. The following day she became frankly hypomanic and almost immediately went into mania.

In another report, a patient who was started on tetrabenazine 10 mg three times daily, 2 days after stopping a week of treatment with nialamid 25 mg daily, collapsed 6 hours after the first dose, and demonstrated epileptiform convulsions, partial unconsciousness, rapid respiration and tachycardia. He recovered within 15 minutes, but 3 days later he had a similar attack and the tetrabenazine was stopped.

Another author states that the use of reserpine or tetrabenazine after pretreatment with iproniazid can lead to a temporary disturbance of affect and memory, associated with autonomic excitation, delirious agitation, disorientation and illusions of experience and recognition, which lasts for up to 3 days.

A prolonged period of increased motor activity after starting reserpine (‘reserpine-reversal’) possibly occurred in 3 patients with schizophrenia treated firstly with phenelzine for 12 weeks, then a placebo for 16 to 33 weeks, and lastly reserpine for 12 weeks, when compared with patients receiving reserpine who had not received an MAOI. Their blood pressures rose slightly and persistently, and their psychomotor activity was considerably increased, lasting in two cases throughout the 12-week period of treatment.

Theoretically, reserpine might cause hypertension in patients treated with non-selective MAOIs (see Mechanism). On the basis of this the US manufacturer of tranylcypromine contraindicates concurrent use. Conversely, the UK manufacturer of isocarboxazid mentions that it may potentiate the hypotensive effect of reserpine (MAOIs alone can have hypotensive effects).

**Mechanism**

Rauwolfia alkaloids such as reserpine cause adrenergic neurons to become depleted of their normal stores of noradrenaline (norepinephrine). In this way they prevent or reduce the normal transmission of impulses at the adrenergic nerve endings of the sympathetic nervous system and thereby act as antihypertensives. Since the brain also possesses adrenergic neurones, failure of transmission in the CNS could account for the sedation and depression observed with these drugs. If rauwolfia alkaloids are given to patients already taking an MAOI, large amounts of accumulated noradrenaline can be released throughout the body. In the brain, 5-HT is also released. The release of these substances results in marked central excitation and hypertension. This would account for the cases reported cited and the effects seen in *animals*.

16. These stimulant effects are sometimes called ‘reserpine-reversal’ because instead of the expected sedation or depression, excitation or delayed depression is seen. It depends upon the order in which the drugs are given.

**Importance and management**

The use of drugs that have the potential to cause depression is generally contraindicated in patients needing treatment for depression. However, one report suggests that if concurrent use is considered desirable, the MAOIs should be given after, and not before the rauwolfia alkaloid, so that sedation rather than excitation will occur. Bear in mind the possibility of hypo- or hypertension.

**MAOIs or RIMAs + SSRRIs**

A number of case reports describe the serotonin syndrome in patients given SSRRIs with MAOIs: some have been fatal. Concurrent use is contraindicated. Some studies suggest that moclobemide may not interact with the SSRRIs, but there have also been case reports of the serotonin syndrome and concurrent use is contraindicated. A suitable washout interval is needed when switching between MAOIs or RIMAs and SSRRIs.

**Clinical evidence, mechanism, importance and management**

A. MAOIs

(a) Fluoxetine

A very high incidence (25 to 50%) of adverse effects occurred in 12 patients taking fluoxetine 10 to 100 mg daily with either phenelzine 30 to 60 mg daily or tranylcypromine 10 to 140 mg daily, and in 6 other patients started on either of these MAOIs 10 days or more after stopping fluoxetine. There were mental changes such as hypomania, racing thoughts, agitation, restlessness and confusion. The physical symptoms included myoclonus, hypertension, tremor, teeth chattering and diarrhoea.

A detailed review of cases reported to the manufacturers described 8 acute cases, 7 of them fatal, in patients given fluoxetine with either tranylcypromine or phenelzine. Uncontrollable shivering, teeth chattering, double vision, nausea, confusion, and anxiety developed in a woman given tranylcypromine after stopping fluoxetine. The problem resolved within a day of stopping the tranylcypromine, and did not recur when fluoxetine was tried again 6 weeks later.

A number of other reports describe similar reactions in patients given fluoxetine and tranylcypromine,3,4 some occurring up to 6 weeks after the SSRI was stopped,6 and several resulting in fatalities.3,7

(b) Sertraline

A man taking tranylcypromine and clonazepam was additionally given sertraline 25 to 50 mg daily. Within 4 days he began to experience chills, increasing confusion, sedation, exhaustion, unsteadiness and incoordination. Other symptoms included impotence, urinary hesitancy and consti-
pation. These problems rapidly resolved when the sertraline was stopped and the tranylcypromine dosage reduced from 30 to 20 mg daily.9 A woman with a major depressive disorder taking lithium, thioucidazine, doxepin and phenelzine was also given sertraline 100 mg daily for worsening depression. Within 3 hours she became semi-comatose, with a temperature of 41°C, a heart rate of 154 bpm and symptoms of rigidity and shivering. She was treated with diazepam, midazolam, ice-packs and dantrolene.10 Two other similar cases, involving the use of sertraline with isocarboxazid11 and phenelzine12 have been reported. The latter case was fatal.12 Another case of mild serotonin syndrome (managed with cyproheptadine) occurred in a woman who took a single dose of sertraline 11 days after stopping isocarboxazid.13

B. RIMAs

(a) Citalopram

A 34-year-old man who had been taking moclobemide 100 mg every 8 hours for several months was switched to citalopram 20 mg daily without a break. An hour later he started getting agitated and had involuntary movements of the legs, which progressed to generalised rigidity. Apart from a heart rate of 100 bpm all other vital signs were normal. He was treated with benzodiazepines and recovered uneventfully.14 Three patients developed the serotonin syndrome (tremor, convulsions, hyperthermia, unconsciousness) and died 3 to 16 hours after taking overdoses of moclobemide and citalopram.15 Other cases of the serotonin syndrome after overdose of moclobemide and citalopram have been reported;16,17 one also included sertraline and sumatriptan.16

(b) Fluoxetine

A placebo-controlled trial in 18 healthy subjects found that the use of fluoxetine 20 mg with moclobemide 100 to 600 mg daily for 9 days gave no evidence of an adverse interaction.18 Other studies in healthy subjects and patients similarly found no evidence of the serotonin syndrome.19,20 A post-marketing analysis found that at least 50 patients switched from fluoxetine to moclobemide within a week had experienced no adverse effects.19,21

However, 3 patients have developed the serotonin syndrome22-24 and one developed agitation and confusion25 following the use of moclobemide and fluoxetine. A fatal case of the serotonin syndrome occurred in a patient who took an overdose of moclobemide, fluoxetine, and clomipramine,26 and another patient taking moclobemide developed the serotonin syndrome after taking an overdose of fluoxetine.27 A study suggests that the combination may cause a high rate of adverse effects (insomnia, dizziness, nausea and headache).22 A double-blind study in 41 healthy subjects found that when they were given fluoxetine 40 mg daily for 7 days, then 20 mg for 9 days, immediately followed by bifeloxine (2.5, 5, 10 or 20 mg daily) for 5 days, no unusual adverse reactions occurred and no changes in body temperature, haemodynamics or ECGs were seen.28

(c) Fluvoxamine

When 13 of 22 healthy subjects given fluvoxamine 100 mg daily for 9 days were also given moclobemide in increasing doses of 50 to 400 mg daily for 4 days from day 7, no serious adverse reactions occurred. Any adverse events were mild to moderate (some increase in headaches, fatigue, dizziness, all of which may occur with both drugs alone) and there was no evidence of the serious serotonin syndrome.18,25 An open study in 6 depressed patients given moclobemide 225 to 800 mg daily and fluvoxamine 50 to 200 mg daily found a marked improvement in depression. Insomnia was the commonest adverse effect (treated with trazodone) but none of the patients showed any evidence of the serotonin syndrome.20 Similar results were found in other studies.20,31 However, a fatal case of the serotonin syndrome occurred in a woman who took an overdose of moclobemide and fluvoxamine, and another fatal overdose was attributed to the same combination.25

(d) Paroxetine

An open 6-week study in 19 patients with major depression taking paroxetine (or fluoxetine) 20 mg daily to which moclobemide up to 600 mg daily was added, indicated that these combinations were possibly effective.23 An extension of this study with 50 patients is reported elsewhere.24 However, a range of adverse effects occurred in some patients, the clearest one being insomnia, and the serotonin syndrome was seen in one patient.22,31 Conversely, the serotonin syndrome was not seen in another study, where low initial doses and gradual up-titration of both paroxetine and moclobemide was used.26 Two possible cases of mild serotonin syndrome occurred in women on moclobemide within 2 to 24 hours of starting additional paroxetine.34 Similarly, cases of severe serotonin syndrome have been reported with overdoses of moclobemide and paroxetine.35,36

(e) Sertraline

In one study, 31 severely ill patients were given moclobemide 35 to 800 mg daily with SSRIs including sertraline 25 to 100 mg daily, initially using lower than usual starting doses of both drugs and then gradually titrating them slowly upwards. The other SSRIs used were fluoxetine, fluvoxamine and paroxetine. There was no evidence of the serotonin syndrome.20 An open study in 5 depressed patients given moclobemide 150 to 600 mg daily and sertraline 25 to 200 mg daily found improvements ranging from minimal to complete remission. Insomnia was the commonest adverse effect (treated with trazodone) but none of the patients showed any evidence of the serotonin syndrome.30 However, one case of possible serotonin syndrome occurred in a woman who took an overdose of moclobemide and sertraline,24 and another after an overdose of moclobemide, citalopram, sertraline and sumatriptan.16 Similarly, a fatality has been reported with an overdose of moclobemide, sertraline and pimozide, with blood levels suggesting that none of the drugs individually would have been fatal.37

(f) Unspecified SSRIs

Serotonin toxicity (the serotonin syndrome) occurred in 5 patients who took an overdose of moclobemide with an SSRI [specific drugs not mentioned]. In this analysis of moclobemide overdoses, the risk of developing serotonin toxicity was increased 35 times in patients who also took another serotoninergic drug. Of the 11 cases mentioned 5 patients were taking SSRIs.38

Mechanism

MAO-A is involved in the metabolism of serotonin, so combined use of MAOIs or RIMAs with SSRIs may lead to excessive serotonin levels, which can result in the serotonin syndrome. For more information see ‘the serotonin syndrome’, (p.9).

Importance and management

Direct information about the interaction between MAOIs and SSRIs is limited. However, it is clear that severe, sometimes fatal interactions (the serotonin syndrome or similar) have occurred with MAOIs and fluoxetine or sertraline, so these reports should certainly be taken seriously. The incidence appears to be low, possibly as the combined use of any MAOI and any SSRI is contraindicated. In addition, at least 2 weeks should elapse between stopping any MAOI and starting any SSRI to allow for the effects of the MAOI to diminish. Moreover, the manufacturers of each SSRI give guidance on the appropriate intervals that should be left between stopping the SSRI and starting an MAOI, that is, 14 days for sertraline,40 seven days for citalopram,41 escitalopram,42 fluvoxamine43 or paroxetine44 (14 days in the US),45-47 and at least 5 weeks for fluoxetine, with an even longer interval if long-term or high-dose fluoxetine has been used.46,47

The RIMAs (e.g. moclobemide) also have serotoninergic effects, and so they are unlikely to be any safer than the non-selective MAOIs in regard to interactions with SSRIs. The few cases of serotonin syndrome cited with therapeutic doses of this combination confirm that it is not necessarily safe. The combination may be particularly problematic in overdose, and negates the generally benign course of moclobemide overdose alone. It should be noted that the manufacturer of moclobemide contraindicates its use with SSRIs.30 Because the effects of moclobemide are readily reversible, only one day need elapse between stopping moclobemide and starting an SSRI. However, if stopping an SSRI and starting moclobemide, the same intervals are required as for the irreversible MAOIs. For the management of serotonin syndrome, see Importance and management under ‘MAOIs or RIMAs + Tricyclic and related antidepressants’, p.1149.

The concurrent use of non-selective MAOIs and amfetamines and related drugs can result in a potentially fatal hypertensive crisis and/or serotonin syndrome. Interactions have also been reported for amfetamines, dexamfetamine, metamfetamine, and methylphenidate. These adverse effects are a combination of the adverse effects of both drugs, it seems possible that a mutual interaction (perhaps saturation of the acetylcholine mechanisms in the liver) was responsible. This appears to be a separate report, but bear it in mind in the event of an unexpected response to treatment.

Clinical evidence, mechanism, importance and management

A woman who had been taking phenezline 15 mg three times daily for about 3 weeks complained of weakness, ataxia, vertigo, tinnitus, muscle pains and paraesthesia within 7 days of starting to take sufluzoxazole 1 g four times daily. These adverse effects continued until the 10-day sulfoxide course was completed, and did not occur again in the following 8 weeks.1 The reasons are not understood, but as these adverse effects are a combination of the adverse effects of both drugs, it seems possible that a mutual interaction (perhaps saturation of the acetylcholine mechanisms in the liver) was responsible. This appears to be a separate report, but bear it in mind in the event of an unexpected response to treatment.

Clinical evidence

A. MAOIs

(a) Amfetamines

A 30-year-old depressed woman who was taking phenezline 15 mg three times daily and dexffluorazine 2 mg at night, acquired some dexametamine sulfate tablets from a friend and took 20 mg. Within 15 minutes she complained of severe headache, which she described as if “her head was bursting”. An hour later her blood pressure was 150/100 mmHg. Later she became comatose with a blood pressure of 170/100 mmHg and died. A postmortem examination revealed a haemorrhage in the left cerebral hemisphere, disrupting the internal capsule and adjacent areas of the corpus striatum.1

This interaction has been reported with single oral doses of amfetamine,2,3 single intravenous doses of amfetamine,4 single doses of illicit amfetamine/dexamfetamine,5,6 or single doses of intravenous metamfetamine,7,8 in patients taking tranylcypromine,2,7 phenezline,5,6,8,9 and isocarboxazid.8,10 A woman who had been addicted to high-dose dexamfetamine/amobarbital was hospitalised and had the dexamfetamine/amobarbital withdrawn. Five days later she was given a single dose of tranylcypromine and within an hour had a 20 minute episode of hypertension, tachycardia, headache, sweating, lacrimation and altered consciousness, which abated without treatment. She had similar attacks at 2-hourly intervals over about 5 days when they gradually became milder and shorter.11

Extreme hyperpyrexia, apparently without hypertension, has been described in a woman who took tranylcypromine with dexamfetamine/amobarbital. She developed progressive agitation, diaphoresis, hypertension, opisthotonus, coma and convulsions, but recovered following the use of an ice bath and other supportive measures.12,13

(b) Dexamfetamine or fenfluramine

The manufacturer recommended that fenfluramine should not be used in patients with a history of depression, or during treatment with antidepressants (especially the MAOIs), and there should be an interval of 3 weeks between stopping the MAOIs and starting fenfluramine.14 A woman taking phenezline developed severe headache, neck stiffness and nausea within an hour of taking fenfluramine 20 mg, and then collapsed and re-
mainly stuporous for about 4 hours. This reaction was considered similar to that seen with MAOIs and amphetamines.15

The manufacturer of dexfenfluramine similarly contraindicated its use with or within 2 weeks of stopping an MAOI,16 and advised waiting 3 weeks between stopping dexfenfluramine and starting an MAOI. This is due to the potential risk of the serotonin syndrome,17,18 which has rarely occurred with the use of more serotoninergic drugs (see ‘the serotonin syndrome’, (p.9)). The manufacturer of dexfenfluramine and fenfluramine had found no clinical evidence of serious problems with either of these drugs when taken with MAOIs,19 so that the published warnings about possible interactions would appear to be based on theoretical considerations.

Note that dexfenfluramine and fenfluramine have generally been withdrawn because their use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

(c) Ecstasy (MDMA, methylenedioxymethamphetamine)

Marked hypertension, diaphoresis, altered mental status and hypotonicity (slow forceful twisting and arching movements) occurred in one patient taking phentolamine with ecstasy.20 Increased muscle tension, decontorticate-like posturing, fever, tachycardia and coma occurred in another patient taking phentolamine, 15 minutes after drinking juice containing ecstasy.21 Both patients recovered.20,21

(d) Methylphenidate

A patient started treatment with tranylcypromine, then 4 days later methylphenidate was added. After 15 days of concurrent use he had a hypertensive crisis and both drugs were stopped.22 In a study of the use of phentolamine as an antagonist to stimulants, 3 patients took oral or intravenous methadone and all three experienced moderate to severe headache.23 An episode of symptoms consistent with the serotonin syndrome occurred in a man taking isocarboxazid and trazodone, 2 months after the dose of these drugs was increased and methylphenidate was added. He had experienced two concurrent episodes 4 and 8 weeks previously, which had each resolved spontaneously over 12 hours. All three drugs have serotoninergic properties and where thought to have contributed to the reaction.23

Conversely, a man taking tranylcypromine for depression was successfully treated with methylphenidate for attention deficit/hyperactivity disorder (ADHD). He was given methylphenidate 2.5 mg daily, which was very gradually increased over a number of months to 45 mg daily. He was successfully treated with the combination for 6 months and periodic blood pressure measurements did not change significantly from baseline.24 Another similar case has been described with phentolamine and methylphenidate.25 No cases of hypertensive crisis were seen in 4 patients taking tranylcypromine or phentolamine when treated concurrently with methylphenidate for periods of 6 to 30 months.26

B. RIMAs

Four patients died after taking moclobemide and ecstasy (MDMA, methylenedioxymethylamphetamine). The clinical evidence is limited, but in each case the forensic pathologist concluded that the cause of death was the combined use of these drugs. It was suggested that what happened is consistent with the serotonin syndrome, although the evidence is fairly slim. Two patients had taken maximum therapeutic doses and two moderate overdoses of moclobemide. Note that moclobemide had not been prescribed to any of them. Post-mortem analysis also found the presence of dextromethorphan in one patient, which was thought to have contributed.27 See also ‘MAOIs or RIMAs + Dextromethorphan’, p.1134.

Mechanism

The hypertensive reaction can be attributed to overstimulation of the adrenergic receptors of the cardiovascular system.28 During treatment with non-selective MAOIs, large amounts of noradrenaline (norepinephrine) accumulate at adrenergic nerve endings not only in the brain, but also in the sympathetic nerve endings, which innervate arterial blood vessels. Stimulation of these latter nerve endings by sympathetic amines with indirect actions causes the release of the accumulated noradrenaline and results in the massive stimulation of the receptors. An exaggerated blood vessel constriction occurs and the blood pressure rise is proportionately excessive. Intracranial haemorrhage can occur if the pressure is so high that a blood vessel ruptures.1

Some of the reactions may also possibly be related to the serotonin syndrome. Amphetamines act by releasing serotonin (and possibly also dopamine) from neurons in the brain, so that increased stimulation of the serotonin receptors occurs. This possibly explains their mood-modifying effects. MAOIs prevent the breakdown of serotonin within neurons so that more serotonin is available for release, and in excess this can apparently result in the toxic and even fatal serotonin syndrome. The RIMAs (such as moclobemide) appear to behave like the older non-selective MAOIs in this context.

Importance and management

The hypertensive reaction is a very well-documented, serious, and potentially fatal interaction, whereas the serotonin syndrome appears to be rarer. Patients taking any of the non-selective MAOIs should not normally take amphetamines, or related drugs such as methylphenidate. A possible exception to this prohibition is that this tissue damage is not likely to occur in very well controlled conditions. Dexamphetamine and methylphenidate may sometimes be effectively (and apparently safely) used with MAOIs for refractory depression,25,56,29 or ADHD.24 Direct evidence implicating central stimulants such as diethylpropion, mazindol, pemoline, phenidimetrizine, and phentemazine seems not to have been documented, but on the basis of their known pharmacology their concurrent use with the MAOIs should be avoided. Patients on MAOIs should also be warned to avoid the illicit use of amphetamines and ecstasy. It would also be prudent to avoid moclobemide with monoamines and related drugs, although the incidence of the interactions with moclobemide is unlikely to be as great as that seen with the non-selective MAOIs. In the cases with ecstasy, it seems likely that high doses of moclobemide were used to try to enhance the actions of the ecstasy, but these cases, nevertheless, show that combined use is potentially life threatening.

Treatment

For a brief mention of the treatment of hypertensive crisis, see Importance and Management under ‘MAOIs or RIMAs + Sympathomimetics; Indirectly-acting’, p.1147. For the management of fever and other symptoms of the serotonin syndrome, see Importance and Management under ‘MAOIs or RIMAs + Tricyclic and related antidepressants’, p.1149.

An isolated case of tachycardia and apprehension has been described in an asthmatic taking phenelzine after salbutamol (albuterol) was added. Hypomania was seen in another asthmatic taking phenelzine when inhaled isocetarine was added. Hypertensive crisis occurred in a woman taking toloxatone and phenylephrine when given [oral] terbutaline.

Clinical evidence

(a) MAOIs

A report briefly describes a case of tachycardia and apprehension in a patient taking tranylcypromine ([oral]) 10 mg three times daily for 7 days, there was no significant change in pressor response to intravenous adrenaline (epinephrine) or isoprenaline (isoproterenol) after treatment with the MAOI. However, the tachycardia caused by isoprenaline was antagonised by the MAOIs (109 bpm with the MAOI versus 127 bpm without). No clinically significant potentiation of the pressor effect of noradrenaline was seen, although one of the subjects taking tranylcypromine had a twofold increase in the pressor response in the mid-range of noradrenaline concentrations infused, but not in the upper or lower ranges. None of these 4 subjects had a change in blood pressure or heart rate caused by the MAOI alone. In yet another study in 3 healthy subjects given tranylcypromine for 8 to 14 days, the effects of intravenous noradrenaline were slightly increased, while with intravenous adrenaline a moderate two to fourfold increase in the effects on heart rate and diastolic pressure took place, but a less marked increase in systolic pressure. Intravenous isoprenaline behaved very much like adrenaline, but there was no enhancement of systolic pressure. This study did not state the effect of the MAOI alone on blood pressure.

A patient using 1% adrenaline eye drops twice daily had no increase in blood pressure or heart rate when treated with tranylcypromine 20 mg, rising to 50 mg daily. Another patient taking phenelzine presented with severe anaphylaxis after taking two doses of fluclaxacillin, and was initially treated unsuccessfully with hydrocortisone, chlorpheniramine and ranitidine because of concerns about using adrenaline with MAOIs. However, as her condition worsened she was given two 100-microgram doses of intravenous adrenaline, with rapid improvement. No adverse reaction was noted. In another study, one healthy subject given phenelzine for 8 days experienced a marked reduction in blood pressure, but showed no significant changes in pressor response to noradrenaline.

(b) RIMAs

In a randomised, double-blind, placebo-controlled study in 12 healthy subjects, moclobemide 100 mg three times daily for 7 days had no effect on the dose of intravenous noradrenaline required to raise the systolic blood pressure by 25 mmHg. In addition, moclobemide had no effect on the diastolic blood pressure rises and heart rate reductions seen with noradrenaline. In this study, moclobemide itself had no effect on blood pressure or heart rate. A review paper also briefly mentions that moclobemide 600 mg daily for 3 weeks had no relevant effect on the heart rate response to intravenous isoprenaline.

Mechanism

These sympathomimetic amines act directly on the receptors at the nerve endings, which innervate arterial blood vessels, so that the presence of the MAOI-induced accumulation of noradrenaline within these nerve endings would not be expected to alter the extent of direct stimulation (contrast ‘Sympathomimetics; Indirectly-acting’, (p.1147)). The enhancement seen on the dose of intravenous noradrenaline required to raise the systolic blood pressure by 25 mmHg. In addition, moclobemide had no effect on the diastolic blood pressure rises and heart rate reductions seen with noradrenaline. In this study, moclobemide itself had no effect on blood pressure or heart rate. A review paper also briefly mentions that moclobemide 600 mg daily for 3 weeks had no relevant effect on the heart rate response to intravenous isoprenaline.

Importance and management

These appear to be isolated cases, and are possibly not of general importance. Bear them in mind in the event of an unexpected response to treatment.

tion. It is worth noting that there are no case reports of interactions with these drugs.

Direct evidence about methoxamine is even more limited, but it seems to behave similarly. None of the studies demonstrated any marked changes in the effects of isoprenaline.

The situation in patients who show a reduced blood pressure due to the use of an MAOI is less clear. One early study found an increase in the pressor effects of noradrenaline and methoxamine in hypertensive patients who had developed orthostatic hypotension on pheniprazine or tranylcypromine. Bear this possibility in mind.

Moclobemide does not appear to alter the pressor response to noradrenaline.

The interaction between phenylephrine and the MAOIs is dealt with elsewhere (see ‘MAOIs or RIMAs + Sympathomimetics; Phenylephrine’, p.1148). Consider also ‘MAOIs or RIMAs + Sympathomimetics; Beta-agonist bronchodilators’, p.1146 and ‘Inotropes and Vasopressors; Dopamine + Selegiline’, p.893, for dosing advice with when dopamine is given to patients taking MAOIs.

The use of indirectly-acting sympathomimetic amines concurrently with, and for 2 weeks after stopping, non-selective MAOIs can result in a potentially fatal hypertensive crisis and should be avoided. Note that these amines are commonly used as vasoconstrictor decongestants (e.g. ephedrine, phenylpropanolamine and pseudoephedrine) in many proprietary cough, cold and influenza preparations, or for their vasoconstrictor effects in migraine (e.g. isometheptene). Indirectly-acting amines are also used parenterally for treating hypotension occurring during spinal anaesthesia (e.g. ephedrine, methephentermine, metaraminol). Potentially serious interactions have also been seen with moclobemide and indirectly-acting sympathomimetics.

Clinical evidence

(a) MAOIs

A study in 3 healthy subjects, given phenelzine 45 mg or tranylcyromine 30 mg daily for 5 to 14 days, found that the blood pressure rise following oral ephedrine 30 mg was enhanced. The maximal increase in mean arterial pressure was 22 mmHg (compared with 4 to 6 mmHg without the MAOI). A similar increase was seen up to 10 days after discontinuation of the MAOI. A similar increase in blood pressure was also seen in one of the subjects given intravenous ephedrine 2 mg per minute for 6 minutes. In a different subject given tranylcyromine 30 mg daily for 20 to 30 days, phenylpropanolamine in capsules or a lincept preparation caused a rapid and marked rise in blood pressure to 210/140 mmHg within 2 hours, necessitating the use of phenolamine to reverse the effect. Slow-release phenylpropanolamine caused a smaller and more gradual rise to 160/100 mmHg over 2 hours. Similarly, the pressor effect of intravenous phenylpropanolamine was potentiated about four to fivefold (systolic) and three to tenfold (diastolic) in 3 subjects given tranylcyromine 30 mg daily for 8 to 14 days, and the reflex bradycardia was potentiated about 2.5- to 6-fold.

Numerous case reports describe similar rapid and serious rises in blood pressure, accompanied by tachycardia, chest pains and severe occipital headache with concurrent use of MAOIs and indirectly-acting sympathomimetics. Other symptoms that have occurred include neck stiffness, flushing, sweating, nausea, vomiting, hypotonicity of the limbs, and sometimes epileptic convulsions, and fatal intracranial haemorrhage, cardiac arrhythmias and cardiac arrest have resulted.

This interaction has been reported with oral ephedrine, oral isometheptene mucate, oral phenylpropanolamine, intramascular metarami- nol, oral phenylpropanolamine, oral pseudoephedrine, in patients taking nialamide, phenelzine, iproniazid, methana- zine, and pargyline.

Tachycardia and hypertension, then pyrexia has been described in a woman who took a single Do-Do tablet (ephedrine, caffeine, theophylline) the day after stopping phenelzine. Similarly, fatal hyperpyrexia without hypertension occurred in a man taking tranylcypromine/trifluoperazine given oral ephedrine, although switching his MAOI without a full washout period may have caused, or contributed to, this reaction (see ‘MAOIs + MAOIs or RIMAs’, p.1137). A woman taking phenelzine developed bradycardia (40 bpm) after taking one tablet of Sinutab (without codeine), which probably contained pseudoephedrine.

No interaction was seen in subjects taking brofaromine 75 mg twice daily for 10 days when given 75 mg of slow-release phenylpropanolamine (Actisrim Late Day), but immediate-release phenylpropanolamine in gelatin capsules caused a 3.3-fold increase in pressor sensitivity. The pressor effects of high-dose oral ephedrine (two doses of 50 mg with a 4-hour interval) in 11 healthy subjects taking moclobemide 300 mg twice daily were increased about three to fourfold, and this resulted in an increase in palpitations and headache.

Mechanism

The reaction can be attributed to overstimulation of the adrenergic receptors of the cardiovascular system. During treatment with non-selective MAOIs, large amounts of noradrenaline (norepinephrine) accumulate at adrenergic nerve endings not only in the brain, but also within the sympathetic nerve endings, which innervate arterial blood vessels. Stimulation of these latter nerve endings by sympathomimetic amines with indirect actions causes the release of the accumulated noradrenaline and results in the massive stimulation of the receptors. An exaggerated blood vessel contraction occurs and the blood pressure rise is proportionately excessive. Intracranial haemorrhage can occur if the pressure is so high that a blood vessel ruptures. Directly-acting sympathomimetics do not cause this effect, see ‘MAOIs or RIMAs + Sympathomimetics; Directly-acting’, p.1146.

Importance and management

(a) MAOIs

A very well-documented, serious, and potentially fatal interaction. Patients taking any of the MAOIs should not normally take any sympathomimetic amines such as ephedrine, mephentermine and metaraminol, phenylpropanolamine and pseudoephedrine. Direct evidence implicating methylephedrine and pholedrine seems not to have been documented, but on the basis of their known pharmacology their concurrent use with the MAOIs should be avoided.

Note that some of the indirectly-acting amines, including ephedrine, phenylpropanolamine and pseudoephedrine, are used as vasoconstrictor decongestants in numerous oral non-prescription cough, cold and influenza preparations. Isometheptene is used in non-prescription analgesic preparations for migraine. Patients on MAOIs should be strongly warned not to take any of these drugs concurrently or for 2 weeks after stopping their MAOI. Also, note that serious interactions have occurred because of confusion between non-prescription products with very similar names that contain different active ingredients.

Physicians should also avoid the use of indirectly-acting vasoconstrictor amines such as ephedrine, mephetremine and metaraminol for reversing hypotension during spinal anaesthesia in patients taking MAOIs or who have recently stopped these (within the previous 2 weeks).

(b) RIMAs

The data with high-dose ephedrine show that moclobemide is not free of this interaction, and the manufacturers of moclobemide advise avoiding sympathomimetics such as ephedrine, pseudoephedrine and phenylpro-
nolamine. It would also be prudent to avoid moclobemide with any of the other indirectly-acting sympathomimetics cited here, although the severity of the interactions with moclobemide is unlikely to be as great as that seen with the MAOIs. For example, ephedrine and phenylephrine have been successfully and uneventfully used in the presence of moclobemide (omitted on the day of surgery) during anaesthesia to control hypotension.24

(c) Treatment

Hypertensive reactions have been controlled by intravenous phenyltolamine, phenoxybenzamine, intramuscular chlorpromazine, labetalol or sublingual nifedipine. The manufacturers of phenelzine state that on the basis of present evidence, slow intravenous injection of phenyltolamine is recommended.25,26 However, it is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice. See also Importance and Management under ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153.

The concurrent use of oral phenylephrine and the non-selective MAOIs can result in a potentially life-threatening hypertensive crisis. Phenylephrine is commonly found in proprietary cough, cold and influenza preparations. The effects of parenteral phenylephrine may be approximately doubled by MAOIs. Some interaction occurs between phenylephrine and the RIMAs moclobemide or brofaromine, but the blood pressure response appears to be much smaller than that seen with the non-selective MAOIs.

Clinical evidence

(a) MAOIs

A study in 3 healthy subjects, given phenelzine 45 mg or tranylcypromine 30 mg daily for 7 days, found that the blood pressure rise following oral phenylephrine was markedly enhanced. On 2 of 3 occasions when 45 mg of phenylephrine was given orally, the rise in blood pressure be-

Importance and management

The interaction between the MAOIs and oral phenylephrine is established, serious and potentially life-threatening. Phenylephrine commonly occurs in oral non-prescription cough, cold and influenza preparations, so patients should be strongly warned about them. Whether the effects of nasal drops and sprays and eye drops are also enhanced is uncertain, but it would be prudent to avoid them until they have been shown to be safe. The response to parenteral administration is also approximately doubled, so that a dosage reduction is necessary.

The few studies that are available suggest that any interaction with RIMAs is less severe than that with MAOIs, but this needs confirmation.

Treatment

These hypertensive reactions have been controlled by intravenous phenyltolamine, hypotension, chlorpromazine, or nifedipine. However, it is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice. In the US, the manufacturers of phenelzine advise intravenous phenyltolamine 5 mg, given slowly to avoid excessive hypotension. See also Importance and management under ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153.

MAOIs or RIMAs + Sympathomimetics; Phenylephrine

The concurrent use of oral phenylephrine and the non-selective MAOIs can result in a potentially life-threatening hypertensive crisis. Phenylephrine is commonly found in proprietary cough, cold and influenza preparations. The effects of parenteral phenylephrine may be approximately doubled by MAOIs. Some interaction occurs between phenylephrine and the RIMAs moclobemide or brofaromine, but the blood pressure response appears to be much smaller than that seen with the non-selective MAOIs.

Clinical evidence

(a) MAOIs

A study in 3 healthy subjects, given phenelzine 45 mg or tranylcypromine 30 mg daily for 7 days, found that the blood pressure rise following oral phenylephrine was markedly enhanced. On 2 of 3 occasions when 45 mg of phenylephrine was given orally, the rise in blood pressure be-

MAOIs or RIMAs + Tricyclic and related antidepressants

Because of the very toxic and sometimes fatal reactions (the serotonin syndrome or similar) that have occurred in patients taking either MAOIs or RIMAs with tricyclic antidepressants, concurrent use is regarded as contraindicated in all but rare circumstances, and a suitable washout interval is needed when switching between MAOIs or RIMAs and tricyclics. Of the tricyclics, clomipramine and imipramine have been most frequently implicated in adverse reactions with the MAOIs.

Clinical evidence

A. MAOIs

The toxic reactions that occur when the tricyclics are given with MAOIs have included (with variations) sweating, flushing, hyperpyrexia, restlessness, excitement, tremor, muscle twitching and rigidity, convulsions and coma. Two illustrative examples:

A woman who had been taking tranylcypromine 10 mg twice daily for about 3 weeks, stopped taking it 3 days before she took a single tablet of imipramine. Within a few hours she complained of an excruciating headache, and soon afterwards lost consciousness and started to convulse. The toxic reactions manifested a temperature of 40.6°C, pulse rate of 120 bpm, severe sensorimotor rigidity, spasm, opisthotons and cyanosis. She was treated with amobarbital and phenytoin, and her temperature was reduced with alcohol-ice-soaked towels. The treatment was effective and she recovered.1

In a recent case, a patient was treated with imipramine 75 mg daily for 7 weeks with lithium as well for the last 3 weeks. These drugs were discontinued and after one week of washout he started tranylcypromine, which was gradually increased to 50 mg twice daily. After 2 weeks at this dose, he received a single 225-mg dose of imipramine in error. Four hours later his condition deteriorated rapidly. He was agitated, confused, with severe rigidity, myoclonic jerks, hyperthermia, hypertension and tachycardia, and 2 hours later he had a cardiac and respiratory arrest. He was resuscitated and treated with midazolam, pancuronium, dantrolene sodium, and a cooling mattress. The following day he had a sudden fall in blood pressure, and was eventually pronounced brain dead, and artificial respiration was terminated.2

Similar reactions have been recorded with oral therapeutic doses of:

• amitriptyline with phenelzine3,4
• clomipramine with phenelzine5-7 or tranylcypromine (with or without trifluoperazine)8-10
• desipramine with phenelzine11
• imipramine with iproniazid,12 isocarboxazid,12 pargyline,13 phenelzine14-6 or tranylcypromine.12,17

There have been a number of fatalities.8,9,11,18 Reactions have also occurred when intramuscular imipramine was given with phenelzine.19-21 In some instances the drugs were not taken together, but were substituted without a washout period in between.6,17 In some other reports there was an overdose of one or both drugs,22-25 and/or the presence of other potentially interacting drugs.23,24 There are many more reports of these interactions than are listed here: those published prior to 1977 have been extensively reviewed elsewhere.16,26,27

Three patients with bipolar disorder developed mania when treated with isocarboxazid and amitriptyline.28

In contrast, there are a number of other uncontrolled studies29-31 and reviews26,27, describing the beneficial use of an MAOI with a tricyclic antidepressant. In addition, one study has reported switching 178 patients from tricyclics to MAOIs within 4 days or less. Of these patients, 63 were given the MAOI while still being tapered from the tricyclic, all without any apparent problems.32 Nevertheless, in a 6-week randomised double-blind trial, the combinations of phenelzine or isocarboxazid plus trimipramine were less effective than trimipramine alone in patients with mild to moderate depression.33 Similarly, in a smaller randomised open study, the combination of amitriptyline and tranylcypromine was no more effective than either drug alone.34

B. RIMAs

(a) Amitriptyline

Two small studies in healthy subjects and patients found no problems when moclobemide was given with, or 24 hours after, amitriptyline,35,36 or when amitriptyline was given immediately after moclobemide.35 However, a patient taking amitriptyline and clomipramine developed the serotonin syndrome after taking a dose of moclobemide and died37 (see also clomipramine below).

Only a minor and clinically unimportant change in the pharmacokinetics of amitriptyline occurs in patients given toltoxatone.38

(b) Clomipramine

A small study in healthy subjects found no problems when moclobemide was given 24 hours after clomipramine.36 However, the serotonin syndrome occurred in 3 patients when clomipramine was replaced by moclobemide without a washout period39,40 or with only a 24-hour washout period,41 and in another patient when moclobemide was replaced by clomipramine after only 12 hours.42 A fatal case of the serotonin syndrome occurred in a patient taking clomipramine and amitriptyline, with symptoms manifesting within 30 minutes of a 300-mg dose of moclobemide.37

Two other patients developed fatal serotonin syndrome after taking moderate overdoses of moclobemide and clomipramine.43 The serotonin syndrome has been reported in at least 8 other cases of moclobemide and clomipramine overdose,44-50 one of which also involved tramadol (see also ‘MAOIs + Opioids; Tramadol’, p.1141), another flutoxetine46 (see also ‘MAOIs or RIMAs + SSRIs’, p.1142), and yet another buspirone (see also ‘MAOIs or RIMAs + Buspirone’, p.1133). Conversely, a case of an overdose of moclobemide and clomipramine resulted in no adverse effects except sinus tachycardia.51

(c) Desipramine

A small single dose study in healthy subjects found no problems when moclobemide was given with desipramine.35

(d) Doxepin

Serotonin toxicity (the serotonin syndrome) occurred in a patient who took an overdose of moclobemide and doxepin. In this analysis of moclobemide overdoses, the risk of developing serotonin toxicity was increased 35 times in patients who also took another serotoninergic drug, of which this case with doxepin was one of 11 mentioned.52

(e) Imipramine

The serotonin syndrome occurred in a patient who had been taking moclobemide for about a month and imipramine (50 mg at night increased to 200 mg at night) for about 17 days.53

(f) Maprotiline

One study found a nonsignificant 25% rise in serum levels of maprotiline (a tetracyclic antidepressant) in 6 patients also taking moclobemide. No serious toxic reactions were reported.54

(g) Trimipramine

One study found a 39% rise in serum trimipramine levels in 15 patients also taking moclobemide. No serious toxic reactions were reported.54

Mechanism

Not understood. One idea is that both drugs cause grossly elevated monoamine levels (5-HT, noradrenaline (norepinephrine)) in the brain,
Importance and management

An established and fairly common interaction, but serious and life-threatening occurrences seem rare. If concurrent use is to be avoided, the following guidelines35,55 are recommended:

- Tricyclic antidepressants should not be started for 2 weeks after treatment with MAOIs has been stopped (3 weeks if starting clomipramine or imipramine).
- An MAOI should not be started until at least 7 to 14 days after a tricyclic or related antidepressant has been stopped (3 weeks in the case of clomipramine or imipramine).
- Moclobemide has a shorter duration of action so no treatment-free period is required after it has been stopped before starting a tricyclic antidepressant. [Note however that some recommend waiting 24 hours.]26
- Moclobemide should not be started until at least a week after a tricyclic antidepressant has been stopped.

No detailed clinical work has been done to find out precisely what sets the scene when the interaction does occur, but some general empirical guidelines have been suggested so that it can, as far as possible, be avoided when concurrent treatment is thought appropriate.15,16,26,27,56

Treatment with both types of drug should only be undertaken by those well aware of the problems and who can undertake adequate supervision.46

Only patients refractory to all other types of treatment should be considered.17

Tranylcypromine, phenelzine, clomipramine and imipramine appear to be high on the list of drugs that have interacted adversely. Combination of clomipramine with tranylcypromine is particularly dangerous. Amitriptyline, trimipramine and isocarboxazid are possibly safer.18

Absence of information documenting unsuitability or hazard does not necessarily imply that the two drugs may be used safely together, but may merely reflect an untried combination.35

Drugs should be given orally, not parenterally.34

It seems safer to give the tricyclic antidepressants first, or together with an MAOI, than to give the MAOI first. If the patient is already taking an MAOI, it may not be safe to start the tricyclic antidepressant until recovery from MAO-inhibition is complete.32

Small doses should be given initially, increasing the levels of each drug, one at a time, over a period of 2 to 3 weeks to levels generally about half those used by each individually.

Treatment of the serotonin syndrome

In the management of serotonin syndrome, it is important to recognise the possibility of the syndrome early, as the patient’s condition can rapidly deteriorate. Potentially precipitating drugs should be stopped and agitation should be managed with benzodiazepines. The intensity of therapy depends on the severity of the condition. Moderately ill patients may benefit from the administration of 5-HT antagonists such as cyproheptadine. The 5-HT 3 antagonist, ondansetron, has also been used and can be beneficial, but should not be given if the patient is hypotensive or if the neuroleptic malignant syndrome is a possible diagnosis. Hyperthermic patients should be immediately sedated, given neuromuscular blockers and intubated, since the rise in temperature is due to muscular activity. MAOI-induced hypotension should be managed with low doses of direct-acting sympathomimetics. Propanolol, bromocriptine, and dantrolene have been used, but these are no longer recommended. Because of the potential severity of the condition, a poison-control centre, clinical pharmacology service or medical toxicologist should be consulted for up-to-date advice.57
MAOIs + Tryptophan

A number of patients have developed severe behavioural and neurological signs of toxicity (some similar to the serotonin syndrome) after taking MAOIs with tryptophan, and fatalities have occurred.

Clinical evidence

A man taking phenelzine 90 mg daily developed behavioural and neurological toxicity within 2 hours of being given 6 g of tryptophan. He had shivering and diaphoresis, his psychomotor retardation disappeared and he became jocular, fearful, and moderately labile. His neurological signs included bilateral Babinski signs, hyperreflexia, rapid horizontal ocular oscillations, shivering of the jaw, trunk and limbs, mild dysmetria and ataxia. The situation resolved on withdrawal of the drugs.

Similar symptoms have been reported in other studies and cases. In an early study, giving tryptophan 20 to 50 mg/kg to 7 patients with hypertension taking an unknown MAOI produced neurological effects including alcohol-like intoxication, drowsiness, hyperreflexia and clonus.2 Similar symptoms of toxicity (some similar to the serotonin syndrome) after taking MAOI produced neurological effects including early study, giving tryptophan 20 to 50 mg/kg to 7 patients with hypertensive crisis in a patient switched from fluoxetine to phenelzine when tryptophan was added to its accumulation.3,9

Importance and management

MAOIs may inhibit the metabolism of serotonin syndrome', (p.9)). MAOIs may inhibit the metabolism of tryptophan, or within 1 day of increasing the dose of tryptophan.15 A further patient also experienced delirium within hours of tryptophan being added to her phenelzine treatment.16

In contrast, concurrent use has been reported as both safe and effective.17

Mechanism

Not understood. The reactions appear to be related to the serotonin syndrome, which can occur with two or more serotonergic drugs (see ‘The serotonin syndrome’, (p.9)). MAOIs may inhibit the metabolism of 5-hydroxytryptamine (serotonin), formed from tryptophan, so resulting in its accumulation.1,9

Importance and management

Information seems to be confined to the reports listed. Concurrent use can be effective in the treatment of depression,17 but occasionally and unpredictably severe and even life-threatening toxicity occurs. The authors of one of the reports detailed above1 recommend that patients on MAOIs should be started on a low dose of tryptophan (0.5 g). This should be gradually increased while monitoring the mental status of the patient for changes suggesting hypomania, and neurological changes, including oral oscillations and upper motor neurone signs.

Note that products containing tryptophan for the treatment of depression were withdrawn in the USA, UK, and many other countries because of a possible association with the development of an eosinophilia-myalgia syndrome. However, since the syndrome appeared to have been associated with tryptophan from one manufacturer, tryptophan preparations were reintroduced in the UK in 1994 for restricted use.18,19

MAOIs or RIMAs + Tyramine-rich drinks

Patients taking the non-selective MAOIs (e.g. tranylcypromine, phenelzine) can suffer a serious hypertensive reaction if they drink tyramine-rich drinks (some beers or lagers, including low-alcohol brands, or wines), but no serious interaction is likely with the RIMAs (e.g. moclobemide). The hypothetic adverse effects of the MAOIs may be exaggerated in a few patients by alcohol, and they may experience dizziness and faintness after drinking relatively modest amounts. Moclobemide does not appear to alter the psychomotor effects of alcohol to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

A. Hypertensive reactions

A severe and potentially life-threatening hypertensive reaction can occur in patients taking MAOIs if they consume alcoholic drinks containing significant amounts of tyramine. The details of the tyramine/MAOI reaction, its mechanism, the names of the non-selective MAOIs that interact, and the RIMAs that are unlikely to do so are described in the monograph ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153. The specific case reports for various tyramine-containing drinks are outlined in the sub-section below. Note that an 8 to 20-mg dose of tyramine is required before an important rise in blood pressure takes place in a patient taking tranylcypromine, and this dose may be higher for other MAOIs (see under ‘tyramine-rich foods’, (p.1153)). ‘Table 32.2’, (p.1152) summarises the reported tyramine-content of some drinks,1,12 and more extensive lists have been published elsewhere.6–8 These can be used as a broad general guide when advising patients, but they cannot be an absolute guide because alcoholic drinks are the end-product of a biological fermentation process and no two batches are ever absolutely identical. For example there may be a 50-fold difference even between wines from the same grape stock.9

There is no way of knowing for certain the tyramine-content of a particular drink without a detailed analysis.

(a) Ales, Beers and Lagers

Some ales, beers and lagers in ‘social’ amounts contain enough tyramine to reach the 8 to 20 mg dose needed to provoke a reaction; for example a litre (a little under two pints) of some samples of **Canadian ale or beer** (see ‘Table 32.3’, (p.1154)). Case reports of reactions have been published. A man taking **phenelzine** 60 mg daily developed a typical hypertensive reaction after drinking only 14 oz. (about 400 mL) of **Upper Canada lager beer on tap** (containing about 113 mg of tyramine/litre).8

In addition, **alcohol-free beer** and **lager** may have a tyramine-content that is equal to ordinary beer and lager.9,10 One patient taking **tranylcypromine** suffered an acute cerebral haemorrhage after drinking a **de-alkoholised Irish beer,**3 hypertensive reactions occurred in three other patients taking **tranylcypromine** or **phenelzine** after drinking no more than about 375 mL of **alcohol-free beer or lager**,10 and a further patient taking **tranylcypromine** developed a vascular headache after drinking 3 bottles of non-alcoholic beer.11 A very extensive study of 79 different brands of beer (from Canada, England, France, Germany, Holland, Ireland, Scotland, USA) found that the tyramine content of the **bottled** and **canned beers** examined was generally too low to matter (less than 10 mg/L), but four of 37 **beers on tap** (all 4 were lagers) contained more than enough tyramine (27 to 113 mg/L) to cause a hypertensive reaction.8

It was concluded in this report that the consumption of **canned** or **bottled beer**, including **de-alkoholised beer**, in moderation (fewer than four bottles, 1.5 litres in a 4-hour period) was safe in patients on MAOIs, but, to be on the cautious side, all **beers on tap**, including lagers should be avoided.8 The RIMAs are less likely to interact, see ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153.

(b) Spirits

**Gin**, **whisky**, **vodka** and other spirits do not contain significant amounts of tyramine because they are distilled, and the volumes drunk are relatively small.7 There seem to be no reports of hypertensive reactions in patients taking MAOIs after drinking spirits and none would be expected. One author12 anecdotally noted that “bottles of whisky have been drunk by some patients on the MAOIs, the only result being that they got drunk more easily and cheaply.” However, a 38-year-old man collapsed with tachycardia the morning after taking an overdose of moclobemide and drinking half a bottle of **whisky** (more than 350 mL). He then suffered a cardiac arrest, and resuscitation was unsuccessful. Blood pressure was not recorded. The authors attributed this case to an interaction between moclobemide and tyramine,13 although the tyramine content of the whisky was not assessed, so any interaction is not established, especially since whisky does not usually contain tyramine.

(c) Wines

In the context of adverse interactions with MAOIs, **Chianti** has developed a sinister reputation, because 400 mL of one early sample of **Italian Chianti wine** (see ‘Table 32.2’, (above)) contained enough tyramine to reach the 8 to 20 mg threshold for causing important hypertensive reactions. However, it is claimed by the **Chianti** producers14 and others15 that the newer methods that have replaced the ancient ‘governo alla toscana’ process result in negligible amounts of tyramine in today’s **Chianti**. This seems to be borne out by the results of analyses3,5,7 two of which failed to find any tyramine at all in some samples.3,7 Some of the other wines listed in ‘Table 32.2’, (above) also contain tyramine, but patients would have to drink as much as 2 litres or more before reaching what is believed to be the threshold dosage. This suggests that small or moderate amounts (1 or 2 glasses) are unlikely to be hazardous in patients taking MAOIs.

B. Hypotensive reactions

Some degree of hypotension can occur in patients taking MAOIs and this may be exaggerated by the vasodilation and reduced cardiac output caused by alcohol. In one report, a patient on an MAOI describes having a **gin** and orange and then becoming unsteady when standing up and hitting her head on the wall.16 Patients should therefore be warned of the possibility of orthostatic hypotension and syncope if they drink. They should be advised not to stand up too quickly, and to remain sitting or lying if they feel faint or begin to ‘black out’.

C. Psychomotor performance

The possibility that **alcohol**-induced deterioration in psychomotor skills (i.e. those associated with safe driving) might be increased by the RIMAs has been studied. Moclobemide appears to have only a minor and clinically unimportant effect.17,18

---

A potentially life-threatening hypertensive reaction can develop in patients on the non-selective MAOIs (tranylcypromine, phenelzine etc.) who eat tyramine-rich foods. Deaths from intracranial haemorrhage have occurred. Significant amounts of tyramine occur in some aged cheeses, yeast extracts (e.g., Marmite) and some types of salami. Caviar, pickled herrings, soy sauce, avocados and other foods have been implicated in this interaction. Note that any food high in aromatic amino acids can become high in tyramine if spoilage occurs or after storage. The RIMAs (moclobemide, toloxatone) interact with tyramine to a lesser extent, such that dietary restrictions are generally unnecessary.

**Clinical evidence**

A. Reactions to foods

(a) MAOIs

A rapid, serious, and potentially fatal rise in blood pressure can occur in patients taking MAOIs who ingest tyramine-rich foods or drinks. A violent occipital headache, pounding heart, neck stiffness, flushing, sweating, nausea and vomiting may be experienced. One of the earliest recorded observations specifically linking this reaction to cheese was in 1963 by a pharmacist called Rowe, who wrote to Blackwell after seeing the reaction of his wife who was taking Parstelin (tranylcypromine with trifluoperazine).

“After cheese on toast: within a few minutes face flushed, felt very ill; head and heart pounding most violently, and perspiration was running down her neck. She vomited several times, and her condition looked so severe that I dashed over the road to consult her GP. He diagnosed ‘palpitation’ and agreed to call if the symptoms had not subsided in an hour. In fact the severity diminished and after about 3 hours she was normal, other than a severe headache — but ‘not of the throbbing kind’. She described the early part of the attack ‘as though her head must burst’”.

Blackwell and his colleagues discuss a series of 25 early cases, and the information that led to this interaction becoming established. Tranylcypromine was the most frequently implicated MAOI: of 25 cases, 17 were with tranylcypromine, 6 with phenelzine and one each with pargyline and mebanazine. In addition, cheese was the most frequently implicated food, in 18 of 25 cases, with Marmite (yeast extract) in 3 and pickled herrings in one. Four patients had intracranial haemorrhages and one died. From 1961 up to February 1964 the US FDA found about 500 cases of induced hypertension with tranylcypromine and 38 cases of cerebral vascular accidents with 21 deaths. As a result, tranylcypromine was withdrawn in the US, although it was later reintroduced with many restrictions, including the need to avoid cheese while taking the drug.

In addition to reactions to cheese, cases of hypertensive reactions have been reported with avocados, beef livers and chicken livers, caviar, pickled herrings, sour creams, tinned fish, tinned milk, peanuts, soy sauce, miso, a powdered protein diet supplement (Ever-so-slim or Complan) packet soup (containing hydrolysed yeast), sour cream in coffee, and New Zealand prickly spinach (Tetragonia tetragonioides). [Note this is not a true spinach as found in the USA or Europe.]

These reactions occurred with tranylcypromine, phenelzine or unspecified MAOIs.

(b) Moclobemide

There do not appear to be any published reports of the ‘cheese reaction’ with moclobemide. The combination of Bovril (yeast extract) 12 g and moclobemide 150 mg, both three times daily, was used to normalise blood pressure in a patient with severe postural hypotension as a result of central autonomic failure.

B. Pharmacodynamic studies

Pharmacodynamic studies comparing RIMAs with MAOIs using oral tyramine sensitivity tests have revealed that only 20 to 50 mg of oral tyramine (given with a meal) is required to raise the systolic BP by 30 mmHg in subjects taking tranylcypromine 10 mg twice daily. In another study, the pressor tyramine dose was only 8 mg in those given tranylcypromine, but higher (33 mg) in those taking phenelzine. These pharmacodynamic studies confirm the clinical evidence that the cheese reaction is more likely with tranylcypromine.

The mean dose of oral tyramine (added to a meal) required to raise systolic BP by 30 mmHg (the tyramine 30 dose) was decreased fivefold (from 1450 mg to 306 mg, range 150 to 500 mg) by moclobemide 200 mg three times daily, in a double-blind, parallel group, placebo-controlled study in healthy subjects. In comparison, tranylcypromine 10 mg twice daily decreased the tyramine 30 dose by about 38-fold. In another study, the reduction in the tyramine 30 dose for moclobemide 150 mg three times daily was sevenfold; for phenelzine 60 mg daily, 13-fold; and for tranylcypromine 20 mg daily, 55-fold. After stopping the drugs, the pressor effect to tyramine normalised within 3 days for moclobemide, and 30 days for tranylcypromine. However, the pressor response had normalised in only 2 subjects 2 to 4 weeks after they stopped phenelzine, and had not normalised during the 11-week study period in the other 4 subjects. In a further study the tyramine 30 dose was reduced by about 4-fold by moclobemide 100 mg three times daily and 10.3-fold by phenelzine 15 mg three times daily. Numerous other pharmacological studies have confirmed the low increase in pressor response to tyramine with moclobemide.

The pressor response to oral tyramine 200 mg was not altered by pretreatment with toloxatone 200 mg or 400 mg three times daily in healthy subjects, although the effect of higher doses of tyramine was increased. Similar results were reported in an earlier study.

**Mechanism**

Tyramine is formed in foods such as cheese by the bacterial degradation of milk and other proteins, firstly to tyrosine and other amino acids, and the subsequent decarboxylation of the tyrosine to tyramine. This interaction is therefore not associated with fresh foods, but with those which have been allowed to over-ripen or ‘mature’ in some way, or if spoilage occurs. Tyramine is an indirectly-acting sympathomimetic amine, one of its actions being to release noradrenaline (norepinephrine) from the adrenergic neurones associated with blood vessels, which causes a rise in blood pressure by stimulating their constriction.

Normally any ingested tyramine is rapidly metabolised by the enzyme monoamine oxidase in the gut wall and liver before it reaches the general circulation. However, if the activity of the enzyme at these sites is inhibited (by the presence of an MAOI), any tyramine passes freely into the circulation, causing not just a rise in blood pressure, but a highly exaggerated rise due to the release from the adrenergic neurones of the large amounts of noradrenaline that accumulate there during inhibition of MAO. This final step in the interaction is identical to that which occurs with any other indirectly-acting sympathomimetic amine in the presence of an MAOI (see ‘MAOIs or RIMAs + Sympathomimetics; Indirectly-acting’, p.1147). RIMAs such as moclobemide and toloxatone selectively inhibit MAO-A, which leaves MAO-B still available to metabolise tyramine. This means that they have less effect on the tyramine pressor response than non-selective MAOIs.

**Importance and management**

An extremely well-documented, well-established, serious interaction. A potentially fatal hypertensive reaction can occur between the irreversible, non-selective MAOIs (see ‘Table 32.1’, (p.1130)) and tyramine-rich foods. Tranylcypromine is more likely to cause the reaction than phenelzine. The incidence is uncertain, but early estimates of hypertensive reactions to tranylcypromine (before restrictions in its use with indirectly-acting sympathomimetics and foods) range from 0.03% to 20%,2,24,25 Patients taking any of the non-selective MAOIs (isocarboxazid, nialamide,

phenelzine, pargyline, tranylcypromine, and iproniazid) should not eat foods reported to contain substantial amounts of tyramine (see ‘Table 32.3’, (above) and ‘Table 32.4’, (p.1155)). As little as 8 to 20 mg of tyramine can raise the blood pressure in patients taking tranylcypromine, and this may be present in usual portions of hard cheeses.6 In addition, avoidance of the prohibited foods should be continued for 2 to 3 weeks after stopping the MAOI to allow full recovery of the enzymes. However, note that in one study some patients took over 11 weeks to recover from the effects of phenelzine.16

Because tyramine levels vary so much it is impossible to guess the amount present in any food or drink. Old, over-ripe strong smelling cheeses with a salty, biting taste or those with characteristic holes due to fermentation should be avoided as they generally contain high levels of tyramine. Fresh cheeses made from pasteurised milk tend to have lower levels of tyramine. Fresh cheeses made from pasteurised milk tend to have lower levels of tyramine. Fresh cheeses made from pasteurised milk tend to have lower levels of tyramine.34,35 The tyramine-content can even differ significantly within a single cheese: the centre having the lowest levels of tyramine, and the rind, containing the most.34,35 There is no guarantee that patients who have uneventfully eaten these hazardous foodstuffs on many occasions may not eventually experience a full-scale hypertensive crisis, if all the many variables conspire together.28

The need to plan a sensible and safe diet for those taking MAOIs is clear, and over the years attempts have been made to produce simplified, practical diets for those taking MAOIs.29,30 A total prohibition should be imposed on the following: aged cheese and yeast extracts such as Marmite, and possibly also Bovril and pickled herring (see ‘Table 32.3’, (above)). A number of other foods should also be viewed with suspicion such as sauerkraut, fermented bologna and salami, pepperoni, and summer sausage because some of them may contain significant amounts of tyramine (see ‘Table 32.3’, (above)). Some preserved and fermented Far Eastern foods such as fermented soya beans, soya bean paste and soya bean curd (Tofu) can also contain relatively high tyramine levels.33,36 However, yoghurt, fresh cream and possibly chocolate are often viewed with unjustifiable suspicion. It also seems very doubtful if either cream cheese or cottage cheese represent a hazard, or processed cheese slices.32 Whole green bananas contain up to 65 micrograms of tyramine per gram, but this is mostly in the skin as the pulp contains relatively small amounts. Although case reports have occurred with a variety of other foods, it is generally acknowledged that widespread restrictions should not be imposed on a food based solely on an unsubstantiated isolated report,29,30,32 and that some reports could equally be attributed to spoilage.34,35 Therefore, of more importance is the advice to only eat protein-based foods (particularly meat, fish and liver) when fresh (within their sell-by date and after correct storage).30,35 Note that cooking does not inactivate tyramine. For the need to avoid broad-bean pods because of their dopamine content, see ‘MAOIs + Dop-a-rich foods’, p.1135. The RIMAs are safer (in the context of interactions with tyramine-rich foods and drinks) than the older MAOIs, because they are more readily reversible and selective. Therefore the risk of a serious hypertensive reaction with moclobemide is very much reduced. The authors of one study calculate...

Table 32.4 The tyramine content of some cheeses (continued)
This table is principally intended to show the extent and the variation that can occur

that the lowest amount of tyramine (150 mg) found to cause a 30 mmHg rise in systolic BP with moclobemide is equivalent to that found in about 200 g of Stilton cheese or 300 g of Gorgonzola cheese, which are really excessive amounts of cheese to be eaten in a few minutes. Moreover, no ‘cheese reactions’ appear to have been published for moclobemide. Most patients therefore do not need to follow the special dietary restrictions required with the older MAOIs, but, to be on the safe side, the manufacturers of moclobemide advise all patients to avoid large amounts of tyramine-rich foods, because a few individuals may be particularly sensitive to tyramine. This warning would also seem appropriate for all of the other RIMAs. Note that if moclobemide were given with an MAO-B inhibitor such as selegiline, it would essentially be the same as giving a non-selective MAOI, and dietary tyramine restrictions would then be required, see ‘MAO-B inhibitors + Tyramine-rich foods’, p.693.

Treatment
Severe hypertensive reactions require urgent immediate treatment. The drug most commonly used to control hypertensive reactions with MAOIs is phentolamine, given as a slow intravenous injection. However, the need for the patient to get to an emergency treatment centre delays treatment, and as a consequence, providing the patient with a drug they could self administer has been suggested. Sublingual nifedipine has been advocated, but does not appear to have been widely adopted, perhaps because the possibility of a sudden dramatic drop in blood pressure is just as dangerous. Another similar option is a small dose of chlorpromazine.

It is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice.

The manufacturer of moclobemide noted that in 1992 there were data available from 110 patients given moclobemide 150 to 400 mg daily with various antipsychotics, namely acepromazine, aceprometazine, alimemazine, bromperidol, chlorpromazine, chlorprothixene, clothiapine, cyamemazine, flupentixol, fluphenazine, fluspirilene, haloperidol, levomepromazine, penfluridol, pipamperone, prothipendyl, sulpiride, thioridazine, or zuclopenthixol. There was no evidence of any clinically relevant interactions. There was, however, some evidence that hypotension, tachycardia, sleepiness, tremor and constipation were more common, suggesting synergistic adverse effects.1

Cimetidine increases the plasma levels of moclobemide. Moclobemide dosage reductions are recommended.

**Clinical evidence, mechanism, importance and management**

After taking cimetidine 200 mg five times daily for 2 weeks the maximum plasma levels of a single 100-mg dose of moclobemide in 8 healthy subjects was increased by 39% and the clearance was reduced by 52%.1 The probable reason is that the cimetidine (a well-recognised enzyme inhibitor) reduces the first-pass metabolism of the moclobemide.

It has been recommended that if moclobemide is added to treatment with cimetidine it should be started at the lowest therapeutic dose, and titrated as required. If cimetidine is added to treatment with moclobemide, the dosage of the moclobemide should initially be reduced by 50% and later adjusted as necessary.2 3

Omeprazole doubled the AUC of moclobemide in extensive metabolisers of CYP2C19, effectively making them poor metabolisers. The clinical relevance of this is uncertain.

**Clinical evidence**

Omeprazole 40 mg daily for 7 days increased the AUC of a single 300-mg dose of moclobemide by about twofold in 8 healthy subjects who were extensive metabolisers of CYP2C19.1 After this increase, the AUC of moclobemide in these subjects was still lower than that seen in 8 healthy subjects who were poor metabolisers of CYP2C19 (without omeprazole). Omeprazole had no appreciable effect on the pharmacokinetics of moclobemide in the 8 subjects who were poor metabolisers of CYP2C19.

**Mechanism**

Omeprazole is an inhibitor of cytochrome P450 isoenzyme CYP2C19, by which moclobemide is extensively metabolised. Activity of this enzyme is genetically determined with about 5% of Caucasians and up to 20% of Asians being poor metabolisers. Consider also ‘Genetic factors’, (p.4).

**Importance and management**

The pharmacokinetic interaction is established, but its clinical relevance is unclear. Omeprazole effectively makes extensive metabolisers of moclobemide into poor metabolisers. Moclobemide is a fairly safe drug, and metaboliser status is usually unknown. Bear in mind the possibility of an interaction if adverse effects are seen in a patient on moclobemide given omeprazole.

Respiratory drugs

This section includes the diverse drugs that are principally used in the management of asthma and chronic obstructive pulmonary disease (COPD), with the exception of corticosteroids, which are covered elsewhere.

(a) Antimuscarinic bronchodilators

The parasympathetic nervous system is involved in the regulation of bronchomotor tone and antimuscarinic drugs have bronchodilator properties. Ipratropium bromide and other antimuscarinic bronchodilators used in COPD are listed in ‘Table 33.1’, (p.1159). A wide range of drugs have antimuscarinic (anticholinergic) adverse effects. Enhanced antimuscarinic effects occur when drugs with these properties are given concurrently, see ‘Antimuscarinics + Antimuscarinics’, p.674. However, these interactions do not usually occur with drugs such as ipratropium, given by inhalation.

(b) Beta2-agonist bronchodilators

Salbutamol and terbutaline are examples of short-acting beta agonists that selectively stimulate the beta2 receptors in the bronchi causing bronchodilation. They are used in the treatment of asthma and the management of COPD. Long-acting beta2 agonists such as salmeterol are used in patients with asthma who also require anti-inflammatory therapy. ‘Table 33.1’, (p.1159) lists the beta2 agonists available. The beta2 agonists represent a significant improvement on isoprenaline (isoproterenol), which also stimulates beta2 receptors in the heart, and on ephedrine, which also stimulates alpha receptors. The beta2 agonists can cause hypokalaemia, which can be increased by the concurrent use of other ‘potassium-depleting drugs’, (p.1162).

(c) Leukotriene antagonists

Montelukast and zafirlukast block the effects of cysteinyl leukotrienes, which cause effects such as airways oedema, bronchoconstriction and inflammation. The leukotriene antagonists are used in the treatment of asthma, either alone, or with inhaled corticosteroids. They should not be used to relieve an acute asthma attack. Both drugs are metabolised in the liver by the cytochrome P450 isoenzymes such as CYP3A4 and CYP2C9 (montelukast) and CYP2C9 (zafirlukast). Zafirlukast is thought to inhibit CYP2C9 and CYP3A4, and this is thought to be the mechanism for its interaction with ‘warfarin’, (p.423). There is therefore a possibility that interactions could occur with other drugs that undergo metabolism by these isoenzymes but clinical evidence of this varies.

(d) Xanthines

The main xanthines used in medicine are theophylline and aminophylline, the latter generally being preferred when greater water solubility is needed (e.g. in the formulation of injections). Xanthines are given in the treatment of asthma because they relax the bronchial smooth muscle. In an attempt to improve upon theophylline, various different derivatives have been made, such as diprophylline and enprofylline. ‘Table 33.1’, (p.1159) lists these xanthines. Theophylline is metabolised by the cytochrome P450 isoenzymes in the liver, principally CYP1A2, to demethylated and hydroxylated products. Many drugs interact with theophylline by inhibition or potentiation of its metabolism. Theophylline has a narrow therapeutic range, and small increases in serum levels can result in toxicity. Moreover, symptoms of serious toxicity such as convulsions and arrhythmias can occur before minor symptoms suggestive of toxicity. Within the context of interactions, aminophylline generally behaves like theophylline, because it is a complex of theophylline with ethylenediamine.

Caffeine is also a xanthine and it is principally used as a central nervous system stimulant, increasing wakefulness, and mental and physical activity. It is most commonly taken in the form of tea, coffee, cola drinks (‘Coke’) and cocoa. ‘Table 33.2’, (p.1159) lists the usual caffeine content of these drinks. Caffeine is also included in hundreds of non-prescription analgesic preparations with aspirin, codeine and/or paracetamol, but whether it enhances the analgesic effect is debatable. Caffeine is also used to assess the activity of hepatic enzyme systems (particularly the cytochrome P450 isoenzyme CYP1A2) and can usefully demonstrate altered liver function, notably from drugs, as well as disease states.

Caffeine, like theophylline, also undergoes extensive hepatic metabolism, principally by CYP1A2, and interacts with many drugs, but it has a wider therapeutic range. However, other xanthines may act differently (e.g. diprophylline does not undergo hepatic metabolism), so it should not be assumed that they all share common interactions.

Note though, that all xanthines can potentiate hypokalaemia caused by other drugs and that the toxic effects of different xanthines are additive.

The chewing of betel nuts may worsen the symptoms of asthma.

Clinical evidence
A study of a possible interaction with betel nuts was prompted by the observation of two Bangladeshi patients with severe asthma that appeared to have been considerably worsened by chewing betel nuts. One out of 4 other asthmatic patients who regularly chewed betel nuts developed severe bronchoconstriction (a 30% fall in FEV₁) on two occasions when given betel nuts to chew, and all 4 patients said that prolonged betel nut chewing induced coughing and wheezing. A double-blind study found that the inhalation of arecoline (the major constituent of the nut) caused bronchoconstriction in 6 of 7 asthmatics, and 1 of 6 healthy control subjects.1

A study in asthmatic patients who regularly chewed betel nuts found that 4 patients had a mean increase in their FEV₁ of 10 to 25%, whereas 11 patients had significant falls in their FEV₁ of 11 to 25%. Interestingly, 5 of the patients who did not think chewing betel nut affected their asthma experienced a reduction in their FEV₁.2

A survey in 61 asthmatic patients found that 22 of the 34 patients who still chewed betel nut, either for occasional use or regularly, reported that it worsened their asthma.3

Mechanism
Betel nut ‘quids’ consist of areca nut (Areca catechu) wrapped in betel vine leaf (Piper betle) and smeared with a paste of burnt (slaked) lime. It is chewed for the euphoric effects of the major constituent, arecoline, a cholinergic alkaloid, which appears to be absorbed through the mucous membrane of the mouth. Arecoline has identical properties to pilocarpine and normally has only mild systemic cholinergic properties; however, asthmatic subjects seem to be particularly sensitive to the bronchoconstrictor effects of this alkaloid and possibly other substances contained in the nut.

Importance and management
Direct evidence appears to be limited to the above reports, but the interaction seems to be established. It would not normally appear to be a serious interaction, but asthmatics should be encouraged to avoid betel nuts. This is a drug-disease interaction rather than a drug-drug interaction.

Anti-asthma drugs + Beta blockers
Non-cardioselective beta blockers (e.g. propranolol, timolol) should not be used in asthmatic subjects because they may cause serious bronchoconstriction, even if given as eye drops. Non-cardioselective beta blockers oppose the bronchodilator effects of beta-agonist bronchodilators, and higher doses may be required to reverse bronchospasm. Even cardioselective beta blockers (e.g. atenolol) can sometimes cause acute bronchospasm in asthmatics. However, cardioselective beta blockers do not generally inhibit the bronchodilator effect of beta-agonist bronchodilators.

Clinical evidence
(a) Cardioselective beta blockers
A review of 29 studies (including 19 single-dose studies) on the use of cardioselective beta blockers in patients with reversible airway disease indicated that in patients with mild to moderate disease, the short-term use of cardioselective beta blockers does not cause significant adverse respiratory effects. Information on the effects in patients with more severe or less reversible disease, or on the frequency or severity of acute exacerbations was not available.2 Another review indicated that when low doses of cardioselective beta blockers are given to patients with mild, intermittent or persistent asthma, or moderate persistent asthma, and heart failure or myocardial infarction, the benefits of treatment outweigh the risks. However, it was considered that further study is required to establish long-term safety, and also that beta blockers should be avoided in severe persistent asthma.2

The cardioselective beta blockers would not be expected to affect the beta receptors in the bronchi, but bronchospasm can sometimes occur following their use by asthmatics and others with obstructive airways diseases.15,16 Beta-blockers are used. Deterioration of asthma was reported in a patient taking oral betaxolol with theophylline and pranlukast, although betaxolol is considered to be highly cardioselective and less likely to cause pulmonary adverse effects than other cardioselective beta blockers.3

No adverse pharmacodynamic interaction normally occurs between beta-agonist bronchodilators and cardioselective beta blockers. This has been demonstrated in studies with:
- Atenolol with salbutamol (albuterol) inhalation.4,5
- Celiprolol in asthmatic patients with isoprenaline (isoproterenol), or salbutamol,6,7 or terbutaline infusion or inhalation.8
- Metoprolol in asthmatic patients at rest with isoprenaline infusion.9,10

In contrast, another study found that the increase in forced expiratory volume (FEV₁) with a terbutaline inhalation and infusion was reduced by about 500 mL by atenolol and metoprolol. The authors considered that this would be clinically relevant in severe asthma.11

Another study in 12 patients with mild asthma found that single doses of celiprolol 200 mg or nebivolol 5 mg reduced the FEV₁ by 272 mL and 193 mL, respectively, when compared with placebo. Increasing inhalation of salbutamol to a total dose of 800 micrograms reversed these reductions but did not restore the FEV₁ back to its initial value. None of these changes was considered to be clinically significant by the authors.12

Fifteen patients with mild to moderate COPD and airways hyperresponsiveness were given celiprolol 200 mg daily, metoprolol 100 mg daily or propranolol 80 mg daily for 4 days. Propranolol significantly reduced the FEV₁ and increased airways hyper-responsiveness compared with placebo whereas metoprolol only increased airways hyper-responsiveness. Celiprolol had no significant effects on pulmonary function. The bronchodilating effects of a single 12-microgram dose of formoterol were significantly reduced by propranolol, but not by metoprolol or celiprolol.13

(b) Non-selective beta blockers
Non-selective beta blockers (e.g. propranolol) are contraindicated in asthmatic subjects because they can cause bronchospasm, reduce lung ventilation and may possibly precipitate a severe asthmatic attack in some subjects. An example of the danger is illustrated by an asthmatic patient who developed fatal status asthmaticus after taking just one dose of propranolol.14

Another case report describes a patient with bronchial asthma receiving salbutamol who collapsed and died after taking three 20-mg propranolol tablets, which had been supplied in error instead of 20-mg prednisone tablets.14 The manufacturers of propranolol note that from 1965 to 1996, the CSM in the UK had received 51 reports of bronchospasm due to propranolol, 13 of them fatal, and 5 of them in patients who had a history of asthma, bronchospasm or wheeze.15 The non-cardioselective beta blockers expenrolol16 and propranolol17–19 oppose the effects of bronchodilators such as isoprenaline (isoproterenol).4,9,10 Salbutamol (albuterol),4,5 and terbutaline.4 Even eye drops containing the non-selective beta blockers timolol16,17 and metipranol18 have been reported to precipitate acute bronchospasm. In patients with heart failure treated with carvedilol, 3 of 12 with concurrent asthma had wheezing requiring carvedilol withdrawal. In contrast, only 1 of 31 patients with COPD had wheezing.19

Mechanism
Non-selective beta blockers such as propranolol also block the beta₂ receptors in the bronchi so that the normal bronchodilation, which is under the control of the sympathetic nervous system, is reduced or abolished. As a result the bronchoconstriction of asthma can be made worse. Cardioselective beta blockers on the other hand, preferentially block beta₁ receptors in the heart, with less effect on the beta₂ receptors, so that beta₂ stimulating bronchodilators, such as isoprenaline, salbutamol and terbutaline, continue to have bronchodilator effects.

Importance and management
A well established drug-disease interaction. In 1996, the CSM in the UK re-issued the following advice: “Beta blockers, including those considered to be cardioselective, should not be given to patients with a history of asth-
Anti-asthma drugs + NSAIDs

Aspirin and many other NSAIDs can cause bronchoconstriction in some asthmatic patients. Celecoxib, etoricoxib and meloxicam do not usually cause bronchospasm in aspirin or NSAID-sensitive patients. Aspirin, nimesulide and piroxicam appear not to alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) NSAIDs in asthma

About 10% of asthmatics are hypersensitive to aspirin, and in some individuals life-threatening bronchoconstriction can occur. This is not a drug-drug interaction but an adverse response of asthmatic patients to aspirin, whether taking an anti-asthmatic drug or not. The reasons are not fully understood. Those known to be sensitive to aspirin may also possibly react to other NSAIDs, in particular the acetylated salicylates, the indole and indene acetic acids, and the propionic acid derivatives (see ‘Table 6.1’). The salicinates, oxazepam and pyrazolidinediones are better tolerated.1 The nonacetylated salicylates (sodium salicylate, salicylamide, choline magnesium trisalicylate) are among those well tolerated. Aspirin-sensitive individuals are also less likely to react to nimesulide.1,2

In 60 patients with proven aspirin-sensitivity, celecoxib 100 mg on day one and 200 mg on day two caused no decline in forced expiratory volume.2 Two more studies found similar results.3,4 Celecoxib is a selective inhibitor of cyclooxygenase-2 and this supports the suggestion that inhibition of cyclooxygenase-1 may be critical in the precipitation of respiratory reactions in aspirin-exacerbated respiratory disease.1 This suggests that celecoxib may be an alternative in patients who are known to be aspirin sensitive. Nevertheless, the manufacturer of celecoxib contraindicates its use in patients who are sensitive to aspirin or NSAIDs.4 In a study in 21 patients with either asthma, nasal polyps, allergic rhinitis or a combination of these, challenged with meloxicam 7.5 mg, only one patient with a history of aspirin allergy developed bronchospasm and erythema with meloxicam.1 Another study found no reaction in 24 patients with a history of NSAID-induced respiratory hypersensitivity given meloxicam 7.5 to 15 mg daily.5 However, the manufacturer of meloxicam contraindicates its use in patients who are sensitive to aspirin or NSAIDs.5 Seventy-seven rheumatology patients with a history of asthma caused by aspirin or a NSAID and given ascending doses of etoricoxib 60 to 120 mg daily for 3 days had no respiratory or cutaneous reaction to etoricoxib even after rechallenge 5 days later.9

(b) NSAIDs with theophylline

Piroxicam 20 mg daily for 7 days had no effect on the pharmacokinetics of theophylline (given as a single 6–mg/kg intravenous dose of aminophylline) in 6 healthy subjects.10 Enteric-coated aspirin 650 mg daily for 4 weeks had no effect on the steady-state serum levels of theophylline in 8 elderly patients (aged 60 to 81) with chronic obstructive pulmonary disease.11 Nimesulide 100 mg twice daily for 7 days did not affect lung function in 10 patients with chronic obstructive airways disease taking slow-release theophylline 200 mg twice daily, although there was a slight, clinically insignificant fall in theophylline levels, possibly due to enzyme induction.2 The pharmacokinetics of the nimesulide were unchanged.12

Apart from checking that the patient is not sensitive to aspirin or any other NSAID (see (a) above), there would seem to be no reason for avoiding aspirin or piroxicam in patients taking theophylline.

Beta-agonist bronchodilators + Potassium-depleting drugs

Beta agonists (e.g. fenoterol, salbutamol (albuterol), terbutaline) can cause hypokalaemia. This can be increased by other potassium-depleting drugs such as the corticosteroids, diuretics (e.g. bendroflumethiazide, furosemide) and theophylline. The risk of serious cardiac arrhythmias in asthmatic patients may be increased.

Clinical evidence

(a) Corticosteroids

1. Hypokalaemia. The hypokalaemic effects of beta agonists, use of corticosteroids. Twenty-four healthy subjects had a fall in their serum potassium levels when they were given either salbutamol (albuterol) 5 mg or fenoterol 5 mg by nebuliser over 30 minutes. The fall in potassium levels was increased after they took prednisolone 30 mg daily for a week. The greatest fall (from 3.75 to 2.78 mmol/L) was found 90 minutes after fenoterol and prednisolone were taken. The ECG effects observed included ectopic beats and transient T wave inversion, but no significant ECG disturbances were noted in these healthy subjects.1

2. Anti-inflammatory/bronchodilator effects. A marked rise in asthma deaths was noted in New Zealand in the 1980s. A case-control study found that the risk of death was increased in oral corticosteroid-dependent asthmatics (severe asthma) who were also taking inhaled fenoterol.2 This, and other data, suggested the possibility that combined use of short-acting beta2 agonists and corticosteroids might be deleterious in some situations, prompting numerous studies, which were reviewed in 2000.3 The overall findings were that although inhaled corticosteroids do not prevent the pro-inflammatory effects of short-acting beta2 agonists, the combination is beneficial in the treatment of asthma at usual therapeutic doses of both drugs. The authors caution that this might not apply with excessive use of short-acting beta2 agonists.4 The addition of a long-acting beta2 agonist (e.g. salmeterol) to treatment in patients with chronic asthma inadequately controlled by inhaled corticosteroids and ‘as required’ short-acting beta2 agonists is beneficial.5,6

(b) Diuretics

The serum potassium level of 15 healthy subjects was measured after they were given inhaled terbutaline 5 mg with either a placebo, furosemide 40 mg daily, or furosemide 40 mg with triamterene 50 mg daily for 4 days. With terbutaline alone the potassium levels fell by 0.53 mmol/L; after taking furosemide as well they fell by 0.75 mmol/L; and after furosemide and triamterene they fell by 0.59 mmol/L. These falls were reflected in some ECG (T wave) changes.5

After 7 days of treatment with bendroflumethiazide 5 mg daily the serum potassium levels of 10 healthy subjects had fallen by 0.71 mmol/L. After taking 100 micrograms to 2 mg of inhaled salbutamol (albuterol) as well, the levels fell by 1.06 mmol/L, to 2.72 mmol/L. ECG changes consistent with hypokalaemia and hypomagnesaemia were seen.6 In another study the same authors found that the addition of bendroflumethiazide 5 mg daily to inhaled salbutamol 2 mg further reduced serum potassium levels by 0.4 mmol/L, to 2.92 mmol/L. This reduction was abolished by the addition of triamterene 200 mg (serum potassium increased to 3.43 mmol/L) or spironolactone 100 mg (serum potassium increased to 3.53 mmol/L) but triamterene 50 mg only attenuated the effect of bendroflumethiazide (serum potassium 3.1 mmol/L). ECG effects with this combination were also reduced by the addition of triamterene or spironolactone.7 Other diuretics that can cause potassium loss include bumetanide, furosemide, etacrynic acid, the thiazides, and many other related diuretics. See ‘Table 26.1,’ (p.944).

(c) Theophylline

The concurrent use of salbutamol (albuterol) or terbutaline and theophylline can produce a further fall in serum potassium levels, and other beta2 agonists will interact similarly. See ‘Theophylline + Beta-agonist bronchodilators’, p.1174.

Mechanism

Additive potassium-depleting effects.

Importance and management

Established interactions. The CSM in the UK8 advises that, as potentially serious hypokalaemia may result from beta2 agonist therapy, particular caution is required in severe asthma, as this effect may be potentiated by theophylline and its derivatives, corticosteroids, diuretics, and by hypoxia. Hypokalaemia with concurrent use of thiazide and loop diuretics may be reduced or even abolished by the addition of spironolactone or high-dose triamterene. Plasma potassium levels should therefore be monitored in patients with severe asthma. Hypokalaemia may result in cardiac arrhythmias in patients with ischaemic heart disease and may also affect the response of patients to drugs such as the digitalis glycosides and antiarrhythmics.

Note that the combined use of beta2 agonists and corticosteroids in asthma is usually beneficial.

Caffeine + Allopurinol

Allopurinol may invalidate the results of studies using caffeine as a probe drug for determining acetylator status or activity of CYP1A2.

Clinical evidence, mechanism, importance and management

In 21 healthy subjects, allopurinol 300 mg daily for 8 days altered the levels of urinary caffeine metabolites of a single 200–mg dose of caffeine. In particular, the metabolic ratio used to determine whether people are fast or slow acetylators was substantially changed. Thus, allopurinol may invalidate the results of phenotyping with the urinary caffeine test. In addition, the caffeine metabolite ratio used to express the activity of the cytochrome P450 isoenzyme CYP1A2 was not stable when allopurinol was used.1 This interaction is of relevance to research rather than clinical practice.

### Caffeine + Antiepileptics

Phenytoin can increase the clearance of caffeine, and possibly invalidates the caffeine breath test. Whether carbamazepine increases caffeine metabolism is unclear. Valproate appears not to have any effect on caffeine.

#### Clinical evidence

The clearance of caffeine was about twofold higher and its half-life was reduced by about 50% in patients with epilepsy taking phenytoin, when compared with healthy subjects not taking any medications. In the same study, there were no significant differences in caffeine pharmacokinetics between healthy subjects and patients receiving carbamazepine or sodium valproate.1 Conversely, carbamazepine was considered to have induced the metabolism of caffeine in 5 children with epilepsy, as assessed by the caffeine breath test.2 In another study in healthy subjects, there was a reduction in the AUC of carbamazepine when it was given with caffeine, but caffeine had no effect on the pharmacokinetics of sodium valproate.3

#### Mechanism

Phenytoin acts as an enzyme inducer, thereby increasing the metabolism of caffeine, lowering its levels. Carbamazepine possibly has the same effect.

#### Importance and management

Phenytoin may possibly invalidate the caffeine breath test, but normally no special precautions are needed if both drugs are taken. The interaction between carbamazepine and caffeine requires further study.

### Caffeine + Antifungals

Fluconazole and terbinafine cause a modest rise in serum caffeine levels. Ketoconazole appears to have less effect.

#### Clinical evidence, mechanism, importance and management

A study in 6 young subjects (average age 24) given fluconazole 400 mg daily and 5 elderly subjects (average age 69) given fluconazole 200 mg daily for 10 days found that fluconazole reduced the plasma clearance of caffeine by an average of 25% (32% in the young and 17% in the old).1 In a single-dose study in 8 healthy subjects, terbinafine 500 mg and ketoconazole 400 mg decreased caffeine clearance by 21% and 10%, respectively, and increased its half-life by 31% and 16%, respectively.2

It seems unlikely that these moderately increased serum caffeine levels will have a clinically important effect, but this needs confirmation.

### Caffeine + Artemisinin

Artemisinin reduces the metabolism of caffeine.

#### Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that a single 500-mg dose of artemisinin reduced clearance of a single 136.5-mg dose of caffeine by 35%. The metabolism of caffeine to one of its major metabolites, paraxanthine, was reduced by 66%.1 It was suggested that artemisinin inhibits the metabolism of caffeine by the cytochrome P450 isozyme CYP1A2 in the liver.1 There is too little information to advise patients taking artemisinin to completely avoid caffeine-containing beverages, foods or medication, but bear this interaction in mind if the adverse effects of caffeine (insomnia, jitteriness etc) become troublesome.

### Caffeine + Cimetidine

The clearance of caffeine is decreased by cimetidine but this seems unlikely to be clinically significant.

#### Clinical evidence, mechanism, importance and management

In 5 subjects cimetidine 1 g daily for 6 days increased the half-life of a single 300-mg dose of caffeine by about 70% and reduced caffeine clearance.1 In another study, cimetidine 1.2 g daily for 4 days increased the caffeine half-life by 45% in 6 smokers and by 96% in 6 non-smokers. The caffeine clearance was reduced by 31% in the smokers and by 42% in the non-smokers.2 A further study found that the caffeine half-life was increased by 59% and the clearance decreased by 40% by cimetidine.3 Conversely, in a further study in children, cimetidine was not found to affect caffeine metabolism as assessed by the caffeine breath test.4

The changes seen in some studies probably occurred because cimetidine, a well-known non-specific enzyme inhibitor reduced the metabolism of caffeine in the liver, resulting in its accumulation in the body.

Any increased caffeine effects are normally unlikely to be of much importance in most people, but they might have a small part to play in exaggerating the undesirable effects of caffeine from food, drinks (e.g. tea, coffee, cola drinks, chocolate) and analgesics, which are sometimes formulated with cimetidine.

### Caffeine + Class I antiarrhythmics

Caffeine clearance is reduced by 30 to 60% by mexiletine, resulting in raised serum caffeine levels. Whether this might result in caffeine toxicity is uncertain. Lidocaine, flecainide and tocainide do not appear to affect caffeine clearance. Caffeine does not significantly alter mexiletine levels.

#### Clinical evidence

(a) Mexiletine

In a study in 7 patients with cardiac arrhythmias taking long-term mexiletine 600 mg daily the clearance of caffeine was found to be reduced by 48%.1 In 5 healthy subjects given a single 200-mg dose of mexiletine, the clearance of a single 366-mg dose of caffeine was reduced by 57%, from 126 to 54 mL/minute, and the elimination half-life rose from approximately 4 to 7 hours.1 The clearance of mexiletine was not affected by caffeine. A preliminary report of this study also noted that fasting caffeine levels were almost sixfold higher during the mexiletine treatment period (1.99 compared with 0.35 micrograms/mL).2

Another study in 14 healthy subjects found that caffeine 100 mg four times daily, for 2 days before and 2 days after mexiletine, did not cause any significant changes in the plasma levels of a single 200-mg dose of mexiletine. Caffeine levels tended to be increased 24 hours after taking mexiletine.3

Mechanism
It is likely that, as with theophylline (see ‘Theophylline + Mexiletine or Tocainide’, p.1188), mexiletine inhibits the hepatic metabolism of caf feine by the cytochrome P450 isoenzyme CYP1A2.

Importance and management
The interaction between caffeine and mexiletine appears to be established, but its clinical importance is uncertain. Some of the adverse effects of mexiletine might be partially due to caffeine-retention (from drinking tea, coffee, cola drinks, etc.).1 In excess, caffeine can cause jitteriness, tremor and insomnia. It has also been suggested that the caffeine test for liver function might be impaired by mexiletine.2 Be alert for these possible effects.

Caffeine + Disulfiram
Disulfiram reduces the clearance of caffeine, which might complicate the withdrawal from alcohol.

Clinical evidence, mechanism, importance and management
A study in healthy subjects and recovering alcoholics found that disulfiram 250 or 500 mg daily reduced the clearance of caffeine by about 30%, but a few of the alcoholics had a more than 50% reduction.1 As a result the levels of caffeine in the body increased. Raised levels of caffeine can cause irritability, insomnia and anxiety, similar to the symptoms of alcohol withdrawal. As coffee consumption is often particularly high among recovering alcoholics, there is the risk that they may turn to alcohol to calm themselves down. To avoid this possible complication it might be wise for recovering alcoholics not to drink too much tea or coffee. Decaffeinated coffee and tea are widely available.

Caffeine + Echinacea
Echinacea appears to have a variable effect on the pharmacokinetics of caffeine.

Clinical evidence, mechanism, importance and management
In a pharmacokinetic study, 12 healthy subjects were given an 8-day course of *Echinacea purpurea* root 400 mg four times daily, with a single 200-mg oral dose of caffeine on day 6. The maximum serum concentration and AUC of caffeine were increased by about 30%. There was a large variation between subjects, with some having a 50% increase in caffeine clearance, and some a 90% decrease. The paraxanthine-to-caffeine ratio (a measure of CYP1A2 activity) was reduced by just 10%.1 In another study in 12 healthy subjects given *Echinacea purpurea* 800 mg twice daily for 28 days, the paraxanthine-to-caffeine ratio was not significantly affected when a single 100-mg dose of caffeine was given at the end of the treatment with *Echinacea purpurea*.2

It is possible that drugs that are metabolised by the cytochrome P450 isoenzyme CYP1A2 and have a narrow therapeutic index may be adversely affected by the concurrent use of Echinacea-containing products. For a list of drugs that are substrates of this enzyme, see “Table 1.2,” (p.4). Further study is required.

Caffeine + Fluvoxamine
The clearance of caffeine is considerably reduced by fluvoxamine. An increase in the stimulant and adverse effects of caffeine would be expected, however this was not demonstrated in one study. Caffeine may cause a reduction in the bioavailability of fluvoxamine.

Clinical evidence
In a randomised, crossover study, fluvoxamine 50 mg daily for 4 days and then 100 mg daily for a further 8 days was given to 8 healthy subjects, with a single 200-mg oral dose of caffeine before and on day 3 of fluvoxamine use. Fluvoxamine reduced the total clearance of caffeine by about 80% (from 107 to 21 mL/minute) and increased its half-life from 5 to 31 hours. Specifically, the clearance of caffeine by N3-, N1- and N7-demethylation was decreased.1 Another study in 30 patients found a positive correlation between plasma fluvoxamine and plasma caffeine levels, suggesting that the interaction is dose-related.2 A further study found that low, sub-therapeutic doses of fluvoxamine 10 or 20 mg daily were sufficient to markedly inhibit caffeine metabolism.3 A study in 7 subjects found that fluvoxamine 100 mg twice daily for 4 days significantly increased the maximum levels of a single 250-mg dose of caffeine by 40%, and increased the AUC and half-life of caffeine by 12.7-fold and 10-fold, respectively. However, this did not result in an increase in caffeine-related adverse effects, and none of the subjects felt they were more alert with the combination than with either drug alone.4

A study in 12 healthy subjects (6 smokers and 6 non-smokers, none were poor metabolisers of CYP2D6) found that caffeine 150 mg twice daily for 11 days reduced the AUC of a single 50-mg dose of fluvoxamine taken on day 8, by approximately 24%. The plasma concentration of fluvoxamine was also decreased by 12% but this was not significant.3

Mechanism
Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, which is the principal enzyme concerned with the metabolism of caffeine. As a result the caffeine is cleared from the body much more slowly and accumulates.1-3

Importance and management
The increase in caffeine levels with concurrent use would seem to be established. There are no reports of caffeine toxicity arising from this interaction and one study4 found no increase in the pharmacodynamic or adverse effects of caffeine despite a large increase in the levels. However, an increase in the stimulant and adverse effects of caffeine (headache, jitteriness, restlessness, insomnia) may be possible in susceptible patients if they continue to consume large amounts of caffeine-containing food or drinks (tea, coffee, cola drinks, chocolate, etc.) or take caffeine-containing medications. They should be warned to reduce their caffeine intake if problems develop. It has been suggested that some of the adverse effects of fluvoxamine (i.e. nervousness, restlessness and insomnia) could in fact be caused by caffeine toxicity. However, a preliminary study, as well as the study reported above,5 found that caffeine intake had a limited effect on the frequency of adverse effects of fluvoxamine.

The clinical significance of the change in the AUC of fluvoxamine with caffeine intake is unclear. This slight decrease is unlikely to be important in most patients.

Grapefruit juice does not interact with caffeine to a clinically relevant extent.

**Clinical evidence, mechanism, importance and management**

In 12 healthy subjects grapefruit juice, at a dose of 1.2 litres, decreased the clearance of caffeine from coffee by 23% and prolonged its half-life by 31%, but these changes were not considered clinically relevant.[^1] A crossover study in 6 healthy subjects given caffeine 3.3 mg/kg found that multiple doses of grapefruit juice (equivalent to 6 glasses) caused a non-significant increase in the AUC of caffeine. No changes in ambulatory systolic or diastolic blood pressure or heart rate were seen.^[2]

---

**Caffeine + Hormonal contraceptives or HRT**

The half-life of caffeine is prolonged to some extent in women taking combined oral contraceptives or HRT.

**Clinical evidence**

- **(a) Contraceptives**

  The clearance of a single 162-mg dose of caffeine was reduced, the half-life prolonged (7.9 compared with 5.4 hours), and the plasma levels were raised in 9 women taking low-dose combined oral contraceptives for at least 3 months, when compared with 9 other women not taking an oral contraceptive.^[3] This finding was confirmed in three other studies,[^4]^[4] which found that caffeine elimination was prolonged, from 4 to 6 hours before the use of combined oral contraceptives, to about 9 hours by the end of the first cycle, and to about 11 hours by the end of the third cycle.^[4] A further study found that there was little difference between the effects of two oral contraceptives (ethinylestradiol 30 micrograms with gestodene 75 micrograms or levonorgestrel 125 micrograms) on caffeine: both increased the half-life of caffeine by a little over 50%, but the maximum serum levels were unchanged.^[5]

- **(b) HRT**

  In one study, 12 healthy postmenopausal women were given a single 200-mg dose of caffeine after taking estradiol ( Estrace) for 8 weeks, treated to give estradiol plasma concentrations of 50 to 150 picograms/mL. The metabolism of caffeine was reduced by 29% overall. If the data for 2 subjects who were found to have taken extra caffeine during the study period are excluded, the caffeine metabolism showed an even greater average reduction of 38%.^[6]

**Mechanism**

Uncertain. Estrogens can inhibit the cytochrome P450 isoenzyme CYP1A2, by which caffeine is metabolised, which may explain its accumulation in the body.

**Importance and management**

An established interaction that is probably of limited clinical importance. Women taking oral contraceptives containing estrogens or HRT who take caffeine-containing analgesics or drink caffeine-containing drinks (tea, coffee, cola drinks, etc.) may find the effects of caffeine, such as jitteriness and insomnia, increased and prolonged.

[^5]: Rietveld EC, Broekman MMM, Houben JKG, Eskes TKAB, van Rossum JM. Rapid onset of the development of psychiatric disorders seen in patients taking idrocilamide, prompted a pharmacokinetic study in 4 healthy subjects. While taking oral idrocilamide 400 mg three times a day the half-life of caffeine (150 to 200 mg of caffeine from one cup of coffee) was prolonged from about 7 to 59 hours. The overall clearance of caffeine was decreased by about 90%.^[2]

---

**Caffeine + Menthol**

**Clinical evidence, mechanism, importance and management**

The possibility that caffeine ingestion might have had some part to play in the development of psychiatric disorders seen in patients taking idrocilamide, prompted a pharmacokinetic study in 4 healthy subjects. While taking oral idrocilamide 400 mg three times a day the half-life of caffeine (150 to 200 mg of caffeine from one cup of coffee) was prolonged from about 7 to 59 hours. The overall clearance of caffeine was decreased by about 90%.^[1]

Idrocilamide can inhibit the cytochrome P450 isoenzyme CYP1A2 by which caffeine is metabolised, leading to its accumulation. Evidence is limited but the interaction appears to be established. Patients taking oral idrocilamide should probably avoid or minimise their intake of caffeine, including caffeine-containing drinks (tea, coffee, cola drinks, etc.), otherwise caffeine toxicity may develop. Decaffeinated teas and coffee are widely available. Some medicines may contain caffeine, so these should also be used with care.

[^4]: Rietveld EC, Broekman MMM, Houben JKG, Eskes TKAB, van Rossum JM. Rapid onset of the development of psychiatric disorders seen in patients taking idrocilamide, prompted a pharmacokinetic study in 4 healthy subjects. While taking oral idrocilamide 400 mg three times a day the half-life of caffeine (150 to 200 mg of caffeine from one cup of coffee) was prolonged from about 7 to 59 hours. The overall clearance of caffeine was decreased by about 90%.^[2]

---

**Caffeine + Kava**

There are conflicting results from studies of the interaction of kava and caffeine. It appears that kava is unlikely to affect the pharmacokinetics of caffeine, although further study is required to confirm this.

**Clinical evidence, mechanism, importance and management**

In a study in 6 subjects (3 of whom smoked tobacco) who regularly took 7 to 27 g of kavalactones weekly as an aqueous kava extract, the metabolic ratio of caffeine was increased twofold when kava was withheld for 30 days, which suggested that kava inhibits the cytochrome P450 isoenzyme CYP1A2, which is involved in the metabolism of caffeine.^[1]

However, in a study in 12 non-smoking healthy subjects given kava kava root extract 1 g twice daily for 28 days before receiving a single 100-mg dose of oral caffeine, no significant change in the metabolic ratio of caffeine was noted.^[2] It is possible that the inhibitory effect of tobacco smoke on CYP1A2, and the lack of standardisation of kava intake may have influenced the results.

---

**Caffeine + Menthol**

A crossover study in 11 healthy subjects found that a single 100-mg dose of menthol taken with coffee containing 200 mg caffeine increased the time to maximum caffeine concentration by about 30 minutes. The increase in the actual maximum concentration was not significant, and there were no significant effects on caffeine half-life. It was thought that menthol reduced the rate of caf-
feine absorption. The clinical importance of this is not clear but it is seems likely to be small.

### Caffeine + Psoralens

Oral methoxsalen and 5-methoxypsoralen markedly reduce caffeine clearance but the clinical significance of this is uncertain. Topical methoxsalen does not interact with caffeine.

#### Clinical evidence

A single 1.2-mg/kg oral dose of methoxsalen (8-methoxypsoralen), given to 5 subjects with psoriasis 1 hour before a single 200-mg oral dose of caffeine, reduced the clearance of caffeine by 69%. The elimination half-life of caffeine over the period from 2 to 16 hours after taking the methoxsalen increased tenfold (from 5.6 to 57 hours). In a similar study, 8 patients with psoriasis were given caffeine 200 mg with or without 5-methoxypsoralen 1.2 mg/kg. The AUC of caffeine increased by about threefold and there was a threefold decrease in its clearance.

A study in patients receiving PUVA therapy (methoxsalen either orally, in 4 patients, ortopically as a bath in 7 patients, plus UVA) found that the clearance of a single 150-mg dose of caffeine was markedly reduced in the patients given oral methoxsalen but not altered in those given topical methoxsalen.

#### Mechanism

Both methoxsalen and 5-methoxypsoralen inhibit the hepatic metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2, thereby markedly increasing caffeine levels.

#### Importance and management

The practical consequences of this interaction are as yet uncertain, but it seems possible that the toxic effects of caffeine will be increased. In excess, caffeine (including that from tea, coffee and cola drinks) can cause jitteriness, headache and insomnia. The interaction does not appear to occur with topical methoxsalen.

### Caffeine + Quinolones

Enoxacin markedly increases caffeine levels. The effects of caffeine derived from drinks such as tea, coffee or cola, would be expected to be increased. Pipemidic acid interacts to a lesser extent, and ciprofloxacin, norfloxacin and pefloxacin interact less still. Fleroxacin, lomefloxacin, ofloxacin, rufloxacin, and trovafloxacin do not interact.

#### Clinical evidence

A study in patients receiving PUVA therapy (methoxsalen either orally, in 4 patients, or topically as a bath in 7 patients, plus UVA) found that the clearance of a single 150-mg dose of caffeine was markedly reduced in the patients given oral methoxsalen but not altered in those given topical methoxsalen.

#### Mechanism

Both methoxsalen and 5-methoxypsoralen inhibit the hepatic metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2, thereby markedly increasing caffeine levels.

#### Importance and management

The practical consequences of this interaction are as yet uncertain, but it seems possible that the toxic effects of caffeine will be increased. In excess, caffeine (including that from tea, coffee and cola drinks) can cause jitteriness, headache and insomnia. The interaction does not appear to occur with topical methoxsalen.

### Caffeine + Saw palmetto

Saw palmetto does not appear to affect the pharmacokinetics of caffeine.

#### Clinical evidence, mechanism, importance and management

Saw palmetto 160 mg twice daily was given to 12 healthy subjects for 28 days with a single 100-mg dose of caffeine at the end of treatment with saw palmetto. The metabolism of caffeine was not affected by the concurrent use of saw palmetto, which suggests that saw palmetto does not significantly affect the cytochrome P450 isoenzyme CYP1A2. Therefore the metabolism of other drugs that are substrates of CYP1A2 would not be expected to be affected by saw palmetto. For a list of drugs that are substrates of this isoenzyme, see ‘Table 1.2’, p.4.

*Unless otherwise stated quinolones were given for 3 to 5 days.
†Unless otherwise stated caffeine was given as a single dose.

Caffeine + Sho-saiko-to

Sho-saiko-to slightly reduces the metabolism of caffeine, but this is not expected to be clinically important.

Clinical evidence, mechanism, importance and management

In a study, 26 healthy subjects were given sho-saiko-to 2.5 g twice daily for 5 days, with a single 150-mg dose of caffeine on days 1 and 5. By assessing the metabolites of caffeine, it was estimated that sho-saiko-to caused a 16% inhibition of the cytochrome P450 isoform CYP1A2. The clinical significance of this finding is unclear, but is likely to be small, although further studies will help clarify this.1

Caffeine + St John’s wort (Hypericum perforatum)

St John’s wort appears to increase the metabolism of caffeine in women, but not men.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects given a single 200-mg dose of caffeine before and after St John’s wort 300 mg (containing 900 micrograms of hypericin) three times daily for 14 days, found no overall change in the pharmacokinetics of caffeine. However, when the subset of 8 female patients was considered, it was found that there was an induction of CYP1A2 in this group of patients resulting in an increase in the production of caffeine metabolites.1 More study is needed, as this may have important implications for other CYP1A2 substrates.

Caffeine + Tiabendazole

Tiabendazole reduces the metabolism of caffeine.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that a single 500-mg dose of tiabendazole reduced the clearance of caffeine by 66% and increased the half-life and AUC by 140% and 57%, respectively. The metabolism of caffeine to one of its major metabolites, paraxanthine, was reduced by 92%.1 It was suggested that tiabendazole inhibits the metabolism of caffeine by the cytochrome P450 isoform CYP1A2 in the liver. Tiabendazole is known to have clinically significant inhibitory effects on the metabolism of theophylline, (p.1171), and therefore would also be expected to affect caffeine metabolism. There is too little information to suggest that patients taking tiabendazole should avoid caffeine-containing beverages, foods or medication, but bear this interaction in mind if the adverse effects of caffeine (e.g. insomnia, jitters) become troublesome.1

Caffeine + Venlafaxine

Venlafaxine does not affect the pharmacokinetics of caffeine.

Clinical evidence, mechanism, importance and management

In 15 healthy subjects venlafaxine 37.5 mg twice daily for 3 days then 75 mg twice daily for 4 days did not affect the AUC or clearance of caffeine 200 mg daily (equivalent to about 3 cups of coffee). A slight but significant decrease in the half-life from 6.1 to 5.5 hours was noted.1 On the basis of this study, no special precautions are needed if both drugs are taken together.

Caffeine + Verapamil

A small and relatively unimportant decrease in the clearance of caffeine may occur in patients given verapamil.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects verapamil 80 mg three times daily for 2 days decreased the total clearance of a single 200-mg dose of caffeine by 25%, and increased its half-life by 25% (from 4.6 to 5.8 hours).1 These changes are small, and unlikely to be of much importance in most patients.

Doxofylline + Miscellaneous

There is some limited evidence to suggest that erythromycin may increase the effects of doxofylline, but the clinical importance of this is uncertain. Digoxin initially raises, then lowers serum doxofylline levels, but the bronchodilator effects do not appear to be significantly affected. Allopurinol and lithium carbonate appear to have no significant effects on doxofylline.

Clinical evidence, mechanism, importance and management

Healthy subjects were given doxofylline 400 mg three times daily, either alone, or with allopurinol 100 mg once daily, erythromycin 400 mg three times daily or lithium carbonate 300 mg three times daily. None of the pharmacokinetic parameters measured, including the maximum serum levels, were significantly altered by any of these drugs apart from the AUC of doxofylline, which was raised by about 40% by allopurinol, 70% by erythromycin, and 35% by lithium carbonate. Only the erythromycin result was statistically significant.1 The clinical significance of these changes is uncertain, and their mechanism is not understood. Until the sit-

---

---

tion is much clearer it would be prudent to check the outcome of adding erythromycin to established treatment with doxofylline, being alert for evidence of increased effects.

In a comparative study in 9 patients taking doxofylline 800 mg daily, di-goxin 500 micrograms daily was given to 5 patients. It was found that di-goxin increased the serum levels of doxofylline by 50% on the first day of treatment, 3 hours after administration but then reduced doxofylline levels by about 30% at steady-state (day 30). Nevertheless, the bronchodilating effects of the doxofylline were little different between the two groups. It was concluded that concurrent use is normally safe and effective, but the initial doxofylline dose should be chosen to avoid too high a serum level on the first day, and pulmonary function should be well monitored.2

Ipratropium bromide + Salbutamol (Albuterol)

Acute angle-closure glaucoma developed rapidly in eight patients given nebulised ipratropium and salbutamol. Increased intra-ocular pressure has been reported in others, including one patient using an ipratropium metered-dose inhaler with nebulised salbuta-mol.

Clinical evidence

Five patients with an acute exacerbation of chronic obstructive airways disease given nebulised ipratropium and salbutamol, developed acute an-gle-closure glaucoma, four of them within 1 to 36 hours of starting treat-ment. Two of the patients had a history of angle-closure glaucoma. Three other similar cases of acute angle-closure glaucoma due to the concurrent use of salbutamol and ipratropium are reported elsewhere.2 An increase in intra-ocular pressure has also been reported in other patients given both drugs by nebuliser.4 One case of acute angle-closure glaucoma has been reported in a patient treated with inhaled ipratropium, via a metered-dose inhaler, and nebulised salbutamol.5

Mechanism

This reaction appears to occur because the antimuscarinic action of the ipratropium causes semi-dilatation of the pupil, partially blocking the flow of aqueous humour from the posterior to the anterior chamber, thereby bowing the iris anteriorly and obstructing the drainage angle. The salbuta-mol increases the production of aqueous humour and makes things worse. Additional factors are that higher levels of both drugs are achieved by using a nebuliser, and that some drug may escape round the edge of the mask and have a direct action on the eye.1

Importance and management

An established but uncommon interaction, which appears to occur mainly in patients receiving these drugs by nebuliser and those already predis-posed to angle-closure glaucoma. The authors of the first report1 advise care in the placing of the mask to avoid the escape of droplets (the use of goggles and continuing the application of any glaucoma treatment is also effective)3 and, if possible, the avoidance of their concurrent use by nebuliser in patients predisposed to angle-closure glaucoma.

Montelukast + Antiepileptics

Phenobarbital modestly reduces montelukast levels, but this is not thought to be clinically significant. Phenytoin is predicted to interact similarly.

Clinical evidence, mechanism, importance and management

(a) Beta agonists

A study in patients with moderately severe asthma found no adverse interactions when salbutamol (albuterol) was given with montelukast 100 mg or 250 mg, with or without inhaled corticosteroids.1 The British Thoracic Society guidelines recommend that a leukotriene antagonist is used as an add-on therapy in patients using short-acting inhaled beta, agonists.2

(b) Corticosteroids

A study in healthy subjects (55 taking montelukast and 36 taking a placebo) found that the plasma profiles of oral prednisone 20 mg and of intra-venous prednisolone 250 mg were unaffected by montelukast 200 mg daily for 6 weeks.3 The manufacturers also report that licensed doses of montelukast do not have any clinically significant effect on the pharmacokinet-ics of prednisone and prednisolone.4 Other studies in patients using inhaled and/or oral corticosteroids have found that concurrent use is benefi-cial and well tolerated.5,7

However, an isolated report describes a case of marked peripheral oede-ma possibly linked to the use of prednisone and montelukast. A 23-year-old patient with severe allergic and exercise-induced asthma and rhinoconjunctivitis treated with salmeterol and fluticasone by inhalation and oral cetirizine was given prednisone 40 mg daily for one week then 20 mg daily for a further week. When Prednisone was stopped, severe asthma reoc-curred and he was given prednisone 60 mg daily for one week then 40 mg daily for a further week with montelukast 10 mg daily. After 10 days of treatment he developed severe peripheral oedema, gaining 13 kg in weight. Renal and cardiovascular function were normal. Prednisone was stopped and the asthma was controlled by continued montelukast and the excess weight was lost as the oedema resolved. The patient had good tol-erance of both prednisone and montelukast alone. Corticosteroid-induced renal tubular sodium and fluid retention may have occurred when mon-te lukast was also given.8

This isolated report is of uncertain general relevance. Usually, no special precautions appear to be needed if these drugs are used concurrently, and the British Thoracic Society guidelines recommend that a leukotriene an-tagonist is used as an add-on therapy to inhaled steroids in adults and children over five years of age.2

metric mean AUC and the maximum serum levels of the montelukast were reduced by 38% and 20%, respectively, but it was concluded that no montelukast dosage adjustment is needed. The reason for these reductions is almost certainly because phenobarbital induces the cytochrome P450 isozyme CYP3A4 so that montelukast metabolism is increased. The manufacturers therefore caution the use of montelukast with inducers of CYP3A4, such as phenytoin and phenobarbital, especially in children. However, there is so far no clinical evidence that the montelukast dosage needs adjustment in the presence of any of these drugs.

Montelukast + Magnesium Sulfate

Subcutaneous terbutaline and intravenous magnesium sulfate appear not to interact adversely.

Clinical evidence, mechanism, importance and management

Eight healthy adults were given two subcutaneous doses of terbutaline 250 micrograms 30 minutes apart, with and without intravenous magnesium sulfate 4 g in 250 mL of sodium chloride 0.9%, given over the same 30-minute period. Most of the effects of terbutaline, such as those on respiratory rate, blood pressure, glucose and calcium levels, were found to be moderately increased by magnesium sulfate at 60 minutes but these changes were all considered to be small. It was concluded that there appear to be no good reasons for avoiding their concurrent use, for example in the emergency treatment of asthma and other conditions.

Montelukast + Antihistamines

Montelukast does not interact to a clinically relevant extent with loratadine or terfenadine.

Clinical evidence, mechanism, importance and management

Healthy subjects were given terfenadine 60 mg every 12 hours for 14 days, with montelukast 10 mg daily from day 8 to day 14. It was found that the terfenadine pharmacokinetics and the QTc interval were unaltered by concurrent use. No adverse interactions were seen in large numbers of patients given montelukast 10 or 20 mg and loratadine 10 mg, and the combination was found to be beneficial in the treatment of allergic rhinitis and conjunctivitis. No special precautions are therefore needed if these drugs are given concurrently.

Montelukast + Rifampin (Rifampin)

The manufacturers of montelukast caution its use with inducers of the cytochrome P450 isozyme CYP3A4, such as rifampicin, especially in children. This is because phenobarbital (an inducer of CYP3A4) has been found to reduce the AUC and serum levels of montelukast. However, there is currently no clinical evidence that the montelukast dosage needs adjustment in patients taking rifampicin.

Theophylline + Allopurinol

Evidence from clinical studies and a single case report indicate that the effects of theophylline may be increased by allopurinol.

Clinical evidence

The peak plasma levels of theophylline 450 mg daily rose by 38% in a patient who took allopurinol for 3 days. In a study in 12 healthy subjects, allopurinol 300 mg twice daily for 14 days increased the half-life of a single 5-mg/kg oral dose of theophylline by 25%, and increased its AUC by 27%. Similar increases were seen when a second dose of theophylline was given 28 days after starting the allopurinol.

However, in two other studies allopurinol 300 mg daily for 7 days did not have any effect on the pharmacokinetics of theophylline, following a single 5-mg/kg intravenous dose of aminophylline.

Similarly, steady-state theophylline levels were not affected by allopurinol 100 mg three times daily in 4 subjects. However, there was an alteration in the proportion of different urinary theophylline metabolites: methyluric acid decreased and methylxanthine increased.

Mechanism

Uncertain. Allopurinol, a xanthine oxidase inhibitor, can block the conversion of methylxanthine to methyluric acid, but this had no effect on theophylline levels in two studies. One suggestion is that allopurinol inhibits the oxidative metabolism of theophylline by the liver.

Importance and management

Evidence appears to be limited to a single case report and the studies in healthy subjects. The interaction only appears to be of moderate importance. Nevertheless, it would seem prudent to check for any signs of theophylline adverse effects (headache, nausea, tremor) during concurrent use, particularly in situations where the metabolism of the theophylline may already be reduced (other drugs or diseases), or where high doses of allopurinol are used. For mention that allopurinol may invalidate the results of phenotyping tests using caffeine, see ‘Caffeine + Allopurinol’, p.1162.

Theophylline + Aloestron

Aloestron does not alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 10 healthy women were given aloestron 1 mg twice daily for 16 days with oral theophylline 200 mg twice daily from day 8 to day 16. No clinically relevant changes in the pharmacokinetics of theophylline were seen, and concurrent use was well tolerated. The effect of theophylline on aloestron pharmacokinetics was not measured but the authors of the report say that no metabolic interaction seems likely.1 No special precautions would therefore appear to be needed if these drugs are used together.

Theophylline + Aminogluthethimide

Theophylline clearance is increased by aminogluthethimide, which may result in a moderate reduction in the serum levels and therapeutic effects of theophylline.

Clinical evidence, mechanism, importance and management

Aminogluthethimide 250 mg four times a day increased the clearance of theophylline 200 mg twice daily by 18 to 43% in 3 patients.1 Theophylline clearance was assessed before starting aminogluthethimide as well as during weeks 2 to 12 of concurrent use.

It seems probable that aminogluthethimide, a known enzyme inducer, increases the metabolism of theophylline by the liver, thereby decreasing its levels. The clinical importance is uncertain, but it seems likely that the effects of theophylline would be reduced to some extent. Monitor the effects and if necessary take theophylline levels. Increase the theophylline dosage accordingly.

Theophylline + Altostron

An isolated case report describes an elderly man who developed raised theophylline levels and toxicity when he was given altostron.

Clinical evidence, mechanism, importance and management

An 86-year-old man taking furosemide, digoxin, domperidone and a sustained-release theophylline developed signs of theophylline toxicity when altostron 600 mg daily was given. After 9 days his serum theophylline levels had doubled, from about 16.8 to 35 mg/L. The toxicity disappeared when the theophylline was stopped.1 The reason for this adverse reaction is not understood but it has been suggested that altostron may lower the metabolism of theophylline by the liver.1 This is an isolated case and its general importance is uncertain. More study is needed.

Theophylline + Antacids

The extent of absorption of theophylline from the gut does not appear to be significantly affected by aluminium or magnesium hydroxide antacids. However, an increase in the rate of absorption of some sustained-release theophylline preparations may occur.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, there was no difference in the steady-state maximum serum concentrations or AUC of theophylline given as Nuclin-Depot or Theodur when an antacid (Novalac, containing aluminium/magnesium hydroxide and magnesium carbonate) was given. However, the antacid caused a faster absorption of theophylline from Nuclin-Depot, which resulted in greater fluctuations in the serum levels. It was considered that the adverse effects of theophylline might be increased in those patients with serum levels at the top of the range.1 Similar results have been found in single-dose studies when aminophylline,2 Slo-Phyllin Gyrocaps,3 Somophyllin CRT,4 and Theo-Dur were given with aluminium/magnesium hydroxide antacids, and in multiple dose studies in patients when Armophyllin,5 Aminophyllin or Theodur were given with aluminium/magnesium hydroxide antacids. Administration of 30 mL of an aluminium/magnesium hydroxide antacid (Maalox) four times daily did not affect the trough levels of theophylline in a patient taking Theo-Dur 400 mg three times daily.4 Care should be taken extrapolating this information to other sustained-release preparations of theophylline, but generally speaking no special precautions seem to be necessary if antacids are given with theophylline.

Theophylline + Anthelmintics; Benzimidazoles

Theophylline serum levels can be markedly increased by tiabendazole and toxicity may develop. Neither albendazole nor mebendazole appear to interact with theophylline.

Clinical evidence

(a) Albendazole

A study in 6 healthy subjects found that the pharmacokinetics of a single dose of theophylline were unaffected by a single 400-mg dose of albendazole.1

(b) Mebendazole

A study in 6 healthy subjects found that the pharmacokinetics of a single dose of intravenous aminophylline were unaffected by mebendazole 100 mg twice daily for 3 days.1 The absence of a significant interaction was reported in another similar study using the same mebendazole dosage.2

(c) Tiabendazole

An elderly man taking prednisone, furosemide, terbutaline and orciprenaline was switched from oral to intravenous aminophylline, giving a stable serum level of 21 mg/L after 48 hours. When he was also given tiabendazole 4 g daily for 5 days, for persistence of a Strongyloides stercoralis infestation, he developed theophylline toxicity (severe nausea) and his serum levels were found to be 46 mg/L. Three months previously, he had been treated with tiabendazole 3 g daily for 3 days without any symptoms of toxicity (no theophylline levels were measured).3 The theophylline levels of another patient rose from 15 to 22 mg/L when he was given tiabendazole 1.8 mg twice daily for 3 days, despite a theophylline dosage reduction of one-third, made in anticipation of the interaction. Theophylline levels were still elevated 2 days after the tiabendazole was stopped, and the theophylline dose was further reduced. Levels returned to normal after 5 days, and the theophylline dose was eventually increased again.4 A retrospective study of patients given theophylline and tiabendazole found that 9 out of 40 (23%) had developed elevated serum theophylline levels and of those 9 patients, 5 experienced significant toxicity, with 3 re-
Theophylline + Anti-histamines and related drugs

Azelastine, cetirizine, ketotifen, mequitazine, mizolastine, pemirast, repirinast, and terfenadine do not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

Azelastine 2 mg twice daily had no significant effect on the clearance of theophylline 300 mg twice daily in 10 subjects with bronchial asthma. However, one patient had a 20.8% increase and another a 25.3% decrease in clearance.1

A single 240-mg dose of intravenous theophylline was given to 6 healthy subjects after they had taken cetirizine 10 mg twice daily for 3.5 days. There was no change in theophylline pharmacokinetics, but the half-life of cetirizine was decreased by 19%. This change in cetirizine pharmacokinetics was not considered to be clinically relevant.2

Two studies, one in healthy adults1 and one in asthmatic children,4 showed that ketotifen did not affect the pharmacokinetics of a single oral dose of either theophylline1 or aminophylline.4 It was suggested that concurrent use might actually decrease the CNS adverse effects of each drug.3

In 7 asthmatic patients the steady-state pharmacokinetics of theophylline were not significantly affected when mequitazine 6 mg daily was given for 3 weeks.5

Mizolastine 10 mg daily had virtually no effect on the steady-state pharmacokinetics of theophylline in 17 healthy subjects, although a 13% increase in mean trough level and an 8% increase in the AUC was seen. These changes were not considered clinically relevant.6

Pemirast 10 mg daily for 4 days was found to have no significant effect on the steady-state serum levels or clearance of theophylline in 7 healthy subjects.7

Repirinast 300 mg daily had no effect on the pharmacokinetics of theophylline in 10 asthmatics given a single dose of aminophylline.8 Another study in 7 asthmatics found that repirinast (dosage unclear) for 3 weeks had no effect on the pharmacokinetics of theophylline 400 to 800 mg, given in two divided doses.9

In 10 healthy subjects the pharmacokinetics of a single 250-mg dose of theophylline were unchanged by terfenadine 120 mg twice daily for 16 days.10 Similarly, terfenadine 60 mg twice daily did not affect the steady-state pharmacokinetics of theophylline 4 mg/kg daily.11 Another study in 17 healthy, male subjects found no change in the pharmacokinetics of a single 4-mg/kg oral dose of theophylline (rounded to nearest 50 mg) when taken with a single 60-mg dose of terfenadine.12

No special precautions seem to be necessary if any of these drugs is given with theophylline.

Theophylline + Anticholinesterases; Centrally acting

The serum levels of theophylline are increased by tacrine. Donepezil has no effect on theophylline levels.

Clinical evidence, mechanism, importance and management

(a) Donepezil

An open-label, crossover study in 12 healthy subjects found that donepezil 5 mg daily for 10 days had no significant effects on the pharmacokinetics of theophylline. Dose modification or additional monitoring is not required during concurrent use.1

(b) Tacrine

Healthy subjects were given theophylline 158 mg alone or while taking tacrine 20 mg every 6 hours. The clearance of the theophylline was reduced by 50%, probably because the tacrine inhibits its metabolism by the cytochrome P450 isoenzyme CYP1A2 in the liver.2 Be alert for the need to reduce the theophylline dosage to avoid toxicity if tacrine is added. More study of this interaction is needed in patients given multiple doses of both drugs.

Theophylline + Azoles

Theophylline levels are normally unaffected or only minimally affected by fluconazole and ketoconazole. An isolated report describes a rise in serum theophylline levels due to fluconazole, and another describes falls in theophylline levels in three patients taking ketoconazole.

Clinical evidence

(a) Fluconazole

A crossover study in 5 healthy subjects found that fluconazole 100 mg given every 12 hours for 7 doses caused only a non-significant 16% decrease in the clearance of a single 300-mg oral dose of aminophylline.1 Another study in 10 healthy subjects found that fluconazole 100 mg daily for one week had no significant effect on the serum levels of theophylline 150 mg twice daily.2 The clearance of a single 6-mg/kg oral dose of theophylline was reduced by 13.4% in 9 subjects who took fluconazole 400 mg daily for 10 days.3 In contrast, an isolated and brief report says that one of 2 patients given theophylline and fluconazole had a rise (amount not specified) in serum theophylline levels.4

(b) Ketoconazole

No significant changes in the pharmacokinetics of a single 3-mg/kg intravenous dose of theophylline (given as aminophylline) were seen in 12 healthy subjects who took a single 400-mg dose of ketoconazole, or in 4 subjects who took ketoconazole 400 mg daily for 5 days.5 Similar results were found in another study in 10 healthy subjects who took ketoconazole 200 mg daily for 7 days.6 Ketoconazole 400 mg daily for 6 days increased the half-life of a single 250-mg oral dose of theophylline by 21.7% in 6 healthy subjects, but had no effect on its clearance.7 In contrast, a case report describes a man whose serum theophylline levels fell sharply from 16.5 to 9 mg/L (reference range 10 to 20 mg/L) over the 2 hours immediately after taking 200 mg of ketoconazole. A less striking fall was seen in 2 other patients.8

Mechanism

These antifungals appear to have minimal effects on the cytochrome P450 isoenzyme CYP1A2, which is concerned with the oxidative metabolism of theophylline.9,10 It is not clear why a few individuals show some changes in theophylline levels.

Importance and management

Information seems to be limited to these reports. Neither fluconazole nor ketoconazole normally appears to interact to a relevant extent in most patients. However, it seems that very occasionally some changes occur so bear this interaction in mind in the case of unexpected changes in theophylline levels, adverse effects or uncontrolled symptoms. Other azole antifungals such as itraconazole, posaconazole and voriconazole, which are substrates for and inhibitors of CYP2C19, CYP2C9, and/or CYP3A4, are also unlikely to interact with theophylline.11

Theophylline + Barbiturates

Theophylline serum levels can be reduced by phenobarbital or pentobarbital. A single report describes a similar interaction with secobarbital and it would be expected to occur with other barbiturates.

Clinical evidence

(a) Pentobarbital

A single case report describes a man receiving intravenous aminophylline who had a 95% rise in the clearance of theophylline after he was given high-dose intravenous pentobarbital.1 In healthy subjects pentobarbital 100 mg daily for 10 days increased the clearance of oral theophylline by a mean of 40% and reduced the AUC by 26%, although there were marked intersubject differences.2

(b) Phenobarbital

After taking phenobarbital (2 mg/kg daily to a maximum of 60 mg) for 19 days the mean steady-state serum theophylline levels in 7 asthmatic children aged 6 to 12 years were reduced by 30%, and the clearance was increased by 35% (range 12 to 71%).3 In contrast, two earlier studies (one by the same group of authors) found no significant change in the pharmacokinetics of theophylline, in asthmatic children given phenobarbital 2 mg/kg daily, or 16 or 32 mg three times daily.4,5

The mean theophylline clearance, from a single intravenous dose of aminophylline, was increased by 34% in healthy adult subjects given phenobarbital.6 In another study the clearance of theophylline was increased by 17% when phenobarbital was given for 2 weeks, although this was not significant.7 The effects of phenobarbital can be additive with the effects of phenytoin and smoking: one patient required 4 g of theophylline daily to maintain therapeutic serum levels and to control her asthma.8

One retrospective study found that premature infants needed a higher dose of intravenous aminophylline for neonatal apnoea when they were given phenobarbital,9 but a later prospective study failed to confirm this.10 A study in one set of newborn twins given intravenous aminophylline found that the serum theophylline levels of the twin given phenobarbital were about half those of the twin not given phenobarbital.11

(c) Secobarbital

The clearance of theophylline increased by 337% over a 4-week period in a child treated with periodic doses of secobarbital and regular doses of phenobarbital.12

Mechanism

The barbiturates are potent liver enzyme inducers, which possibly increase the metabolism of theophylline by the liver, thereby hastening its removal from the body. This has been shown in animal studies, although N-demethylation (the main metabolic route for theophylline) was not affected.13

Importance and management

A moderately well documented, established and clinically important interaction. Patients given phenobarbital or pentobarbital may need above-average doses of theophylline to achieve and maintain adequate serum levels. Concurrent use should be monitored and appropriate theophylline dosage increases made. All of the barbiturates can cause enzyme induction and may, to a greater or lesser extent, be expected to behave similarly. This is illustrated by the single report involving secobarbital. However, direct information about other barbiturates seems to be lacking. Note that theophylline itself can cause seizures, although mostly in overdose, and should be used with caution in patients with epilepsy.

Theophylline + BCG vaccine

BCG vaccine can increase the half-life of theophylline, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Two weeks after 12 healthy subjects were vaccinated with 0.1 mL of BCG vaccine, the clearance of a single 128-mg dose of theophylline (as choline theophyllinate) was reduced by 21% and the theophylline half-life was prolonged by 14% (range: 10% reduction to 47% increase). It therefore seems possible that the occasional patient may develop some signs of theophylline toxicity if their serum levels are already towards the top end of the therapeutic range but theophylline levels are unlikely to be affected in most patients given BCG vaccine.

Theophylline + Beta-agonist bronchodilators

The concurrent use of xanthines such as theophylline and beta-agonist bronchodilators is a useful option in the management of asthma and chronic obstructive pulmonary disease, but potentiation of some adverse reactions can occur, the most serious being hypokalaemia and tachycardia, particularly with high-dose theophylline. Some patients may have a significant fall in serum theophylline levels if given oral or intravenous salbutamol (albuterol) or intravenous isoproterenol (isoprotenerol).

Clinical evidence

(a) Fenoterol

A study in 12 patients with chronic airways disease found that oral fenoterol 2.5 mg three times daily did not affect the steady-state level of sustained-release theophylline 10.1 mg/kg twice daily. Another study in 8 healthy subjects found that the addition of sustained-release theophylline to inhaled fenoterol 600 and 800 micrograms increased the heart rate and systolic blood pressure. Theophylline levels were not affected.

(b) Formoterol

In a single-dose study, 8 healthy subjects were given oral doses of theophylline 375 mg and formoterol 144 micrograms. Combined use caused no significant pharmacokinetic interaction, but a significantly greater drop in the potassium level was seen, when compared with either drug given alone.

(c) Isoprenaline (Isoprotenerol)

An infusion of isoprenaline increased the clearance of theophylline (given as intravenous aminophylline) by a mean of 19% in 6 children with status asthmaticus and respiratory failure. Two of them had increases in clearance of greater than 30%. Another study in 12 patients with status asthmaticus found that an isoprenaline infusion (mean maximum rate 0.77 micrograms/kg per minute) caused a mean fall in serum theophylline levels of almost 6 micrograms/mL. The levels rose again when isoprenaline was stopped. A critically ill patient receiving intravenous aminophylline, methylprednisolone and nebulised terbutaline had a marked 4.5-fold increase in theophylline clearance when an isoprenaline infusion and intravenous aminophylline were added to the regimen.

2. Effects on theophylline levels.

(a) Isoprenaline (Isoproterenol)

In 6 healthy subjects isoprenaline 20 mg given every 8 hours by mouth or 1.95 mg given every 6 hours by inhalation for 3 days had no effect on the pharmacokinetics of theophylline (given as a single intravenous dose of aminophylline). This confirms a previous finding in asthmatic children, in whom it was shown that oral orciprenaline did not alter steady-state serum theophylline levels.

(e) Salbutamol (Albuterol)

1. Effects on heart rate or potassium levels. Pretreatment with oral theophylline for 9 days significantly increased the hypokalaemia and tachycardia caused by an infusion of salbutamol (4 micrograms/kg loading dose then 8 micrograms/kg for an hour) in healthy subjects. A potentially dangerous additive increase in heart rate of about 35 to 40% was seen in one study in 9 patients with COPD given infusions of aminophylline and salbutamol. Similarly, heart rate was significantly higher in 15 asthmatic children given single doses of oral theophylline and salbutamol (109 bpm) when compared with a control group given oral theophylline alone (91 bpm). However, another study in 18 patients with COPD and heart disease found that neither the occurrence nor the severity of arrhythmias seemed to be changed when oral theophylline was given with inhaled salbutamol. A 10-year-old girl given theophylline and salbutamol had a respiratory arrest, possibly related to hypokalaemia.

2. Effects on theophylline levels. Theophylline clearance was increased by a mean of 14%, and in 3 cases by greater than 30%, when salbutamol was given orally to 10 healthy subjects, but no changes in clearance were seen when salbutamol was given by inhalation. Another study reported a 25% reduction in serum theophylline levels in 10 patients who took oral salbutamol 16 mg. A child of 19 months given intravenous theophylline was also given an infusion of salbutamol: theophylline clearance was increased and the theophylline dose needed to be increased threefold to compensate. Peak flow readings were decreased in 15 children (aged 5 to 13 years) given single doses of oral salbutamol and theophylline, but theophylline levels were not significantly decreased. These reports contrast with another study in 8 healthy subjects, which found no change in the steady-state pharmacokinetics of oral theophylline given with oral salbutamol.

(f) Terbutaline

In 7 healthy subjects pretreatment with oral theophylline for at least 4 days significantly increased the fall in serum potassium levels and rises in blood glucose, pulse rate, and systolic blood pressure caused by an infusion of terbutaline. A study in children given slow-release formulations of both theophylline and terbutaline found no increases in reported adverse effects and simple additive effects on the control of their asthma. Oral terbutaline decreased serum theophylline levels by about 10% in 6 asthmatics, but the control of asthma was improved. Another study in asthmatic children, found that terbutaline elixir 75 micrograms/kg three times daily reduced steady-state serum levels of theophylline by 22%, but the symptons of cough and wheeze improved. Yet another study found no changes in the pharmacokinetics of aminophylline in asthmatic children given terbutaline.

(g) Unspecified beta2 agonists

In 1990, the CSM in the UK noted that, of 26 reports they had on record involving theophylline levels.8

Mechanism

Beta2 agonists can cause hypokalaemia, particularly when they are given parenterally or by nebulisation. Xanthines such as theophylline can also cause hypokalaemia, and this is a common feature of theophylline toxicity. The potassium-lowering effects of both these groups of drugs are additive. Why some beta agonists lower serum theophylline levels is not known.

Importance and management

Concurrent use is beneficial, but the reports outlined above illustrate some of the disadvantages and adverse effects that have been identified. In particular, it has been suggested that the use of intravenous beta agonists in acutely ill patients receiving theophylline may be hazardous because of the risk of profound hypokalaemia and cardiac arrhythmias. Monitoring of serum potassium in these situations was suggested. Moreover, the CSM in the UK particularly recommends monitoring potassium levels in those with severe asthma as the hypokalaemic effects of beta2 agonists can...
be potentiated by theophylline and its derivatives, corticosteroids, diuretics and hypoxia.1,2

See ‘betaxolol with theophylline and pranlukast’, (p.1160), for mention of a patient who had a deterioration of asthma with this combination.

23. Committee on Safety of Medicines. Theophylline + Beta blockers

Propranolol reduces the clearance of theophylline. More importantly, non-cardioselective beta blockers such as nadolol and propranolol, should not be given to asthmatic patients because they can cause bronchospasm. The concurrent use of theophylline and cardioselective beta blockers such as atenolol, bisoprolol or metoprolol is not contraindicated, but some caution is still appropriate. Atenolol and bisoprolol do not affect the pharmacokinetics of theophylline. Clinical evidence

(a) Pharmacokinetics

A study in 8 healthy subjects (5 of whom smoked 10 to 30 cigarettes daily) found that the clearance of a single 5.7 to 6.4 mg/kg dose of theophylline (as intravenous aminophylline) was reduced by 37% by propranolol 40 mg every 6 hours, when compared with theophylline alone. Metoprolol 50 mg every 6 hours did not alter the clearance in the group as a whole, but the smokers had an 11% reduction in clearance.1 Another study, in 7 healthy subjects, found that the steady-state plasma clearance of theophylline was reduced by 30% by propranolol 40 mg every 8 hours, and by 52% by propranolol 240 mg every 8 hours.2 However, a further study found no significant pharmacokinetic interaction between theophylline and propranolol.3 Three other studies found that the cardioselective beta blockers atenolol 50 to 150 mg,4 and bisoprolol 10 mg,5 and the non-selective beta blocker nadolol 80 mg4 did not affect the pharmacokinetics of theophylline.

(b) Pharmacodynamics

Beta blockers, particularly those that are not cardioselective, can cause bronchoconstriction, which opposes the bronchodilatory effects of theophylline. See ‘betaxolol with theophylline and pranlukast’, (p.1160), for mention of a patient who had a deterioration of asthma with this combination.

In a study in 8 healthy subjects both propranolol 40 mg every 6 hours and metoprolol 50 mg every 6 hours prevented the mild inotropic effect seen with theophylline alone.6

An infusion of propranolol reduced the hypokalaemia and tachycardia that occurred after a theophylline overdose.7 Esmolol has been used similarly.10

Mechanism

Propranolol possibly affects the clearance of theophylline by inhibiting its metabolism (demethylation and hydroxylation).3,11

Importance and management

The risk of severe, possibly even fatal bronchospasm when beta blockers are taken by asthmatics would seem to be far more important than any pharmacokinetic interaction with theophylline. See the warning in ‘Anti-asthma drugs + Beta blockers’, p.1160. Therefore the non-cardioselective beta blockers, such as propranolol, are contraindicated in patients with asthma or chronic obstructive pulmonary disease (COPD). Bronchospasm can occur with beta blockers given by any route of administration, even topically as eye drops. Cardioselective beta blockers do have less effect on the airways, but can still cause bronchoconstriction. See ‘Table 22.1’, (p.833), for details of the selectivity of beta blockers.

Consumption of caffeine-containing beverages can raise serum theophylline levels, but the clinical relevance of this is unclear. Clinical evidence, mechanism, importance and management

Caffeine can decrease the clearance of theophylline by 18 to 29%, prolong its half-life by up to 49% and increase its average serum levels by as much as 23%.1,2 In addition, caffeine plasma levels were increased about twofold when theophylline was given.2 In these studies, caffeine was given in the form of tablets1,2 or as 2 to 7 cups of instant coffee.3 In one study, 2 of the subjects who did not normally drink coffee experienced headaches and nausea.1 The probable mechanism of the interaction is that the two drugs compete for the same metabolic pathway resulting in a reduction in their metabolism and accumulation. In addition, when caffeine levels are high, a small percentage of it is converted to theophylline. There would, however, seem to be no good reason for patients taking theophylline to avoid caffeine (in coffee, tea, cola drinks, medications, etc.), but if otherwise unexplained adverse effects occur it might be worth checking if caf-

Theophylline + Caffeine

Consumption of caffeine-containing beverages can raise serum theophylline levels, but the clinical relevance of this is unclear.
feine is responsible. In addition, caffeine intake could have an impact on the interaction of theophylline with other drugs.

### Theophylline + Calcium-channel blockers

Giving calcium-channel blockers to patients taking theophylline normally has no adverse effect on the control of asthma, despite the small or modest alteration that may occur in serum theophylline levels with diltiazem, felodipine, nifedipine and verapamil.

However, there are isolated case reports of unexplained theophylline toxicity in two patients given nifedipine and two patients given verapamil. Isradipine appears not to interact.

#### Clinical evidence

**a**. Diltiazem

In 9 healthy subjects diltiazem 90 mg twice daily for 10 days reduced the clearance of theophylline (given as a single 6-mg/kg dose of aminophylline) by 21%, and increased its half-life from 6.1 to 7.5 hours.1 A 12% fall in the clearance of a single 5-mg/kg oral dose of theophylline was found when healthy subjects were given diltiazem 90 mg three times daily.2 In 8 patients with asthma or chronic obstructive pulmonary disease (COPD), diltiazem 60 mg three times daily for 5 days reduced the clearance of steady-state theophylline (given as a continuous infusion of aminophylline 12 mg/kg/day) by 22% and increased its half-life from 5.7 to 7.5 hours.3 Conversely, other studies found no significant changes in peak steady-state theophylline levels in 18 patients with asthma given diltiazem 240 to 480 mg daily for 7 days,4 or in 7 healthy subjects given diltiazem 120 mg twice daily for 7 days.5 Similarly, there was no significant change in the half-life or clearance of theophylline (given as a single 250-mg intravenous dose of aminophylline) in healthy subjects given diltiazem 120 mg three times daily for 6 days.6

**b**. Felodipine

In 10 healthy subjects felodipine 5 mg every 8 hours for 4 days reduced the plasma AUC of theophylline (given as theophylline aminopropanol; Oxyphylline) by 18.3%, but had no effect on metabolic or renal clearance.7

**c**. Isradipine

A three-way, crossover study in 11 healthy subjects found that isradipine 2.5 or 5 mg every 12 hours for 6 days had no significant effect on the pharmacokinetics of a single 5-mg/kg dose of aminophylline oral solution.8

**d**. Nifedipine

In one study, slow-release nifedipine 20 mg twice daily reduced the mean steady-state theophylline levels of 8 asthmasics by 30%, from 9.7 to 6.8 mg/L. Levels fell by 50%, 56%, and 64% in three of the patients, but no changes in the control of the asthma (as measured by peak flow determinations and symptoms) were seen.9 However, many other studies have found no changes, or only small to modest changes, in the pharmacokinetics of theophylline (given as oral theophylline or as intravenous lysine theophylline10 or aminophylline11) in healthy subjects10,11-12 or asthmatic patients13,14 given nifedipine. The control of the asthma was unchanged by nifedipine.13,14 Yet another study found that the combined use of slow-release theophylline and nifedipine improved pulmonary function and blood pressure control.15

In contrast, there are 2 case reports of patients who developed theophylline toxicity (theophylline levels raised to 30 mg/L and 41 mg/L), apparently due to the addition of nifedipine.16,17 In one case, the toxicity recurred on rechallenge, and resolved when the theophylline dosage was reduced by 60%.17 During a Swan Ganz catheter study of patient response to nifedipine for pulmonary hypertension, 2 patients developed serious nifedipine adverse effects, which responded to intravenous aminophylline.18

**e**. Verapamil

In one study, verapamil 80 mg every 6 hours for 2 days had no effect on the pharmacokinetics of theophylline (200 mg aminophylline every 6 hours) given to 5 asthmatics, and no effect on their spirometry (FVC, FEV1, FEF25-75).19 Similarly, another study found that verapamil 80 mg every 8 hours had no effect on the steady-state levels of sustained-release theophylline 3 mg/kg per day in healthy subjects.20 In contrast, numerous other studies in healthy subjects (given intravenous or oral aminophylline or theophylline) have found modest reductions in theophylline clearance of between 8% and 23% with verapamil 40 to 120 mg taken every 6 to 8 hours, 2,6,12,21-23 One study showed that the extent of reduction in clearance depended on the verapamil dosage.21 An isolated report describes a woman taking digoxin and sustained-release theophylline who developed signs of toxicity (tachycardia, nausea, vomiting) after starting to take verapamil 80 mg, increased to 120 mg every 8 hours. Her theophylline serum levels doubled over a 6-day period. Theophylline was later successfully reintroduced on one-third of the original dosage.24 Another isolated report describes a patient who needed a 50% reduction in their theophylline dose while taking verapamil 120 mg daily.25

#### Mechanism

It is believed that diltiazem and verapamil can, to a limited extent, decrease the metabolism of theophylline by the liver, possibly by inhibiting the cytochrome P450 isoenzyme CYP1A2.25 Similarly, nifedipine may alter hepatic theophylline metabolism,26 or it may increase the volume of distribution of theophylline.10,21 Felodipine possibly reduces theophylline absorption.7

#### Importance and management

The evidence for this interaction is adequately documented but the results are not entirely consistent. However, the overall picture is that the concurrent use of theophylline and these calcium-channel blockers is normally safe. Despite the small or modest decreases in the clearance or absorption of theophylline seen with diltiazem, felodipine and verapamil, and the quite large reductions in serum levels seen in one study with nifedipine, no adverse changes in the control of the asthma were seen in any of the studies. However, very occasionally and unpredictably theophylline levels have risen enough to cause toxicity in patients given nifedipine (2 case reports) or verapamil (2 case reports), so that it would be prudent to be aware of the possibility of an interaction when these drugs are given.
Theophylline + Cannabis

Cannabis smokers may need more theophylline than non-smokers to achieve the same therapeutic benefits, because the theophylline is cleared from the body more quickly.

Clinical evidence, mechanism, importance and management

One study found that tobacco or cannabis smoking similarly caused higher total clearances of theophylline (given as oral aminophylline) than in non-smokers (about 74 mL/kg per hour compared with 52 mL/kg per hour), and that clearance was even higher (93 mL/kg per hour) in those who smoked both. A later analysis by the same authors, of factors affecting theophylline clearance, found that smoking 2 or more joints of cannabis weekly was associated with a higher total clearance of theophylline than non-use (82.9 mL/kg per hour versus 56.1 mL/kg per hour). Tobacco and cannabis smoke contain poly cyclic hydrocarbons, which act as inducers of the cytochrome P450 isoenzyme CYP1A2, and this results in a more rapid clearance of theophylline from the body.

Little is known about the effects of smoking cannabis on theophylline levels, but be alert for the need to increase the theophylline dosage in regular smokers.

Consider also ‘Theophylline + Tobacco’, p.1201.

Theophylline + Carbamazepine

Two case reports describe a marked fall in serum theophylline levels when carbamazepine was given. Another single case report and a pharmacokinetic study describe a fall in serum carbamazepine levels when theophylline was given.

Clinical evidence

(a) Theophylline serum levels reduced

An 11-year-old girl with asthma was stable for 2 months taking theophylline, and phenobarbital until the phenobarbital was replaced by carbamazepine. The asthma worsened, her theophylline serum levels became subtherapeutic and the half-life of the theophylline was reduced from 5.25 to 2.75 hours. Asthmatic control was restored, and the half-life returned to pre-treatment levels 3 weeks after the carbamazepine was replaced by ethosuximide. The clearance of theophylline in an adult patient was doubled by carbamazepine 600 mg daily.

(b) Carbamazepine serum levels reduced

The trough carbamazepine levels of a 10-year-old girl were roughly halved when she was given theophylline for 2 days, and she experienced a grand mal seizure. Her serum theophylline levels were also unusually high at 26 mg/L for the 5 mg/kg dosage she was taking, so it may be that the convulsions were as much due to this as to the fall in carbamazepine levels.

A single-dose pharmacokinetic study in healthy subjects found that the AUC and maximum serum levels of carbamazepine were reduced by 31% and 45%, respectively, by oral aminophylline.

Mechanism

Not established, but it seems probable that each drug increases the liver metabolism and clearance of the other drug, resulting in a reduction in their effects. It is also possible that aminophylline interferes with the absorption of carbamazepine.

Theophylline + Cefalosporins

Ceftibuten and cefalexin appear not to interact with theophylline. Cefaclor has been implicated in two cases of theophylline pharmacokinetic interaction.

Clinical evidence, mechanism, importance and management

Ceftibuten 200 mg daily for 7 days was found to have no significant effect on the pharmacokinetics of a single intravenous dose of theophylline given to 12 healthy subjects. A study in 9 healthy adults given a single 5-mg/kg intravenous dose of aminophylline found that cefalexin 500 mg, then 250 mg every 6 hours for 48 hours, had no significant effect on the pharmacokinetics of theophylline.

A case report suggested that cefaclor might have been responsible for the development of theophylline toxicity in 2 children. However, a single-dose study and a steady-state study in healthy adults found that cefaclor 250 mg three times daily for 8 and 9 days, respectively, had no effect on the pharmacokinetics of oral or intravenous theophylline. Although the pharmacokinetics of theophylline differ in adults and children a significant interaction with cefaclor seems unlikely.

No special precautions seem to be necessary with any of these antibiotics. Note that acute infections per se can alter theophylline pharmacokinetics.

Theophylline + Clonipidine or Ticlopidine

Ticlopidine reduces the clearance of theophylline and is expected to raise its serum levels. Clonipidine, an analogue of ticlopidine, appears not to interact.

Clinical evidence, mechanism, importance and management

(a) Clonipidine

Clonipidine 75 mg daily for 10 days did not alter the steady-state pharmacokinetics of theophylline given to 12 healthy subjects. No problems are therefore anticipated with the concurrent use of these two drugs.

(b) Ticlopidine

In 10 healthy subjects ticlopidine 250 mg twice daily for 10 days reduced the clearance of a single 5-mg/kg oral dose of theophylline by 37% and increased the half-life by 44%, from about 8.5 hours to 12 hours. The reason for these effects is not known but it seems possible that ticlopidine inhibits the metabolism of theophylline by the liver. Information is limited, but it would seem prudent to monitor the effects of concurrent use: it may
be necessary to reduce the dosage of theophylline, particularly when serum levels are already at the top end of the range.

Theophylline + Codeine

A study in 6 healthy subjects found that codeine 30 mg prolonged the oral to caecal transit time of a single 500-mg dose of sustained-release theophylline (Theo-Dur). The mean amount left to be absorbed from the colon was reduced from 58% to 33%, but the time to 90% absorption of theophylline was not significantly affected (7.1 hours compared with 8.5 hours). Therefore codeine does not appear to significantly affect the rate or extent of absorption of theophylline, and concurrent use need not be avoided.1

Clinical evidence

(a) Betamethasone

The elimination half-life of theophylline (given as intravenous aminophylline) was no different in premature infants who had been exposed to betamethasone in utero than in those who had not, although the exposed neonates had a wider range of theophylline metabolites indicating greater hepatic metabolism.1,2

(b) Dexamethasone

In one study it was briefly mentioned that theophylline did not appear to affect dexamethasone metabolism.3

(c) Hydrocortisone

Three patients in status asthmaticus with relatively stable serum concentrations of theophylline were given a 500-mg intravenous bolus of hydrocortisone followed 6 hours later by 200 mg of hydrocortisone given every 2 hours for 3 doses. In each case the serum theophylline levels rose from about 20 mg/L to between 30 and 50 mg/L. At least 2 of the patients complained of nausea and headache.4 In contrast, 7 healthy subjects given sustained-release theophylline had no significant change in steady-state theophylline clearance when they were given a single 33-mg/kg dose of intravenous hydrocortisone, although there was a trend towards increased clearance.5 Intravenous bolus doses of hydrocortisone 500 mg or 1 g did not affect theophylline levels in patients taking choline theophyllinate 400 mg every 12 hours for 8 days.6

(d) Methylprednisolone

An 88% increase in the clearance of a single dose of intravenous aminophylline was seen in one of 3 healthy subjects pretreated with oral methylprednisolone.7 There was no significant change in clearance in the other 2 subjects. Another study in 10 children (aged 2 to 6) with status asthmaticus found that intramuscular methylprednisolone tended to increase the half-life of theophylline (given as oral aminophylline or theophylline).8 A further study also reported that when intravenous aminophylline was given to 16 children taking corticosteroids (route and type not specified) the theophylline half-life was prolonged from 5 to 6.2 hours, and the clearance was reduced by about one-third, when compared with 10 children not taking corticosteroids.9 Similarly, 7 healthy subjects given sustained-release theophylline had no significant change in steady-state theophylline clearance when they were given a single 1.6-mg/kg dose of intravenous methylprednisolone, although there was a trend towards increased clearance.5

(e) Prednisone or Prednisolone

A study in 6 healthy subjects showed that a single 20-mg oral dose of prednisone had no significant effect on the pharmacokinetics of a single 200-mg oral dose of aminophylline.10 The pharmacokinetics of a single 5.6-mg/kg intravenous dose of aminophylline was unchanged in 9 patients with chronic airflow obstruction when they were given prednisolone 20 mg daily for 3 weeks.11

Mechanism

Not understood.

Importance and management

The concurrent use of theophylline and corticosteroids is common and therapeutically valuable, whereas the few reported interactions of theophylline with oral or parenteral corticosteroids are poorly documented and their clinical importance is difficult to assess because both increases, small decreases and no changes in the serum levels of theophylline have been seen. It is also questionable whether the results of studies in healthy subjects can validly be extrapolated to patients with status asthmaticus. There do not appear to be any data on the effect of inhaled corticosteroids on the clearance of theophylline. Both theophylline and corticosteroids can cause hypokalaemia, and the possibility that this may be potentiated by concurrent use should be considered.

Theophylline + Corticosteroids

Theophylline and corticosteroids have established roles in the management of asthma and their concurrent use is not uncommon. There are isolated reports of increases in serum theophylline levels (sometimes associated with toxicity) when oral or parenteral corticosteroids are given, but other reports show no changes. The general clinical importance of these findings is uncertain. Both theophylline and corticosteroids can cause hypokalaemia, which may be additive.

Theophylline + Co-trimoxazole

Clinical evidence, mechanism, importance and management

In 6 healthy subjects co-trimoxazole 960 mg twice daily for 8 days had no effect on the pharmacokinetics of theophylline, given as a single 341-mg intravenous dose of aminophylline.1 Another study, in 8 healthy subjects, found that co-trimoxazole 960 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 267-mg oral dose of theophylline.2 No special precautions would seem necessary if these drugs are given concurrently. However, note that acute infections per se can alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects pre-treatment with dextropropoxyphene 65 mg every 8 hours for 5 days did not significantly change the total plasma clearance of steady-state theophylline 125 mg every 8 hours. There was a small reduction in the formation of the hydroxylated metabolite of theophylline. There would seem to be no need to avoid concurrent use or to take particular precautions.

Theophylline + Disulfiram

Theophylline clearance is decreased by disulfiram.

Clinical evidence

After taking disulfiram 250 mg daily for one week, the clearance of a 5-mg/kg intravenous dose of theophylline was decreased by a mean of about 21% (range 14.6 to 29.6%) in 20 recovering alcoholics. Those taking disulfiram 500 mg daily had a mean decrease of 32.5% (range 21.6 to 49.6%). Smoking appeared to have no important effects on the extent of this interaction. None of the patients were reported to have any significant liver disease, such as cirrhosis, which may also affect theophylline metabolism.

Mechanism

Disulfiram inhibits the liver enzymes concerned with the both the hydroxylation and demethylation of theophylline, thereby reducing its clearance from the body.

Importance and management

Information appears to be limited to this study but it would seem to be a clinically important interaction. Monitor the serum levels of theophylline and its effects if disulfiram is added, anticipating the need to reduce the theophylline dosage. Note that the extent of this interaction appears to depend upon the dosage of disulfiram used.

Theophylline + Ephedrine

A man taking theophylline developed marked tachycardia when he was given dobutamine.

Clinical evidence, mechanism, importance and management

An asthmatic patient taking sustained-release theophylline 150 mg twice daily, digoxin and spironolactone was anaesthetised for an aortic valve replacement with fentanyl, midazolam and pipecuronium. Following induction, intubation, and ventilation with 100% oxygen, his systolic blood pressure rose to 190 mmHg. The authors of the report attribute the tachycardia to an interaction between dobutamine and theophylline. They advise the careful titration of dobutamine in cardiac muscle and/or theophylline-induced potentiation of catecholamine action. They advise the careful titration of dobutamine in any asthmatic taking theophylline, particularly if a slow-release preparation is being used. However, more study of this apparent interaction is needed as this appears to be the only report, and so it’s general importance is unknown.

Theophylline + Doxapram

Doxapram pharmacokinetics are unchanged by theophylline in premature infants, but agitation and increased muscle activity may occur in adults.

Clinical evidence, mechanism, importance and management

Intravenous theophylline does not affect the pharmacokinetics of doxapram given to treat apnoea in premature infants. No adjustment of the dosage of doxapram is needed in the presence of theophylline. However, the manufacturers of doxapram say that there may be an interaction between doxapram and aminophylline or theophylline, which is manifested by agitation and increased skeletal muscle activity. Care should therefore be taken if these drugs are used together.

Theophylline + Enoximone

Aminophylline possibly reduces the beneficial cardiovascular effects of enoximone. Theoretically, milrinone would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

An experimental study into the mechanism of action of enoximone in 14 patients with ischaemic or idiopathic dilative cardiomyopathy found that pretreatment with intravenous aminophylline 7 mg/kg given over 15 minutes reduced the beneficial haemodynamic effects of intravenous enoximone 1 mg/kg given over 15 minutes. This appears to occur because each drug competes for inhibition of cAMP specific phosphodiesterases in cardiac and vascular smooth muscle. Milrinone, another phosphodiesterase inhibitor similar to enoximone, would be expected to interact in the same way. However, there are, at present, no published reports of a possible interaction with milrinone, and no case reports of a problem occurring with the concurrent use of either drug with theophylline. The clinical importance of this study therefore awaits evaluation.

The effect of food on theophylline bioavailability is unclear. In general it appears that fat or fibre in food has no effect, whereas high-protein and high-carbohydrate diets decrease and increase the theophylline half-life, respectively. Significant changes in theophylline bioavailability have been seen in patients given both enteral feeds and total parenteral nutrition.

Clinical evidence

(a) Food

The bioavailability of theophylline from sustained-release preparations has been shown to be reduced, increased, or unaffected when the theophylline was given immediately after breakfast. Dose dumping, leading to signs of theophylline toxicity, was seen in 3 children with asthma who were given a dose of Uniphyllin immediately after breakfast. The fat content or fibre content of meals does not seem to significantly affect theophylline absorption. High-protein meals appear to decrease theophylline half-life, whereas high-carbohydrate meals seem to increase it. There was no difference in theophylline metabolism in one study when patients were changed from a high-carbohydrate/low-protein diet to a high-protein/low-carbohydrate diet. One study found that changing from a high-protein to a high-carbohydrate meal had an effect on the metabolism of theophylline similar to that of cimetidine, and that the effects of the meal change and cimetidine were additive. The effects of spicy food have been studied, but the clinical significance of the changes are uncertain.

(b) Enteral feeds

A patient with chronic obstructive pulmonary disease had a 53% reduction in his serum theophylline levels accompanied by bronchospasm when he was fed continuously through a nasogastric tube with Osmolite. The interaction occurred with both theophylline tablets ( Theo-Dur) and liquid theophylline, but not when the theophylline was given intravenously as aminophylline. It was also found that the interaction could be avoided by interrupting feeding 1 hour either side of the oral liquid theophylline dose. Conversely, hourly administration of 100 mL of Osmolite did not affect the extent of theophylline absorption from a slow-release preparation (Solo-bid Gyrocaps) in healthy subjects, although the rate of absorption was slowed. Similarly, in healthy subjects, hourly administration of 100 mL of Ensure for 10 hours did not affect the rate or extent of absorption of theophylline from Theo-24 tablets.

(c) Parenteral nutrition

An isolated report describes an elderly woman treated with aminophylline by intravenous infusion who had a marked fall in her serum theophylline levels (from 16.3 to 6.3 mg/L) when the amino acid concentration of her diet was increased. In 7 patients with malnutrition ( marasmus-kwashiorkor) found only a small, probably clinically irrelevant increase in the elimination of a single intravenous dose of theophylline when they were fed intravenously.

Mechanism

Not fully understood. As with any sustained-release formulation, the presence of food in the gut may alter the rate or extent of drug absorption by altering gastrointestinal transit time. It has been suggested that high-protein diets stimulate liver enzymes thereby increasing the metabolism of the theophylline and hastening its clearance from the body. High carbohydrate diets have the opposite effect. The cytochrome P450 isoenzyme CYP1A2 (the principal enzyme involved in the metabolism of theophylline) is known to be induced by chemicals contained in cruciferous vegetables or formed by the action of high temperatures or smoke on meat. This suggestion is supported by a study in which charcoal-grilled (broiled) beef decreased the half-life of theophylline by an average of 22%. Further, high doses of daidzein, the principal isoflavone in soybeans, may inhibit CYP1A2 resulting in an increase in theophylline levels and half-life of about 33% and 41%, respectively.

Importance and management

Interactions between theophylline and food have been thoroughly studied but there seems to be no consistent pattern in the way the absorption of different theophylline preparations is affected. Be alert for any evidence of an inadequate response that can be related to food intake. Avoid switching between different preparations, and monitor the effects if this is necessary. Consult the product literature for any specific information on food and encourage patients to take their theophylline consistently in relation to meals with this in mind. Advise patients not to make major changes in their diet without consultation. Monitor the effects of both enteral and parenteral nutrition, since theophylline dosage adjustments may be required.

single 25-mg oral dose of furosemide. Conversely, 10 patients with asthma, chronic bronchitis or emphysema, receiving a continuous maintenance infusion of aminophylline, had a 21% rise in their serum theophylline levels, from 13.7 to 16.6 mg/L, 4 hours after being given a 40-mg intravenous dose of furosemide over 2 minutes. A crossover study in 12 healthy subjects failed to find any change in steady-state plasma theophylline levels when two 20-mg doses of oral furosemide were given 4 hours apart, although the overall renal clearance of theophylline was reduced.

Four premature neonates, two given oral and two given intravenous theophylline with furosemide had a fall in steady-state serum theophylline levels from 8 mg/L down to 2 to 3 mg/L when furosemide was given within 30 minutes of the theophylline.

A randomised, placebo-controlled study in 24 infants receiving ECMO (extracorporeal membrane oxygenation) found that theophylline 2 mg/kg enhanced the response to aminophylline 1 mg/kg. If the response were maintained over a 24-hour period an extra 110 mL/kg of fluid would have been lost.

**Mechanism**

Not understood, although in theory furosemide may cause increased renal excretion of theophylline, which could explain the reduced levels.

**Importance and management**

Information is limited and the outcome of concurrent use is inconsistent and uncertain. If both drugs are used be aware of the potential for changes in serum theophylline levels. Consider measuring levels, and make appropriate dosage adjustments as necessary. Both theophylline and diuretics can cause hypokalaemia, and the possibility that this may additive on concurrent use should be considered. More study is needed to assess the clinical significance of the effects of theophylline and furosemide on diuresis.

**Theophylline + Griseofulvin**

Griseofulvin does not appear to alter the pharmacokinetics of theophylline to a clinically relevant extent.

**Clinical evidence, mechanism, importance and management**

A study was initiated because it was suspected that griseofulvin might possibly interact with theophylline. In 12 healthy subjects griseofulvin 500 mg daily for 8 days reduced the half-life of theophylline from 6.6 to 5.7 hours, and increased the clearance of two of its metabolites, after a single oral dose of aminophylline (Teofyllamin). However, these changes are far too small to usually have any clinical relevance. There would appear to be no reason for avoiding concurrent use.

**Theophylline + H2-receptor antagonists**

Cimetidine raises theophylline serum levels and toxicity may develop. However, the extent of the interaction is unlikely to be clinically relevant in most patients with low-dose cimetidine. Famotidine, nizatidine, ranitidine and roxatidine appear not to interact.

**Clinical evidence**

(a) Cimetidine

A number of case reports describe significantly increased theophylline levels, including many that were toxic, in patients (adults and children) given oral or intravenous aminophylline or theophylline with cimetidine. A few cases describe serious adverse effects such as seizures. In a large number of pharmacokinetic studies healthy subjects were given oral or intravenous aminophylline or theophylline and patients were given oral or intravenous theophylline with cimetidine 800 mg to 1.2 g daily in divided doses for 4 to 10 days. It was clearly shown that cimetidine prolonged the half-life of theophylline by about 30 to 65% and reduced theophylline clearance by about 20 to 40%. Steady-state serum theophylline levels were raised about one-third. The effect of cimetidine was maximal in 3 days in one study assessing this. The extent of the interaction did not differ between cimetidine 1.2 g daily and 2.4 g daily in one study, although two further studies found that cimetidine 800 mg daily had less effect than cimetidine 1.2 g daily. A study investigating low-dose cimetidine (200 mg twice daily; UK non-prescription dosage) found only a 12% decrease in theophylline clearance. Two studies found that the effect of cimetidine did not differ between young and elderly subjects, whereas another found it was more pronounced in the elderly. The effects of cimetidine did not differ between smokers and non-smokers in one study, but were more pronounced in smokers in another. In a further study the effects of cimetidine were not affected by gender. Three studies found that the inhibitory effects of cimetidine and ‘ciprofloxacin’, (p.1192), were additive. Three studies found that intravenous cimetidine also inhibited the clearance of theophylline (given as intravenous aminophylline or sustained-release theophylline). In one of these, oral and intravenous cimetidine reduced theophylline clearance to the same extent, but when clearance was corrected for the lower bioavailability of the oral cimetidine, oral cimetidine resulted in a greater inhibition than intravenous cimetidine. Another study found that the effects of a continuous 50-mg/hour infusion of cimetidine were similar to those of an intermittent infusion of 300 mg every 6 hours. In contrast, a further study in healthy subjects found no clinically important interaction between intravenous aminophylline and an intravenous cimetidine infusion, but the aminophylline was given only 12 hours after starting the cimetidine, which may be insufficient for cimetidine to have had an effect. Similarly, a more recent study in 18 critically ill patients given a continuous 50-mg/hour intravenous infusion of cimetidine and low-dose aminophylline (10.8 mg/hour for just 48 hours found no clinically important interaction.

(b) Famotidine

Famotidine 40 mg twice daily for 5 days had no effect on the pharmacokinetics of theophylline (given as intravenous aminophylline) in 10 healthy subjects. In another study, 16 patients with bronchial asthma or chronic obstructive pulmonary disease (COPD) found that famotidine 20 mg twice daily for at least 3 days did not affect the clearance of theophylline. Two further studies also found no interaction between intravenous theophylline and famotidine 20 or 40 mg twice daily for 4 or 9 days in COPD.
patients.9,34 In a post-marketing surveillance study it was noted that 4
asthmatics taking theophylline had also taken famotidine 40 mg daily
for 4 to 8 weeks without any problems.35 In contrast, in a patient with
COPD and liver impairment, the AUC and serum levels of an intravenous
dose of theophylline were raised by 78% and the clearance was halved by famo-
tidine 40 mg daily for 8 days.36 A later study by the same authors in 7
patients with COPD similarly treated, but with normal liver function,
found that the AUC of theophylline was increased by 56% and its clearance
was reduced by 35% by famotidine.37

(c) Nizatidine

A study in 17 patients with chronic obstructive pulmonary disease found
that nizatidine 150 mg twice daily for a month had no effect on the steady-
state pharmacokinetics of theophylline.38 However, there were 6 reports
of apparent interactions in the Spontaneous Adverse Drug Reaction Database
of the FDA in the US up to the end of August 1989. Four patients taking
theophylline developed elevated serum theophylline levels, with symp-
toms of toxicity in at least one case, when given nizatidine. The problems
resolved when either both drugs, or just nizatidine were stopped.39

(d) Ranitidine

Many studies in healthy subjects (given intravenous aminophylline or oral
theophylline)10,11,15,19,41 and patients (given sustained-release theophyl-
line)11,20,42-44 have failed to find that ranitidine affects the pharmacokinet-
ics of theophylline, even in daily doses far in excess of those used
clinically. However, there are 7 reports describing a total of 10 patients, who developed theophylline toxicity
together with symptoms of toxicity in at least one case, when given nizatidine. The problems
resolved when both drugs were stopped.40

(e) Roxadustat

Roxadustat 150 mg daily did not affect the clearance of theophylline.45
Similarly, in 9 healthy subjects, roxadustat 150 mg twice daily did not sig-
nificantly change the pharmacokinetics of a single 250-mg intravenous
dose of aminophylline.46

Mechanism

Cimetidine is an enzyme inhibitor that reduces the metabolism (predomi-
nantly N-demethylation)65 of theophylline by the cytochrome P450 isoen-
zyme CYP1A2 in the liver, thereby raising its serum levels. Famotidine,
nizatidine and ranitidine do not have enzyme-inhibiting effects so that it is
clear why they sometimes appear to behave like cimetidine.

Importance and management

The interaction between theophylline and cimetidine is very well docu-
mented (not all the references being listed here), very well established and clinically
important. Theophylline serum levels normally rise by about

Theophylline + Hormonal contraceptives

Theophylline clearance is reduced to some extent in women taking a combined oral contraceptive, but no toxicity has been reported.

Clinical evidence

The total plasma clearance of a single 4-mg/kg oral dose of aminophylline was about 30% lower in 8 women taking a combined oral contraceptive (ethinylestradiol/norgestrel, Ovral) than in 8 other women not taking oral contraceptives.1 The theophylline half-life was also prolonged by about 30%, from 7.34 to 9.79 hours. Similar results were found in other studies in subjects given intravenous or oral aminophylline and combined oral contraceptives (ethinylestradiol/norgestrel, Ovral and mestranol/etynodiol diacetate, Ovulen or unnamed products).2,3 In contrast, no significant changes were seen in the pharmacokinetics of theophylline (given as intravenous aminophylline) in 10 adolescent women (15 to 18 years) taking low-dose combined or sequential oral contraceptives (ethinylestradiol/norethisterone), when compared with age-matched controls.4 However, in the same women the clearance of oral theophylline was found to be reduced by 33% after they took a triphasic oral contraceptive for 3 to 4 months.5 In a retrospective analysis of factors affecting theophylline clearance, the use of oral contraceptives was associated with a reduced theophylline clearance in women who smoked.6

Mechanism

Uncertain, but it seems possible that the oestrogenic component may inhibit the metabolism of the theophylline by the liver microsomal enzymes, thereby reducing its clearance.

Importance and management

An established interaction, but there seem to be no reports of theophylline toxicity resulting from concurrent use. Women taking combined oral contraceptives may need less theophylline than those not taking oral contraceptives. There is a small risk that patients with severe theophylline levels at the top end of the range may show some toxicity when oral contraceptives are added. It has been proposed that the effects may be more apparent with long-term, high-dose contraceptive use.1,4

Theophylline + Hormonal contraceptives

Theophylline + Imipenem

Seizures developed in three patients taking aminophylline or theophylline when they were given imipenem.

Clinical evidence, mechanism, importance and management

Two patients receiving intravenous aminophylline developed seizures within 11 to 56 hours of starting treatment with intravenous imipenem 500 mg every 6 to 8 hours. Seizures developed in a third patient taking theophylline after imipenem had been given for 6 days. In all 3, seizures occurred 2 to 3 hours after a dose of imipenem.1 The reasons for this effect are not known. Theophylline serum levels appeared to be unchanged.1 In an analysis of data from 1754 patients who had received imipenem in dose-ranging studies, 3% had seizures, and imipenem was judged to be associated with a third of these cases. However, the concurrent use of theophylline or aminophylline was not found to be a significant risk factor for the development of seizures with imipenem.2 The general importance of these cases is therefore uncertain.

Theophylline + Hormonal contraceptives

Theophylline + Idrocilamide

Idrocilamide given orally can increase serum theophylline levels.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects oral idrocilamide 600 mg daily for 3 days then 1.2 g for 4 days increased the half-life of a single dose of theophylline 2.5-fold, from 8.5 to 21.6 hours, and reduced the clearance by 67%.1 This is due to a reduction in the liver metabolism caused by the idrocilamide (see also ‘Caffeine + Idrocilamide’, p.1165). Information is very limited but it indicates that concurrent use should be closely monitored. Anticipate the need to reduce the theophylline dosage with oral idrocilamide.

Theophylline + Influenza vaccines

Normally none of the influenza vaccines (whole-virion, split-virion and surface antigen) interact with theophylline, but there are three reports describing rises in serum theophylline levels in a few patients (some to toxic levels), which was attributed to the use of an influenza vaccine.

Clinical evidence

(a) Evidence of no interaction

Mean steady-state serum theophylline levels were not altered by a trivalent split-virion influenza vaccine (Fluzone) in 12 patients with asthma, although one patient had an increase in levels (see (b), below). Levels were measured before vaccination and 1, 3, 7 and 14 days after vaccination.1 Theophylline levels were unchanged in 5 patients with COPD when they were given 0.5 ml of influenza vaccine (Flugeron).2 Similarly, no evidence of a rise in theophylline levels was found in a number of other studies in healthy subjects, both adults and children, receiving maintenance theophylline or aminophylline, and given various trivalent split-virion vaccines including Fluzone, Flugeron,1,3,4 Influvax,1,5 Mutagr.1,3 In addition, no change in the pharmacokinetics of the theophylline (given as oral aminophylline) was found after use of a whole-virion vaccine in healthy adults.1,3 No evidence of serious theophylline toxicity was seen in 119 elder...
early people taking maintenance theophylline and given an unspecified influenza vaccine.14

(b) Evidence of an interaction

Three patients who had been taking oral theophylline theophylline (6x-phylline) 200 mg (equivalent to 128 mg of theophylline) every 6 hours for at least 7 days had a rise in their serum theophylline levels of 219%, 89%, and 85%, respectively, within 12 to 24 hours of receiving 0.5 mL of trivalent split-virion influenza vaccine (Fluogen, Parke Davis). In some cases effects persisted for up to 72 hours, and two patients showed signs of theophylline toxicity. A subsequent study in 50 healthy subjects found that the same dose of vaccine more than doubled the half-life of theophylline, from 3.3 to 7.3 hours, and halved its clearance.15 A girl had a rise in theophylline levels from 20 to 34 mg/L (with no sign of toxicity) within 5 hours of being given a trivalent split-virion vaccine.16 In a study where 11 of 12 patients had no increase in theophylline levels after vaccination, theophylline was clamped to a normal serum level (from 10 to 24.5 mg/L) accompanied by headaches and palpitations.17

The clearance of theophylline (given as choline theophyllinate) was reduced by 25% one day after influenza vaccination (trivalent influenza vaccine, Fluogen, Parke Davis) in 8 healthy subjects, but this was of borderline significance. Theophylline metabolism had returned to pre-vaccination levels after 7 days.17 A patient with COPD treated with sustained-release theophylline 300 mg twice daily (theophylline levels between 7 and 12 mg/L) developed nausea and palpitations the day after he received a trivalent influenza vaccination (Fluogen). His theophylline level was increased to 26 mg/L. His dose was reduced to 200 mg twice daily and the adverse effects resolved. However, a few days later his COPD had become symptomatic and the theophylline level was found to be subtherapeutic, so the dose was raised to 300 mg twice daily, as before.18

Mechanism

Uncertain. If an interaction occurs, it has been suggested it is probably due to inhibition of the liver enzymes concerned with the metabolism of theophylline, possibly secondary to interferon production, resulting in theophylline accumulation in the body.15,17 One suggestion is that vaccine contaminants, which are potent interferon-inducing agents, may be responsible (rather than the vaccine itself), so that an interaction would seem to be less likely with modern highly-purified subunit vaccines.19 In one study where an interaction occurred, an increase in serum interferon levels was detected, whereas, in two of the studies showing no interaction, no interferon production was detected. Influenza infection per se can result in decreased theophylline clearance and theophylline toxicity.19

Importance and management

A very thoroughly investigated interaction, the weight of evidence being that no adverse interaction normally occurs with any type of influenza vaccine in children, adults or the elderly. Even so, bearing in mind the occasional and unexplained reports of an interaction,11,15,16,18 it would seem prudent to monitor the effects of concurrent use (for nausea headaches, palpitations), although problems are very unlikely to arise now that purer vaccines are used. If an interaction occurs, it has been suggested it is probably due to inhibition of liver enzymes.4,7

Theophylline + Interferons

Theophylline clearance is reduced by up to 50% by interferon alfa and by about 25% by interferon beta.

Clinical evidence

A study in 5 patients with stable chronic active hepatitis B and 4 healthy subjects found that 20 hours after being given a single 9- or 18-million unit intramuscular injection of interferon (recombinant human interferon alfa A), the clearance of theophylline (given as intravenous aminophylline) was approximately halved (range 33 to 81%) in 8 of the 9 subjects. The mean theophylline elimination half-life was increased from 6.3 to 10.7 hours (1.5 to sixfold increases). In the healthy subjects the theophylline clearances were noted to have returned to their former values 4 weeks after the study.11 Another study, in 11 healthy subjects given interferon alfa (Roferon-A) 3 million units daily for 3 days, found that the terminal half-life and AUC of theophylline (given as aminophylline) were only increased by 10 to 15%, with a similar decrease in clearance.18 In patients with cancer interferon alfa (Intron-A) 3 million units given 3 times a week for 2 weeks decreased the clearance of a single 150-mg oral dose of theophylline by 33%.3

Seven patients with chronic hepatitis C receiving interferon beta 3 to 9 million units daily for 8 weeks were given a single 250-mg dose of intravenous aminophylline. Interferon beta reduced the total body clearance of theophylline by 26% (range 5.8 to 57%) and increased the elimination half-life by 39% (range 27 to 139%), but had no significant effect on the volume of distribution, although there was wide inter-patient variability.4

Mechanism

Interferon alfa inhibits the liver enzymes 5 concerned with the metabolism of some drugs, such as theophylline. Therefore the metabolism of theophylline is reduced, and it accumulates. Interferon beta also appears to inhibit liver enzymes.5

Importance and management

Direct information appears to be limited to these reports, only one of which found clear evidence of a clinically important interaction. So far there appear to be no reports of toxicity but it would seem prudent to monitor concurrent use closely (nausea, headaches, palpitations), taking theophylline levels if necessary. Patients with enhanced metabolism (e.g. smokers) are predicted to be most at risk.1

Theophylline + Ipriflavone

An isolated report describes increased theophylline levels in a patient given ipriflavone.

Clinical evidence, mechanism, importance and management

The theophylline serum levels of a patient with chronic obstructive pulmonary disease, taking sustained-release theophylline 300 mg twice daily, rose from 9.5 to 17.3 mg/L when ipriflavone 600 mg daily for about 4 weeks was taken. No symptoms of toxicity occurred. The serum theophylline levels returned to roughly the initial level when the ipriflavone was stopped, and rose again when it was restarted. In vitro studies with human liver microsomes suggest that ipriflavone can inhibit the cytochrome P450 isoenzyme CYP1A2 and the demethylation of theophylline, which would reduce the metabolism of theophylline and increase its levels. Although so far only one case of this interaction has been reported, the in vitro studies suggest that it would be prudent to monitor the theophylline levels of any patient given ipriflavone, making any dosage reductions as necessary.

Theophylline + Leukotriene antagonists

Montelukast does not appear to alter theophylline levels. A single case report describes a rapid rise in theophylline levels in a patient given zafirlukast. Zafirlukast levels are modestly reduced by theophylline, but this does not appear to be clinically important.

Clinical evidence

(a) Montelukast

In a study in 16 healthy subjects, the pharmacokinetics of a single intravenous dose of theophylline were not significantly changed by montelukast 10 mg daily for 10 days, but when they were given montelukast 200 mg and 600 mg daily, the AUC of theophylline was reduced by 43% and 66%, respectively. These doses are 20 and 60-fold higher than the usual 10 mg daily dose, and therefore the clinical relevance of these effects is unclear.

(b) Zafirlukast

When zafirlukast was given with theophylline, the mean serum levels of zafirlukast were reduced by 30%, but the serum theophylline levels remained unchanged. In contrast, an isolated report describes a 15-year-old asthmatic taking sustained-release theophylline 300 mg twice daily (as well as inhaled fluticasone, salbutamol (albuterol) and salmeterol, and oral prednisolone) who became nauseous shortly after zafirlukast (dose not stated) was added to her treatment. An increase in her theophylline level from 11 to 24 mg/L was noted. The theophylline was stopped, and later attempts to reintroduce theophylline at lower doses resulted in the same dramatic increases in serum theophylline levels.

Mechanism

Not understood.

Importance and management

Information about interactions between theophylline and montelukast seems to be limited. The study above indicates that when using normal clinical doses of montelukast no special precautions or dosage alterations are needed. Similarly, no adverse interaction would normally seem to occur with zafirlukast and theophylline; the isolated case is of doubtful general significance.

Theophylline + Loperamide

Loperamide delays the absorption of theophylline from a sustained-release preparation.

Clinical evidence, mechanism, importance and management

A study of the effects of altering the transit time of drugs through the small intestine found that when 12 healthy subjects were given high-dose loperamide (8 mg every 6 hours for a total of 8 doses), the rate, but not extent, of absorption of a single 600-mg dose of sustained-release theophylline (Theo-24) was decreased. The maximum serum theophylline levels were reduced from 4.6 to 3.2 micrograms/mL, and this peak level occurred at 20 hours instead of 11 hours. One suggested reason for these effects is that loperamide inhibits the movement of the gut, thereby decreasing the dissolution rate of the Theo-24 pellets. More study is needed to establish the clinical significance of the interaction in patients receiving long-term theophylline.

Theophylline + Macrolides

Troleandomycin can increase serum theophylline levels, causing toxicity if the dosage is not reduced. Azithromycin, clarithromycin, dirithromycin, josamycin, midecamycin, rokitamycin, spiramycin, and telithromycin normally only cause modest changes in theophylline levels or do not interact at all. There are unexplained and isolated case reports of theophylline toxicity with josamycin and clarithromycin. Roxithromycin usually has no relevant interaction but a significant increase in theophylline levels was seen in one study. See also ‘Theophylline + Macrolides; Erythromycin’, p.1187.

Clinical evidence

(a) Azithromycin

In an analysis of the safety data from clinical studies of azithromycin, there was no evidence that the plasma levels of theophylline were affected in patients given both drugs. Similarly, no adverse effects were reported in another clinical study of patients taking azithromycin and theophylline. Azithromycin 250 mg twice daily did not affect the clearance or serum levels of theophylline in patients with asthma. However, a 68-year-old man had a marked but transient fall in his serum theophylline level when azithromycin was withdrawn, and this was confirmed on rechallenge. The same authors conducted a study in 4 healthy subjects given azithromycin 500 mg on day 1 then 250 mg daily for 4 days and sustained-release theophylline 200 mg twice daily. Theophylline levels were slightly elevated during the use of azithromycin, and a transient drop occurred 5 days after azithromycin was stopped.

(b) Clarithromycin

Clarithromycin 250 mg twice daily for 7 days had no effect on the steady-state serum theophylline levels of 10 elderly patients with COPD. Similarly, two other studies found that clarithromycin had little or no effect on theophylline pharmacokinetics. Another study in healthy subjects given clarithromycin 500 mg twice daily for 4 days found a 17% increase in the AUC and an 18% increase in the maximum plasma levels of theophylline, but this was considered clinically unimportant. In two clinical studies in patients with an acute bacterial exacerbation of chronic bronchitis the number of patients requiring an adjustment in theophylline dosage was similar when those who took clarithromycin were compared with those who took ampicillin. However, there are isolated reports of possible theophylline toxicity, including a case that resulted in rhabdomyolysis with renal failure requiring haemodialysis. For a report of theophylline toxicity in a patient also taking clarithromycin and levofloxacin, see ‘Theophylline + Quinolones’, p.1192.
Mechanism

It is believed that troleandomycin forms inactive cytochrome P450-metabolite complexes within the liver, the effect of which is to reduce the metabolism (N-demethylation and 8-hydroxylation) of theophylline, thereby reducing its clearance and increasing its levels. Clarithromycin, josamycin, midecamycin, and rokitamycin are thought to rarely form complexes, and azithromycin, dirithromycin, rokitamycin and spiramycin are not thought to inactivate cytochrome P450.39

Importance and management

The interaction between theophylline and troleandomycin is established and well documented. If troleandomycin is given, monitor the levels of theophylline closely and adjust the dose as necessary. Reductions of 25 to 50% may be needed.38,40 The situation with troleandomycin is uncertain since only 1 of 4 studies suggested an interaction, but it would be prudent to be alert for the need to reduce the theophylline dosage. Alternative macrolides that usually interact only moderately, or not at all are azithromycin, clarithromycin, dirithromycin, josamycin, midecamycin, rokitamycin and spiramycin. Telithromycin may also be a suitable alternative. However, even with these macrolides it would still be prudent to monitor the outcome because a few patients, especially those with theophylline levels at the high end of the range, may need some small theophylline dosage adjustments. In the case of azithromycin, care should be taken in adjusting the dose based on theophylline levels taken after about 5 days of concurrent use, as they may only be a reflection of a transient drop. In addition, acute infection per se may alter theophylline pharmacokinetics.

Theophylline + Macrolides; Erythromycin

Theophylline serum levels can be increased by erythromycin. Toxicity may develop in those patients whose serum levels are at the higher end of the therapeutic range unless the dosage is reduced. The onset may be delayed for several days, and not all patients demonstrate this interaction. Erythromycin levels may possibly fail to subtherapeutic concentrations.

Clinical evidence

(a) Effect on theophylline

The peak serum theophylline levels of 12 patients with COPD given amniphylline 4 mg/kg orally every 6 hours were raised by 28% by erythromycin. There was often wide inter-subject variability, and not all patients demonstrated the interaction. In addition to the studies, several studies in both healthy adults, and adults with COPD did not demonstrate any clinically significant interaction, although two of these studies found a reduction in the clearance of theophylline in some subjects.

(b) Effect on erythromycin

The peak levels of erythromycin 500 mg every 8 hours were almost halved and the AUC 0-8h was reduced by 38% when healthy subjects were given a single 250-mg intravenous dose of theophylline. Another pharmacokinetic study found that serum theophylline levels fell by more than 30% when intravenous theophylline was given with oral erythromycin. Other studies using intravenous erythromycin found no significant pharmacokinetic changes. The renal clearance was increased, but this did not affect the overall clearance.

Mechanism

The mechanism for the effects of erythromycin on theophylline levels is not fully understood. It seems most likely that erythromycin inhibits the metabolism of theophylline by the liver resulting in a reduction in its clearance and a rise in its serum levels. The human organic anion transporter 2 (hOat2) found in the liver may also be involved in this interaction. The reduction in erythromycin levels may be caused by theophylline affecting the absorption of oral erythromycin.

Importance and management

The effects of erythromycin on theophylline are established (but still debated) and well documented. Not all the reports are referenced here. It does not seem to matter which erythromycin salt is used. Monitor theophylline levels and anticipate the need to reduce the theophylline dosage to avoid toxicity. Not all patients will show this interaction but remember it may take several days (most commonly 2 to 7 days) to manifest itself. Some patients may have a high theophylline level but no clinical signs or symptoms. Therefore do not rely on symptoms alone to monitor for toxicity.

Limited evidence suggests that levels may return to normal 2 to 7 days after stopping erythromycin. There are many factors, such as smoking, which also affect theophylline kinetics, and which may play a role in altering the significance of the interaction in different patients. Those particularly at risk are patients with already high serum theophylline levels and/or taking high dosages (20 mg/kg or more). Ideally, use a non-interacting antibacterial if possible. However, where concurrent treatment cannot be avoided, a 25% reduction in theophylline dose has been recommended for patients with levels in the 15 to 20 μg/L range. but little dosage adjustment is probably needed for those at the lower end of the range, (below 15 μg/L) unless toxic symptoms appear. In practice erythromycin can probably be safely started with theophylline, with the levels monitored after 48 hours and appropriate dosage adjustments then made.

The fall in erythromycin levels caused by theophylline is not well documented, but what is known suggests that it may be clinically important. Be alert for any evidence of an inadequate response to the erythromycin and increase the dosage or change the antibacterial if necessary. Intravenous erythromycin appears not to be affected.

References

Theophylline + Methoxsalen

Oral methoxsalen markedly increases theophylline levels. Topical methoxsalen would not be expected to interact.

Clinical evidence, mechanism, importance and management

In a single-dose study in 3 healthy subjects a 1.2-mg/kg oral dose of methoxsalen increased the AUC of a single 600-mg dose of theophylline (given 1 hour later) 1.7-fold, 2.1-fold and 2.7-fold, in the 3 subjects, respectively. Methoxsalen probably inhibits the metabolism of theophylline by the cytochrome P450 isoenzyme CYP1A2. Although information is limited, the findings support what is known about caffeine and "psoralens", (p.1166). Theophylline dose reductions are likely to be required during concurrent use with systemic methoxsalen but seem unlikely to be necessary with topical use such as PUVA therapy.

No interaction of clinical importance normally takes place if metronidazole and ciprofloxacin or metronidazole are associated with seizures.7,8,9 Other case reports describe 1.5 to threefold increases in theophylline serum levels (accompanied by clear signs of toxicity in some instances) in a total of 10 patients who were given metronidazole.7,9 Theophylline dose reductions of 50% were required in 3 cases,6 although 2 of the patients that did not require dose reductions had initial theophylline levels below the therapeutic range.7 The arrhythmia of one patient was aggravated even at therapeutic serum theophylline levels, and mexiletine was discontinued.4 In 15 healthy subjects, metoxsalen 200 mg three times a day for 5 days reduced the clearance of a single 5-mg/kg intravenous dose of theophylline by 46% in women and 40% in men. The theophylline half-life was prolonged by 96% (from 7.4 to 14.5 hours) in women and 71% (from 8.7 to 14.9 hours) in men.3,4 Further studies in healthy subjects given theophylline with methoxsalen for 5 days found a reduction in steady-state theophylline clearance of about 45%, and an increase in the AUC of about 60%.

Theophylline + Metoclopramide

Metoclopramide does not appear to interact with slow-release theophylline.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects a single 10-mg dose of metoclopramide taken 20 minutes before a 600-mg dose of slow-release theophylline (Theo-Dur), caused a small but insignificant 14.5% reduction in the bioavailability of theophylline. However, adverse effects (nausea, headache, tremors, CNS stimulation) were seen more often in those taking metoclopramide than in those taking placebo, possibly because metoclopramide caused an earlier rise in theophylline levels, and because some of the adverse effects of these two drugs may be additive. A later study in 12 healthy subjects found that metoclopramide 15 mg every 6 hours had no effect on the rate or extent of absorption of a 600–mg dose of sustained-release theophylline (Theo-24). A similar lack of interaction was found in another study using Theo-Dur. There would seem to be no reason for avoiding concurrent use.

Theophylline + Mexiletine or Tocainide

No interaction of clinical importance normally takes place if metronidazole is given to patients taking theophylline, but an isolated report describes seizures in one patient also taking ciprofloxacin.

Clinical evidence, mechanism, importance and management

There were no significant changes in the pharmacokinetics of theophylline given as a single intravenous dose of aminophylline to 5 women taking metronidazole 250 mg three times a day for trichomoniasis.1 Another study in 10 healthy subjects confirmed this finding.2 However, an acutely ill elderly woman taking theophylline had a generalised seizure while being treated with metronidazole and ciprofloxacin, despite her theophylline level being within the therapeutic range (10 to 20 mg/L).3 Both ciprofloxacin and, more rarely, metronidazole are associated with seizures. Al though the evidence is limited, no special precautions would seem to be necessary during concurrent use.

Theophylline + Mexiletine or Tocainide

Serum theophylline levels are increased by mexiletine and toxicity may occur. Tocainide has only a small and probably clinically unimportant effect on theophylline pharmacokinetics.

Clinical evidence

(a) Mexiletine

A man developed theophylline toxicity within a few days of starting to take mexiletine 200 mg three times daily. His serum theophylline level rose from 15.3 to 25 mg/L, but fell to 14.2 mg/L, and the symptoms of toxicity resolved, when the theophylline dosage was reduced by two-thirds.1 Other case reports describe 1.5 to threefold increases in theophylline serum levels (accompanied by clear signs of toxicity in some instances) in a total of 10 patients who were given mexiletine.2,3 Mexiletine dose reductions of 50% were required in 3 cases,2,6 although 2 of the patients that did not require dose reductions had initial theophylline levels below the therapeutic range.3 The arrhythmia of one patient was aggravated even at therapeutic serum theophylline levels, and mexiletine was discontinued.4

In 15 healthy subjects, mexiletine 200 mg three times a day for 5 days reduced the clearance of a single 5-mg/kg intravenous dose of theophylline by 46% in women and 40% in men. The theophylline half-life was prolonged by 96% (from 7.4 to 14.5 hours) in women and 71% (from 8.7 to 14.9 hours) in men.3 Two further studies in healthy subjects given theophylline with mexiletine for 5 days found a reduction in steady-state theophylline clearance of about 45%, and an increase in the AUC of about 60%.9,10

(b) Tocainide

After taking tocainide 400 mg every 8 hours for 5 days, the pharmacokinetics of a single 5-mg/kg intravenous dose of theophylline was measured in 8 healthy subjects. The clearance was decreased by about 10% and the half-life slightly prolonged (from 9.7 to 10.4 hours), but these changes were not thought to be large enough to warrant altering theophylline dosage.

Mechanism

Mexiletine inhibits the metabolism (demethylation) of theophylline by the liver, thereby increasing its effects.8,10,12 It is possible that the interaction is due to competitive inhibition of the cytochrome P450 isoenzyme CYP1A2.13

Importance and management

The interaction between theophylline and mexiletine is established and of clinical importance. Monitor concurrent use and reduce the theophylline dosage as necessary to prevent the development of theophylline toxicity. It has been suggested that 50% dose reductions may be necessary.8 It seems doubtful if the interaction between theophylline and tocainide is clinically important but this needs confirmation.

Theophylline + Moracizine

Moracizine modestly increases theophylline clearance, although conversely animal data suggest that moracizine inhibits theophylline metabolism.

Clinical evidence

Single oral doses of aminophylline and a sustained-release theophylline preparation (TheoDurr) were given to 12 healthy subjects. After they took moracizine 250 mg three times daily for 2 weeks, the AUC of theophylline was reduced by 32% and 36%, its clearance was increased by 44% and 66%, and the elimination half-life decreased by 33% and 20%, for aminophylline and theophylline respectively.1

Mechanism

Uncertain. Moracizine is an enzyme inducer and appears to increase the metabolism of theophylline.1 In contrast, in vitro and animal data show moracizine to be an inhibitor of the cytochrome P450 isoenzyme CYP1A2, which is the main isoenzyme involved in the metabolism of theophylline.2 This would, in theory, be expected to lead to raised theophylline levels.

Importance and management

Information seems to be limited to this study. The clinical importance of this interaction has not been assessed, but monitor the effects of concurrent use and be alert for the need to adjust the theophylline dose. More study is needed.

Theophylline + Nefazodone

Nefazodone does not appear to interact adversely with theophylline.

Clinical evidence, mechanism, importance and management

Nefazodone 200 mg twice daily for 7 days had no effect on the pharmacokinetics or pharmacodynamics of theophylline 600 mg to 1.2 g daily in patients with chronic obstructive airways disease, nor was there any effect on their FEV1 values.1 No special precautions would seem necessary if both drugs are used.

Theophylline + Olanzapine

There appears to be no significant pharmacokinetic interaction between theophylline and olanzapine.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects given olanzapine 5 mg on day one, 7.5 mg on day 2 and then 10 mg daily for 7 days found no significant changes in the pharmacokinetics of theophylline (given as a single 350-mg intravenous dose of aminophylline). The pharmacokinetics of olanzapine also appeared to be unchanged when both drugs were given.1 No special precautions would appear to be necessary on concurrent use. The authors also conclude that olanzapine would not be expected to affect the pharmacokinetics of other drugs that are (like theophylline) substrates for the cytochrome P450 isoenzyme CYP1A2, see ‘Table 1.2’, (p.4).

Theophylline + Penicillins

Ampicillin, with or without sulbactam, and amoxicillin do not alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

A retrospective study in asthmatic children aged 3 months to 6 years found that the mean half-life of theophylline did not differ between those treated with ampicillin and those not.1 The pharmacokinetics of theophylline 8.5 mg/kg daily were not altered in 12 adult patients with chronic obstructive pulmonary disease when they were given ampicillin 1 g plus sulbactam 500 mg every 12 hours for 7 days.2 A study in 9 healthy adult subjects showed that amoxicillin 750 mg daily for 9 days did not affect the pharmacokinetics of theophylline 540 mg twice daily.3,4 No special precautions would seem to be necessary during concurrent use.

Theophylline + Non-prescription theophylline products

Patients taking theophylline should not take other medications containing theophylline (some of which are non-prescription products) unless the total dosage of theophylline can be adjusted appropriately.

Clinical evidence, mechanism, importance and management

A patient taking theophylline developed elevated serum theophylline levels of 35.7 micrograms/mL while taking Quinamm for leg cramps (old formulation containing quinine 260 mg and aminophylline 195 mg). This case report highlights the need to avoid the inadvertent intake of additional doses of theophylline if toxicity is to be avoided. The newer formulation of Quinamm does not contain theophylline.1 Note that non-prescription preparations containing theophylline are available in many countries. For example, some cough and cold preparations in the UK contain theophylline (e.g. Do-Do Chestez, Franol Plus). Patients should be warned.

Theophylline + Pentoxifylline

Pentoxifylline can raise serum theophylline serum levels.

Clinical evidence, mechanism, importance and management

Theophylline serum levels of 9 healthy subjects given sustained-release theophylline (TheoDur) 200 or 300 mg twice daily for 7 days were increased by 30% by pentoxifylline 400 mg three times daily. However, the change in levels ranged from a 12.8% decrease to a 94.8% increase. The subjects complained of insomnia, nausea, diarrhea and tachycardia more frequently while taking both drugs, but this did not reach statistical significance. The mechanism of this interaction is not understood, although note, pentoxifylline is also a xanthine derivative. Patients should be well monitored for theophylline adverse effects (headache, nausea, palpitations) while taking both drugs. More study is needed to clarify this highly variable interaction.

Theophylline + Phenylpropanolamine

Phenylpropanolamine reduces the clearance of theophylline.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects a single 150-mg oral dose of phenylpropanolamine decreased the clearance of theophylline (given as a single 4-mg/kg intravenous dose of aminophylline 1 hour after the phenylpropanolamine) by 50%. Such a large reduction in clearance would be expected to result in some increase in serum theophylline levels, but so far no studies of this potentially clinically important interaction seem to have been carried out in patients. Be alert for evidence of toxicity if both drugs are used. More study is needed. See also ‘Pseudoephedrine and related drugs + Caffeine’, p.1276.

Theophylline + Phenytoin

The serum levels of theophylline can be markedly reduced by phenytoin. Some limited evidence suggests that theophylline may also reduce phenytoin levels.

Clinical evidence

(a) Reduced phenytoin serum levels

A preliminary report noted that the seizure frequency of an epileptic woman taking phenytoin 100 mg four times daily increased when she was given intravenously, and then later oral, theophylline. Her serum phenytoin levels had more than halved, from 15.7 mg/L to around 5 to 8 mg/L. An increase in the phenytoin dosage to 200 mg three times daily raised her serum phenytoin levels to only 7 to 11 mg/L until the drugs were given 1 to 2 hours apart. The patient then developed phenytoin toxicity with a serum level of 33 mg/L. A subsequent single-dose study in 4 healthy subjects confirmed that higher serum levels of both drugs were achieved when the theophylline and phenytoin were given 2 hours apart rather than simultaneously. Another study in 7 healthy subjects found that the AUC of a single 400-mg dose of phenytoin was reduced by 21% when it was given at the same time as a single 7.5-mg/kg dose of theophylline compared with a reduction of 7% when the same doses were given 2 hours apart.

A later preliminary study in 14 subjects (by some of the same authors) found that after 2 weeks of concurrent use, the mean serum phenytoin levels of 5 of the subjects rose by 40% and the mean levels of the group as a whole rose by about 27% when the theophylline was stopped. Urinary concentrations of a phenytoin metabolite were raised.

(b) Reduced theophylline serum levels

The observation that a patient taking phenytoin had lower than expected theophylline levels prompted a study in 10 healthy subjects. After taking phenytoin for 10 days the clearance of theophylline (after a single intravenous dose of aminophylline) was increased by 73%, and both its AUC and half-life were reduced by about 50%.

Another study in 6 healthy subjects showed that after taking phenytoin 300 mg daily for 3 weeks the mean clearance of theophylline (after a single intravenous dose of aminophylline) was increased by 45% (range 31 to 65%). Similar results were found in a further study. Other reports on individual asthmatic patients have shown that phenytoin can increase the clearance of theophylline by about 1.3- to 3.5-fold. Another study and a case report show that the reduction in theophylline levels caused by phenytoin can be additive with the effects of smoking. A subsequent study found that the extent of phenytoin-induced metabolism of theophylline was not affected by age, despite an age-related reduction in theophylline metabolism. Consider also ‘Theophylline + Tobacco’, p.1201.

Mechanism

Uncertain. It has been suggested that theophylline either impairs phenytoin absorption or induces phenytoin metabolism, but neither suggestion seem likely.

It seems probable that phenytoin, a known enzyme inducer, increases the metabolism of theophylline by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby increasing its clearance.

Importance and management

The effect of phenytoin on theophylline is established and of clinical importance. Patients given both drugs should be monitored to confirm that theophylline remains effective. Ideally the serum levels should be measured to confirm that they remain within the therapeutic range. Theophylline dosage increases of up to 50% or more may be required. Conversely, patients should be monitored for signs of toxicity and theophylline levels should be checked in patients who stop phenytoin. The effect of theophylline on phenytoin is not established and the documentation is limited. It may be prudent to monitor phenytoin levels as well. Separating the doses appears to minimise any interaction. Note that theophylline itself can cause seizures, although mostly in overdose, and should be used with caution in patients with epilepsy.

Theophylline + Pirenzepine

Pirenzepine does not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

Pirenzepine 50 mg twice daily for 5 days had no effect on the pharmacokinetics of theophylline (given as aminophylline 6.5 mg/kg, intravenously) in 5 healthy subjects. This would suggest that no special precautions are needed on concurrent use.

Theophylline + Pneumococcal vaccine

Pneumococcal vaccination does not appear to affect theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of oral theophylline 250 mg three times daily for 10 days were unaltered in 6 healthy subjects both the day after and one week after they received 0.5 mL of a pneumococcal vaccine. These findings need confirmation in patients, but what is known suggests that no special precautions are needed during concurrent use.

Mechanism

Uncertain. It has been suggested that propafenone may reduce the metabolism of theophylline by the liver, thereby increasing its levels.

Importance and management

Information is limited to these two reports, but it would seem prudent to monitor the effect of adding propafenone to established treatment with theophylline in any patient. Be alert for increased theophylline levels and signs of toxicity. Controlled studies are needed to further investigate this potential interaction.

Theophylline or Diprophylline + Probencid

Theophylline levels are unaffected by probenecid, but diprophylline levels can be raised.

Clinical evidence

(a) Diprophylline

A study in 12 healthy subjects showed that the half-life of a single 20-mg/kg oral dose of diprophylline was doubled (from 2.6 to 4.9 hours) and the clearance approximately halved by probenecid 1 g, which resulted in raised serum diprophylline levels.

(b) Theophylline

A study in 7 healthy subjects found that probenecid 1 g given 30 minutes before a 5.6-mg/kg oral dose of aminophylline had no significant effect on the pharmacokinetics of theophylline.

Mechanism

Diprophylline is largely excreted unchanged by the kidneys, and probenecid inhibits its renal tubular secretion. Theophylline is largely cleared from the body by hepatic metabolism, and would therefore not be expected to be affected by probenecid.

Importance and management

Based on the findings of this single-dose study, it would seem to be prudent to monitor serum diprophylline levels if probenecid is started or stopped. No special precautions are needed if theophylline and probenecid are given concurrently.

Theophylline + Propafenone

Two isolated reports describe raised serum theophylline levels, with symptoms of toxicity, when two patients were given propafenone.

Clinical evidence

In a 71-year-old man, propafenone 150 mg daily raised the levels of sustained-release theophylline 300 mg twice daily from a range of 10.2 to 12.8 mg/L to 19 mg/L, and signs of theophylline toxicity developed. The day after propafenone was withdrawn the level fell to 10.8 mg/L. When the propafenone was later restarted the theophylline levels rose again to 17.7 mg/L within one week, but fell when the theophylline dosage was reduced by one-third.

In another report, a 63-year-old man had a marked reduction in the clearance of sustained-release theophylline and a rise in theophylline levels from 10.8 mg/L to a maximum of 20.3 mg/L over 7 days when he took propafenone 150 mg every 8 hours, increasing to 300 mg every 8 hours. Theophylline was discontinued.

Mechanism

Uncertain. It has been suggested that propafenone may reduce the metabolism of theophylline by the liver, thereby increasing its levels.

Importance and management

Information is limited to these two reports, but it would seem prudent to monitor the effect of adding propafenone to established treatment with theophylline in any patient. Be alert for increased theophylline levels and signs of toxicity. Controlled studies are needed to further investigate this potential interaction.

Theophylline + Propantheline

A study in 6 healthy subjects found that propantheline 30 mg did not affect the rate or extent of absorption of a single 500-mg dose of theophylline (Theo-Dur). No special precautions would seem necessary on concurrent use.

Theophylline + Protease inhibitors

Ritonavir can reduce the serum levels of theophylline. Indinavir appears not to interact.

Clinical evidence, mechanism, importance and management

(a) Indinavir

A study in 12 healthy subjects given a single 250-mg oral dose of theophylline before and after 5 days of treatment with indinavir 800 mg three times daily found an 18% increase in the AUC of theophylline, which was not considered clinically significant. There have been no further published studies or cases to date to confirm this result, and as indinavir does not inhibit CYP1A2 (see ‘Table 21.2’, (p.773)), the main isoenzyme that metabolises theophylline, it would seem unlikely that special precautions are necessary during concurrent use.

(b) Ritonavir

In a placebo-controlled study, 27 subjects taking theophylline 3 mg/kg every 8 hours were given ritonavir 300 mg increased to 500 mg twice daily for 10 days. Ritonavir reduced the AUC of theophylline by 43% and reduced the maximum and minimum steady-state theophylline levels by 32% and 57%, respectively. The interaction achieved its maximal effect 6 days after starting ritonavir. Ritonavir induces the metabolism of theophylline by CYP1A2. Information is very limited but the interaction appears to be established. Consider monitoring theophylline levels if ritonavir is started and be alert for the need to increase the theophylline dose.

Theophylline + Proton pump inhibitors

Omeprazole may cause a small increase in theophylline clearance, and lansoprazole may cause a small decrease in theophylline levels, neither of which are likely to be clinically relevant. Pantoprazole and rabeprazole do not appear to interact with theophylline.
Clinical evidence

(a) Lansoprazole

Lansoprazole 60 mg daily for 9 days caused only a very slight reduction in the steady-state theophylline levels of 14 healthy subjects. Other studies have also shown little or no change in theophylline pharmacokinetics on concurrent use.1-6

(b) Omeprazole

The changes in the half-life and clearance of theophylline caused by omeprazole were found to be small and clinically unimportant in two studies.7,8 No changes in the steady-state pharmacokinetics of theophylline were found in other studies.9,10 However, one study found that omeprazole produced an 11% increase in the clearance of theophylline in poor metabolisers of omeprazole (i.e. those with low levels of the cytochrome P450 isoenzyme CYP2C19 and therefore higher levels of omeprazole),11 but this seems unlikely to be clinically significant.

(c) Pantoprazole

A crossover study in 8 healthy subjects showed that intravenous pantoprazole 30 mg daily had no clinically important effect on the pharmacokinetics of theophylline given by infusion. No clinically relevant changes in blood pressure, heart rate, ECG and routine clinical laboratory parameters were seen.12 Other studies have also found no significant change in theophylline pharmacokinetics when pantoprazole was given.5,5

(d) Rabeprazole

A single 250-mg oral dose of theophylline was given to 25 patients before and after taking rabeprazole 20 mg or a placebo daily for 7 days. No significant changes in the pharmacokinetics of theophylline were seen.13,14

Mechanism, importance and management

Lansoprazole possibly induces cytochrome P450 isoenzyme CYP1A2 (the enzyme by which theophylline is metabolised) to a small extent, but this is unlikely to be significant unless an individual is particularly sensitive to this effect. Other proton pump inhibitors are unlikely to interact with theophylline, and so no special precautions would seem necessary on concurrent use.

Clinical evidence

An 8-year-old boy with status asthmaticus was treated firstly with intravenous aminophylline and then switched to sustained-release oral theophylline on day 3, at which point his serum theophylline level was 15 mg/L. On day 4 he was given a single 160-mg dose of pyrantel (for an *Ascaris lumbricoides* infection) at the same time as his second theophylline dose. About 2.5 hours later his serum theophylline level was 24 mg/L, and further 1.5 hours later it had risen to 30 mg/L. No further theophylline was given and no symptoms of theophylline toxicity occurred. The patient was discharged later in the day without theophylline.1

Mechanism

Not understood. One suggestion is that the pyrantel inhibited the liver enzymes concerned with the metabolism of the theophylline, thereby increasing its levels. However, this is unlikely as the interaction occurred so rapidly. Another suggestion was that pyrantel may have increased drug release from the sustained-release theophylline preparation.

Importance and management

Information is limited to this single case report. No general conclusions can be based on such slim evidence, but concurrent use should be well monitored because, in this case, the serum theophylline concentration increase was very rapid. More study is needed.

Theophylline + Pyridoxal

There is no evidence of an adverse interaction if pyridoxal (a vitamin B6 substance) and theophylline are taken concurrently. There may be some reduction in theophylline-induced hand tremor.

Clinical evidence, mechanism, importance and management

In a crossover study, 15 young healthy adults were given theophylline (Theo-Dur) for 4 weeks, with the dose adjusted to give plasma levels of 10 mg/L, combined with daily doses of either a placebo or a vitamin B6 supplement containing pyridoxal hydrochloride 15 mg. A variety of psychomotor and electrophysiological tests and self-report questionnaires failed to distinguish between the effects of the placebo or the vitamin B6 supplement, except that the hand tremor induced by the theophylline tended to be reduced.1 In another study by the same research group, 15 healthy subjects (smoking status not indicated) took pyridoxal 15 mg daily for 2 weeks prior to starting, and when also taking, sustained-release theophylline (Theo-Dur), 5 mg/kg daily for one week increased to 8 mg/kg daily for the next 3 weeks. Theophylline levels were subtherapeutic and ranged from 7.6 to 9.9 [mg/L]. Supplementation with pyridoxal did not prevent theophylline-induced reductions in pyridoxine 5-phosphate levels, as an indicator of vitamin B6 status, although these did not drop below the normal range.2

There would seem to be no reason for avoiding concurrent use and it may even have some advantage.

Theophylline + Quinolones

Theophylline serum levels can be markedly increased in most patients by enoxacin. Pipemidic acid and clinafloxac in probably interact similarly. Theophylline levels can also be markedly increased in some patients by ciprofloxacin, and possibly pefloxac in. Norfloxac in, ofloxac in, pazufloxacin, or prulifloxa cin normally cause a much smaller rise in theophylline levels. However, serious toxicity has been seen in few patients given norfloxac in. Fleroxacin, flumequ in, gatifloxac in, gemifloxa cin, levofloxac in, lomefloxac in, moxifloxac in, nalidixic acid, rufloxac in, spar floxac in and trovafloxac in appear not to interact.

Theophylline + Pyrantel

A single case report describes increased serum theophylline levels when a child was also given pyrantel.

Clinical evidence

A. Pharmacokinetic studies

The effects of the quinolones on the pharmacokinetics of theophylline in clinical studies in healthy subjects or patients are listed in “Table 33.4”, (p.1193).

B. Case reports

(a) Ciprofloxacin

There are numerous cases that describe the interaction between ciprofloxacin and theophylline or aminophylline, which commonly report large increases in serum theophylline levels (32 to 478% or 1.3 to 5.6-fold increases), often associated with toxicity.1-11 From 1987 to 1988, the CSM in the UK had received 8 reports of clinically important adverse interactions between these two drugs, with one fatal case.2 By 1991, the FDA in the US had received 39 reports of the interaction, with three deaths.9

An elderly woman taking theophylline developed toxic serum levels and died shortly after starting to take ciprofloxacin.7 Seizures, associated with toxic levels of theophylline, were described in a number of the case reports.5,9-11 Seizures have also occurred when ciprofloxacin was used with theophylline or aminophylline, even when theophylline levels were within the therapeutic range (10 to 20 mg/L).9,12,13 Ciprofloxacin and toxic levels of theophylline are both known to cause seizures independently. It was suggested that, in the case of seizures, there may be a pharmacodynamic interaction between theophylline and the fluoroquinolones as well as a pharmacokinetic interaction.9 In each case seizures began within 1 to 7 days of starting the combination and were reported as being either partial or grand mal. The addition of clarithromycin does not appear to increase the effects of ciprofloxacin on theophylline.14

(b) Clinafloxacin

The apparently stable serum theophylline levels of a 78-year-old man with steroid-dependent chronic obstructive pulmonary disease were approximately doubled after he received intravenous clinafloxacin 200 mg every 12 hours for 5 days. Two theophylline doses were withheld, and then the dosage was reduced from 300 mg every 8 hours to 200 mg every 8 hours. Within another 5 days his serum theophylline levels had returned to his previous steady-state level.15

(c) Enoxacin

Some patients in early studies of enoxacin experienced adverse effects (serious nausea and vomiting, tachycardia, seizures)16,17 and this was found to be associated with unexpectedly high plasma theophylline levels.16,18

(d) Levofloxacin

Levofloxacin has not significantly altered the pharmacokinetics of theophylline in studies, see “Table 33.4”, (p.1193). However, a 59-year-old man developed theophylline toxicity 7 and 5 days after starting clarithromycin and levofloxacin, respectively. His theophylline clearance decreased by about 40% when compared to the value before starting these drugs and so the theophylline dosage was reduced. After stopping the levofloxacin, the theophylline level fell, and the theophylline clearance returned to the initial value, even though clarithromycin was continued.19

(e) Norfloxacin

No clinically significant changes in theophylline levels occurred in a patient given norfloxacin who subsequently had marked changes when given ciprofloxacin.3 This report and the studies in “Table 33.4”, (p.1193) contrast with the records of the FDA in the US, which describe 3 patients (up to 1989)20 and 9 patients (up to 1991)9 who experienced marked increases in theophylline levels ranging from 64 to 171% (mean 103%). Three patients developed seizures, and one died.9

(f) Pefloxacin

An isolated report describes convulsions in a patient, which were attributed to the use of theophylline with pefloxacin.21

Mechanism

The interacting quinolones appear to inhibit the metabolism (N-demethylation) of theophylline to different extents (some hardly at all), so that it is cleared from the body more slowly and its serum levels rise. The quinolones are known to inhibit the cytochrome P450 isoenzyme CYP1A2 by which theophylline is metabolised. Although neither levofloxacin and clarithromycin alone usually interact, the case report suggests that together they may.19 There is some evidence that combined use of theophyllines and quinolones may amplify the epileptogenic activity of the quinolones.9,22

Importance and management

The interactions of enoxacin and ciprofloxacin with theophylline are well documented, well established and of clinical importance. The effect of enoxacin is marked and occurs in most patients, whereas the incidence with ciprofloxacin is uncertain and problems do not develop in all patients. The risk seems greatest in the elderly23 and those with theophylline levels already towards the top end of the therapeutic range. Toxicity may develop rapidly (within 2 to 3 days) unless the theophylline dosage is reduced.

With enoxacin, it has been suggested that the dose of theophylline should be reduced by 50%, although reductions of 75% may possibly be necessary for those with high theophylline clearances.20 Alterations in the theophylline dose should be based on careful monitoring of theophylline levels. New steady-state serum theophylline levels are achieved within about 2 to 3 days of starting and stopping enoxacin.26,27

Although problems do not develop in all patients taking theophylline and ciprofloxacin it would be prudent to be alert for this interaction in any patient. Some recommend an initial reduction in theophylline dose, in the order of 30 to 50% when ciprofloxacin is started.25-29 However, since a proportion of patients will not require a dose reduction, others suggest that the dose should be modified based on the theophylline level on day 2 of ciprofloxacin use.11,24,30-32

Direct information about clinafloxacin and pipemidic acid is more limited, but they also appear to cause a considerable rise in serum theophylline levels, similar to enoxacin, and therefore it would seem prudent to anticipate the need for a dosage reduction and monitor theophylline levels closely.

Keep a check on the effects if norfloxacin, ofloxacin, pefloxacin, or pefloxacin are used because theophylline serum levels may possibly rise to a small extent (10 to 22%), but these antibacterials normally appear to be much safer. However, be aware that norfloxacin has caused a much larger rise on occasions.9,20 Fleroxacin, flumequine, gatifloxacin, gemifloxacin, levofloxacin, lomefoxacin, moxifloxacin, nalidixic acid, rufloxacin, sparflloxacin and trovafloxacin appear not to interact significantly, and no special precautions seem necessary with these drugs. However, note that acute infection per se can alter theophylline pharmacokinetics. The manufacturers of some quinolones include a warning in their product literature about the risk of combining theophylline with quinolones because of their potential additive effects on reducing the seizure threshold. Convulsions have been reported with theophylline and ciprofloxacin, norfloxacin, or pefloxacin. With some of these cases it is difficult to know whether what happened was due to increased theophylline levels, to patient pre-disposition, to potential additive effects on the seizure threshold, or to all three factors combined. However, the literature suggests that seizures attributed to concurrent use are relatively rare, so that the general warning about the risks with all quinolones may possibly be an overstatement.

12. Sennel JD, Allen N. Seizures in patients simultaneously receiving theophylline and imipenem or meropenem or metronidazole. BMJ (1994) 308, 446.
Clinical evidence

A. Effects of the individual antimycobacterial drugs on theophylline

1. Isoxazolid

Theophylline toxicity has been described in one patient receiving isoniazid 5 mg/kg daily and theophylline, and this subsequently recurred on rechallenge.1 In 7 healthy subjects, high-dose isoniazid (10 mg/kg daily) for 10 days increased the AUC of theophylline by only 8%. The theophylline was given as an intravenous infusion of aminophylline and the plasma levels after 6 hours were 22% higher (about 10.5 mg/L compared with 8.7 mg/L). Five subjects also had an increase in the half-life and AUC of isoniazid, but these changes were not statistically significant.2 Another study, in 13 healthy subjects, found that isoniazid 400 mg daily for 2 weeks reduced the mean clearance of theophylline (given as intravenous aminophylline) by 21%.3 However, another study in 4 healthy subjects given isoniazid 300 mg daily for 6 days found that the clearance of oral theophylline was increased by 16%, but no consistent changes were seen in any of the other pharmacokinetic parameters measured.4

2. Ribavirin

The AUC of a single 5-mg/kg dose of theophylline was reduced by 6% in 11 healthy subjects who took ribavirin 300 mg daily for 12 days. The half-life and clearance of theophylline were not affected.5

(c) Rifampicin (Rifampin)

The AUC of theophylline (given as sustained-release aminophylline 450 mg) was reduced by 18% in 7 healthy subjects who took rifampicin 600 mg daily for one week. A parallel study in another 8 healthy subjects given the same dosage of rifampicin showed that the metabolic clearance of theophylline (given as intravenous aminophylline 5 mg/kg) was increased by 45%.6 Similarly, other studies in healthy subjects given oral or intravenous theophylline or intravenous aminophylline and rifampicin 300 to 600 mg daily for 6 to 14 days found 25 to 82% rises in theophylline clearance, and 19 to 31% decreases in its half-life.5,7,12 A 61% fall in the 5-hour post-dose serum levels of theophylline (given as choline theophyllinate) occurred in a 15-month-old boy when he was given a 4-day course of rifampicin 20 mg/kg daily as meningitis prophylaxis.13

B. Effects of combined antimycobacterial drugs on theophylline

A study in patients taking a combination of isoniazid, rifampicin, ethambutol and pyrazinamide for pulmonary tuberculosis with intravenous aminophylline 7.35 mg/kg daily for 7 days found that the clearance of theophylline progressively increased, and was 53% faster on day seven.14 In contrast, in an earlier study by the same authors, after 4 weeks of the same antimycobacterials (isoniazid, rifampicin, ethambutol with or without pyrazinamide) the theophylline clearance in patients receiving long-term theophylline was about 35% slower than in a control group of similar patients started taking antimycobacterials.15 A single report describes unexpectedly high serum theophylline levels 4 days after theophylline 300 mg twice daily was started in an alcoholic patient with hepatic impairment who had started to take rifampicin and isoniazid 2 weeks previously.16

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of the theophylline, thereby increasing its clearance and reducing its serum levels.6 It has been suggested that isoniazid inhibits the metabolism of theophylline by the liver, thereby reducing its clearance and increasing its plasma levels. Ribavirin is a much less potent liver enzyme inducer than rifampicin, and consequently has less of an effect on theophylline metabolism.

With combined therapy, it was suggested that the effects of rifampicin might be more apparent during the initial 7 days, but that by week 4 the effect of isoniazid might predominate, because of its reduced inactivation by rifampicin combined with a reduction in the effect of rifampicin by auto-induction of its own metabolism.15 High theophylline levels in the isolated case above may have been due to liver impairment brought about by the combined use of rifampicin and isoniazid, or alcoholism.13

Importance and management

The interaction between theophylline and rifampicin is established. The levels and therapeutic effects of theophylline are likely to be reduced during concurrent treatment, and this effect can usually be detected within...
Theophylline with a combined anti-tubercular regimen including isoniazid and rifampicin is started or stopped and adjust the theophylline dose accordingly. The effects of rifabutin are considerably less than those of rifampicin, with the one available study showing no significant interaction. On the basis of this, no special precautions appear to be necessary, but it may be prudent to monitor the efficacy of theophylline on concurrent use. The reason for the inconsistent results with isoniazid alone is not understood, nor is this interaction well established. It has been suggested that it may take 3 to 4 weeks for any significant increase in theophylline levels to occur. However, if enzyme inhibition was the cause, the effects would be expected more rapidly than this. All of the studies cited covered a period of only 6 to 14 days, whereas the case report describes the effects over a period up to 55 days. It has also been suggested that the dose of isoniazid may be important, with the clearance of theophylline being unaffected by ‘usual doses’ of isoniazid, but reduced by larger doses. The outcome of concurrent isoniazid and theophylline use is uncertain and may be affected by other antimycobacterials, but it would clearly be prudent to be alert for any evidence of changes in theophylline levels and toxicity if isoniazid is given. Isoniazid and rifampicin are usually taken as part of a combination chemotherapy regimen in the treatment of tuberculosis. There is some evidence that, in the short-term, combined use of these drugs will decrease theophylline levels, but that theophylline levels may increase during long-term therapy. However this requires confirmation. Patients taking theophylline with a combined anti-tubercular regimen including isoniazid and rifampicin should have their theophylline levels closely monitored and the dose adjusted according to the response, bearing in mind that these changes may occur over a longer period of time as reported in the case with isoniazid.

Theophylline + Ropinirole

Theophylline and ropinirole do not appear to interact.

Clinical evidence, mechanism, importance and management

In one study, 12 patients with parkinsonism were given ropinirole, increased from 0.5 mg to 2 mg three times daily over 28 days, then continued for a further 19 days. The pharmacokinetics of theophylline, given as a single intravenous dose of aminophylline, were assessed before ropinirole was started and on day 27. The pharmacokinetics of ropinirole were then assessed before, during, and after, the use of oral controlled-release theophylline twice daily for 13 days (dose titrated to achieve plasma levels in the range 8 to 15 micrograms/mL). In both cases it was found that concurrent use did not alter the pharmacokinetics of either drug, and concurrent use was well tolerated. There would therefore appear to be no reason to take special precautions if both drugs are used, and no need to adjust the dosage of either drug. An interaction had originally been suspected because both drugs are metabolised by the cytochrome P450 isoenzyme CYP1A2.1

Theophylline + SSRIs

Theophylline serum levels can be markedly and rapidly increased by fluvoxamine. Toxicity will develop if the theophylline dosage is not suitably reduced. Some preliminary clinical evidence suggests that fluoxetine and citalopram may not interact, and in vitro evidence suggests that paroxetine and sertraline are also unlikely to interact.

Clinical evidence

(a) Citalopram

In a study in 13 healthy subjects citalopram 40 mg daily for 21 days (to achieve steady-state) did not affect the pharmacokinetics of a single 300-mg oral dose of theophylline.

(b) Fluoxetine

The pharmacokinetics of theophylline were unchanged in 8 healthy subjects when they were given a 6-mg/kg infusion of aminophylline over 30 minutes, 8 hours after a single 40-mg dose of fluoxetine.

(c) Fluvoxamine

The effect of fluvoxamine on theophylline pharmacokinetics has been characterised in two studies in healthy subjects. In the first study the AUC of theophylline (given as a single 442-mg oral dose of aminophylline) was increased almost threefold, the clearance was reduced by 62% and the half-life was prolonged from 7.4 to 32.1 hours by fluvoxamine 50 mg daily for 3 days then 100 mg daily for 13 days.1 In the second study, the clearance of theophylline (given as a single 300-mg oral dose of aminophylline) was reduced by about 70% and the half-life was increased from 6.6 to 22 hours by fluvoxamine 50 to 100 mg daily for 7 days.4 This interaction was shown to be reduced in patients with mild and severe liver cirrhosis (Child class A and C, respectively), whereas the clearance of a single 4-mg/kg dose of theophylline elixir was reduced by 62%, 52%, and 10.5% in healthy patients, patients with mild cirrhosis, and patients with severe cirrhosis, respectively. The half-life of theophylline was increased by 13.6 hours in healthy subjects compared with 10.5 hours in patients with mild cirrhosis and 1 hour in patients with severe cirrhosis, demonstrating the reduced metabolic capabilities of the cirrhotic liver.4 A number of case reports have described fluvoxamine-induced theophylline toxicity. Agitation and tachycardia (120 bpm) developed in an 83-year-old man taking theophylline 600 mg daily (Thetostat) about a week after he started to take fluvoxamine 100 mg daily. His serum theophylline levels were found to have risen from under 15 mg/L to 40 mg/L.6 A 70-year-old man similarly developed theophylline toxicity, with theophylline levels of about 32 mg/L (reference range 10 to 20 mg/L), when fluvoxamine was added. Subsequently the theophylline concentrations were found to parallel a number of changes in the fluvoxamine dosage.7 The clearance of theophylline in an 84-year-old man was approximately halved while he was taking fluvoxamine.8 An 11-year-old boy complained of headaches, tiredness and vomiting within a week of starting to take fluvoxamine. His serum theophylline levels were found to have doubled, from 14.2 to 27.4 mg/L.9 A 78-year-old woman became nauseous within 2 days of starting to take fluvoxamine 50 mg daily, and by day 6, when the fluvoxamine was stopped, her serum theophylline levels were found to have increased about threefold. She experienced a seizure, became comatose, and had supraventricular tachycardia (200 bpm) requiring intravenous digoxin and verapamil. She recovered uneventfully.10 A patient taking fluvoxamine 100 mg daily developed nausea, vomiting, confusion, reduced sleep and a poor appetite 5 days after she began to take theophylline 300 mg twice daily for COPD. Her theophylline level was found to be 25.9 mg/L.11
**Mechanism**

In *vitro* studies with human liver microsomes have shown that fluvoxamine inhibits the cytochrome P450 isoenzyme CYP1A2, the principal enzyme responsible for the metabolism of theophylline.\(^1,12,13\) This results in raised theophylline levels and toxicity. This metabolic function, and hence interaction, appears to be severely reduced in patients with severe cirrhosis, probably due to reduced hepatic expression of CYP1A2 and reduced uptake of fluvoxamine.\(^3\) The other SSRIs, citalopram, fluoxetine, paroxetine and sertraline only weakly inhibited CYP1A2 in *vitro*, and consequently would not be expected to interact.\(^1,12,13\)

**Importance and management**

The interaction between fluvoxamine and theophylline is established and clinically important. The CSM in the UK advise that concurrent use should usually be avoided, but that if this is not possible, reduce the theophylline dosage by half when fluvoxamine is added and monitor theophylline levels.\(^2,12,13\) There is evidence to suggest that the extent of this interaction is markedly reduced in patients with liver cirrhosis, particularly severe Child class C, despite higher levels of fluvoxamine, although caution should still be applied with concurrent use in this patient group as they are more likely to have high levels of theophylline due to reduced metabolism. There is good *in vitro* evidence to suggest that fluvoxamine is the only SSRI likely to interact (because it is the only one that significantly affects CYP1A2). This would seem to be borne out by the lack of studies and case reports in the literature describing problems with any of the other SSRIs.

**Theophylline + St John’s wort (Hypericum perforatum)**

A patient needed a marked increase in the dosage of theophylline while taking St John’s wort, but no pharmacokinetic interaction was found in a 2-week study in healthy subjects.

**Clinical evidence**

A woman, who had previously been stable for several months taking theophylline 300 mg twice daily, was found to need a markedly increased theophylline dosage of 800 mg twice daily to achieve serum levels of 9.2 mg/L. It turned out that 2 months previously she had started to take 300 mg of a St John’s wort supplement (hypericin 0.27%) each day. When she stopped taking the St John’s wort, her serum theophylline levels doubled within a week to 19.6 mg/L and her theophylline dosage was consequently reduced. This patient was also taking a whole spectrum of other drugs (amitriptyline, furosemide, ibuprofen, inhaled triamcinolone, morphine, potassium, prednisone, salbutamol (albuterol), valproic acid, zolpidem and zafirlukast) and was also a smoker. No changes in the use of these drugs or altered compliance were identified that might have offered an alternative explanation for the changed theophylline requirements.\(^1\)

However, a study in 12 healthy subjects found that a standardised preparation of St John’s wort 300 mg (hypericin 0.27%) three times daily for 15 days had no significant effects on the plasma level of a single 400-mg oral dose of theophylline.\(^2\)

**Mechanism**

Uncertain. *In vitro* data suggest one component of St John’s wort (hypericin) can act as an inducer of the cytochrome P450 isoenzyme CYP1A2.\(^2\) It has also been suggested that treatment with St John’s wort for 15 days was unlikely to induce the isoenzymes sufficiently to cause changes in plasma theophylline.\(^2\) The patient in the case report had been taking St John’s wort for 2 months, although at a lower dose, therefore differences in duration of treatment may account for the discrepancy. This is supported by studies in which 4-week\(^1\) but not 2-week treatment\(^1\) with St John’s wort modestly increased the paraxanthine/caffeine ratio, used as a measure of CYP1A2 activity.

**Importance and management**

Direct information about this apparent interaction between theophylline and St John’s wort appears to be limited. No pharmacokinetic interaction was noted in healthy subjects, but the case report describes a marked decrease in theophylline levels. Mechanistic studies suggest a modest interaction at most. Furthermore most clinically significant interactions with St John’s wort are mediated by the cytochrome P450 isoenzyme CYP3A4. However, it would be prudent to monitor the effects and serum levels of theophylline if St John’s wort is started or stopped, and patients should be warned of the possible effects of concurrent use. In 2000, the CSM in the UK recommended that patients taking theophylline should not take St John’s wort. In those patients already taking the combination, the St John’s wort should be stopped and the theophylline dosage monitored and adjusted if necessary.\(^3,4\) More study is needed, as this interaction is potentially of little clinical significance.

5. Committee on Safety of Medicines (UK). Message from Professor A Breckenridge (Chairman of CSM) and Fact Sheet for Health Care Professionals, 29th February 2000.

**Theophylline + Succimer**

A single case report describes a 36% reduction in the serum theophylline levels of a man treated with succimer.

**Clinical evidence, mechanism, importance and management**

A 65-year-old man with chronic obstructive airways disease and chronic lead intoxication was given a 19-day course of lead chelation with succimer. His theophylline level was found to be reduced from about 11 mg/L to 7 mg/L on day 6 and remained at this level until about 9 days after the course of succimer was completed, when it returned to pretreatment levels. His clinical status did not alter despite these changes; possibly because he was also taking prednisone.\(^1\) The reason for these alterations is not understood.

The general importance of this interaction is not known, but it would now be prudent to monitor the situation closely if succimer is added to established treatment with theophylline.

**Theophylline + Sucralfate**

Two studies found that sucralfate caused only minor changes in theophylline pharmacokinetics, but another suggests that the ab-
Clinical evidence, mechanism, importance and management

In 8 healthy subjects no clinically important changes occurred in the absorption of a single 5-mg/kg dose of an oral non-sustained release theophylline preparation given at the same time as sucralfate 1 g four times daily. A slight 5% decrease in the AUC was detected. Another study found that sucralfate 1 g four times daily reduced the AUC of a single dose of a sustained-release theophylline preparation (Theodur) by 9% (timing of the theophylline dose in relation to the sucralfate dose not noted). In contrast, another group of workers found that when sucralfate 1 g was given 30 minutes before a 350 mg dose of sustained-release theophylline (PEG capsules), the theophylline AUC was reduced by 40%. Many patients are given sustained-release theophylline preparations, but neither of these studies clearly shows what is likely to happen in clinical practice, so be alert for any evidence of a reduced response to theophylline. Usually, separating the administration of sucralfate from other drugs by 2 hours is considered sufficient to avoid interactions that occur by reduced absorption. However, the study showing decreased theophylline absorption did not examine the effect of separating the doses. Further study is needed.

Clinical evidence, mechanism, importance and management

In 18 healthy subjects, the pharmacokinetics of a single 600-mg dose of controlled-release theophylline were unchanged when it was given with three doses of tegaserod 6 mg (the first was given about 24 hours before the theophylline, the second simultaneously, and the third 12 hours later). It was suggested that tegaserod would not be expected to affect the pharmacokinetics of other drugs that are (like theophylline) substrates for the cytochrome P450 3A4 isoenzyme.

Clinical evidence, mechanism, importance and management

In double-blind study 10 healthy subjects were given tamsulosin 400 micrograms 30 minutes after breakfast for 2 days then 800 micrograms on the following 5 days with a single 5-mg/kg dose of intravenous theophylline one hour after the last dose of tamsulosin. The pharmacokinetics of theophylline and tamsulosin were not affected by concurrent use. Theophylline is mainly metabolised by the cytochrome P450 2D6 isoenzyme, while tamsulosin is metabolised by CYP3A4 and CYP2D6, and therefore a pharmacokinetic interaction would not be expected. The safety of combined use was considered acceptable and dose adjustments were not considered necessary during concurrent use.

Theophylline + Tadalafil

Tadalafil does not alter the pharmacokinetics of theophylline.

Theophylline + Teicoplanin

Clinical studies in 20 patients with chronic obstructive pulmonary disease found that teicoplanin 200 mg twice daily and aminophylline 240 mg twice daily (both given as intravenous infusions) had no significant effect on the steady-state pharmacokinetics of either drug. No special precautions would seem necessary during concurrent use.

Theophylline + Terbinafine

Preliminary evidence indicates that terbinafine can increase the serum levels of theophylline to some extent, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

In an open-label, randomised, crossover study 12 healthy subjects were given a single 5-mg/kg oral dose of aminophylline before and after taking terbinafine 250 mg daily for 3 days. The AUC and half-life of theophylline were increased by 16% and 23%, respectively, and the theophylline clearance was reduced by 14%. It was suggested that this is due to the inhibitory effect of terbinafine on the activity of the cytochrome P450 2D6 isoenzyme, which is the main isoenzyme involved in the metabolism of theophylline. The changes seen were relatively small, but the study periods only lasted 3 days so that the effects of longer concurrent use are uncertain, but a clinically significant interaction seems unlikely. More study is needed.

Theophylline + Tetracyclines

Serum theophylline levels increased in two patients who were also given minocycline or tetracycline. Some controlled studies have shown both increases and decreases in theophylline clearance with doxycycline and tetracycline, with no significant changes overall.

Clinical evidence

(a) Doxycycline

A study in 10 asthmatic subjects given doxycycline 100 mg twice daily on day 1 and then 100 mg daily for 4 days found that the mean serum theophylline level was not significantly altered. However, there was large inter-individual variation, with 4 subjects showing rises of more than 20% (range 24 to 31%) and 2 having decreases of 22% and 33%. Fluctuations of this size are not unusual with theophylline. Another study in 8 healthy subjects given doxycycline 100 mg daily for 7 days with theophylline 350 mg twice daily failed to find any significant changes in theophylline pharmacokinetics.

(b) Minocycline

The serum theophylline levels of a 70-year-old woman with normal liver function increased from 9.8 to 15.5 mg/L after she was given minocycline 100 mg twice daily by infusion for 6 days. Her serum theophylline level was 10.9 mg/L 14 days after the minocycline was stopped.

(c) Tetracycline

After taking tetracycline hydrochloride 250 mg four times daily for 8 days a patient with chronic obstructive pulmonary disease (COPD) showed evidence of theophylline toxicity. After 10 days of tetracycline her serum theophylline levels had risen from about 13 mg/L to 30.8 mg/L. Both drugs were stopped, and after 24 hours her theophylline level was 12.4 mg/L. A later rechallenge in this patient confirmed that the tetracycline was responsible for the raised theophylline levels.

In an earlier study in 8 healthy subjects tetracycline 250 mg four times daily for 7 days did not affect the mean pharmacokinetics of theophylline (given as a single intravenous dose of aminophylline), although there was large inter-individual variation. Four subjects had a decrease in clearance of over 15%, (32% in one subject), and conversely, one subject had a 21% increase in clearance. Other studies in subjects and patients given tetracycline for shorter periods have not found evidence of an important interaction. A study in 9 healthy adults given single 5-mg/kg intravenous doses of aminophylline found that tetracycline 250 mg every 6 hours for 48 hours had no significant effect on theophylline pharmacokinetics.

Five non-smoking patients with COPD or asthma had an average rise in their theophylline half-life, from 4.6 to 5.9 hours, when they were given carbimazole 45 mg and propranolol 60 mg daily. In this study, a single intravenous dose of aminophylline was given before the treatment of thyrotoxicosis and after the euthyroid state had been achieved. Note that propranolol can reduce the clearance of theophylline but should be avoided in patients with respiratory disease, see ‘beta blockers’, (p.1175), for more information.

Importance and management

Information seems to be limited. There are two isolated cases of increased theophylline levels with minocycline and tetracycline, but controlled studies have not shown any significant changes in overall theophylline pharmacokinetics. It has been suggested that a clinically important interaction may possibly only occur in a few patients. Further study is needed. There seems to be no evidence of adverse interactions with any of the other tetracyclines. However, note that acute infections per se can alter theophylline pharmacokinetics.

Theophylline + Thyroid and Antithyroid compounds

Thyroid dysfunction may modestly affect theophylline requirements. There are two isolated cases of theophylline toxicity in patients being treated for hypothyroidism.

Clinical evidence

The theophylline elimination rate constant after a single intravenous dose of aminophylline was found to be greater in hyperthyroid patients (0.155 h⁻¹) than in euthyroid (0.107 h⁻¹) or hypothyroid patients (0.060 h⁻¹); some other pharmacokinetic parameters were also changed. The authors concluded that thyroid dysfunction may modestly alter theophylline requirements. It is therefore also likely that drug-induced changes in the thyroid status, such as those caused by amiodarone, may also alter the amount of theophylline needed to maintain therapeutic levels.

(a) Antithyroid compounds

The serum theophylline level of an asthmatic patient was found to have doubled, from 15.2 to 30.9 mg/L, accompanied by toxicity, 3 months after treatment for hyperthyroidism with radioactive iodine (¹³¹I). At this point the patient was hypothyroid, and after treatment with levothyroxine was started, his serum theophylline returned to approximately the same level as before radioactive iodine treatment (13.9 mg/L). Another patient with Graves’ disease treated with a combination of thiamazole (methimazole) 10 mg three times daily and Lugol’s solution (iodine and potassium iodide) and taking theophylline 500 mg twice daily (Theodur), had a theophylline level of 4.7 mg/L before radioactive iodine therapy. His level increased to 13.6 mg/L 7 months after thyroid ablation. Five hyperthyroid patients had a 20% reduction in theophylline clearance and an increase in their theophylline half-life, from 4.6 to 5.9 hours, when they were given carbimazole 45 mg and propranolol 60 mg daily.

In this study, a single intravenous dose of aminophylline was given before the treatment of thyrotoxicosis and after the euthyroid state had been achieved. Note that propranolol can reduce the clearance of theophylline but should be avoided in patients with respiratory disease, see ‘beta blockers’, (p.1175), for more information.

(b) Thyroid hormones

One week after starting to take theophylline 1 g daily, a patient who was hypothyroid (serum thyroxine 1.4 micrograms/dL, reference range 4 to 11 micrograms/dL) developed severe theophylline toxicity, with serum theophylline levels of 34.7 mg/L, manifested by ventricular fibrillation (from which he was successfully resuscitated) and repeated seizures over 24 hours. After 2 months treatment with thyroid hormones, which increased his serum thyroxine levels to 4.3 micrograms/dL, his serum theophylline level was 13.2 mg/L, 10 days after reinstitution of the same theophylline dosage.

Mechanism

Thyroid status may affect the rate at which theophylline is metabolised. In hyperthyroidism it is increased, whereas in hypothyroidism it is decreased.

Importance and management

It is established that changes in thyroid status may affect how the body handles theophylline. Monitor the effects and anticipate the possible need to begin to reduce the theophylline dosage if treatment for hyperthyroidism is started (e.g. with radioactive iodine, carbimazole, thiamazole, propylthiouracil, etc.). Similarly, anticipate the possible need to increase the theophylline dosage if treatment is started for hypothyroidism (e.g. with levothyroxine). Stabilisation of the thyroid status may take weeks or even months to achieve so that if monitoring of the theophylline dosage is considered necessary, it will need to extend over the whole of this period.
This monitoring would also apply to drugs that may cause thyroid dysfunction such as amiodarone.

**Theophylline + Tobacco**

Tobacco smokers, and non-smokers heavily exposed to tobacco smoke, may need more theophylline than non-smokers to achieve the same therapeutic benefits, because the theophylline is cleared from the body more quickly. This may also occur in those who chew tobacco or take snuff but not if they chew nicotine gum.

**Clinical evidence**

A study found that the mean half-life of theophylline (given as a single oral dose of aminophylline) was 4.3 hours in a group of tobacco smokers (20 to 40 cigarettes a day) compared with 7 hours in a group of non-smokers, and that theophylline clearance was higher (mean 126%) and more variable in the smokers.1 Almost identical results were found in an earlier study,2 and a number of later studies in subjects given oral or intravenous theophylline or aminophylline confirm these findings.3–7 The ability of smoking to increase theophylline clearance occurs irrespective of gender,3,8 and in the presence of congestive heart failure or liver impairment.7 The effects of ageing on the induction of theophylline metabolism by tobacco smoking is less clear. One study has found that in young subjects (less than 30-years-old) and elderly subjects (more than 67-years-old) smoking decreased the half-life and increased the clearance of theophylline, when compared with non-smokers. The effect was greater in the young subjects.4 However, another study found no difference in the pharmacokinetics of theophylline between asthmatic and healthy smokers and non-smokers aged over 65 years.8 A similar high clearance of theophylline (given as intravenous aminophylline) has been seen in a patient who chewed tobacco (1.11 mL/kg per minute compared with the more usual 0.59 mL/kg per minute).9 The half-life of theophylline (given as intravenous aminophylline) in passive smokers (non-smokers regularly exposed to tobacco smoke in the air they breathe, for 4 hours a day in this study) is reported to be shorter than in non-smokers (6.93 hours compared with 8.69 hours).10 The clearance of theophylline (given as intravenous aminophylline) in asthmatic children exposed to passive tobacco smoke was also found to be greater (1.36 mL/kg per minute compared with 0.09 mL/kg per minute) and their steady-state serum theophylline levels were lower than in children not exposed to passive smoking.11 In one study, 3 of 4 patients who stopped smoking for 3 months (confirmed by serum thiocyanate levels) had a longer theophylline half-life, but only 2 had a slight decrease in theophylline clearance.1 In another study, ex-smokers who had stopped heavy smoking 2 years previously had values for theophylline clearance and half-life that were intermediate between non-smokers and current heavy smokers.1 In another study, 7 hospitalised smokers who abstained from smoking for 7 days had a 35.8% increase in theophylline half-life and a 37.6% decrease in clearance (although clearance after abstinence was still higher than values usually found in non-smokers).12

**Mechanism**

Tobacco smoke contains polycyclic hydrocarbons, which act as inducers of the cytochrome P450 isoenzyme CYP1A2,9,10 and this results in a more rapid clearance of theophylline from the body. Both the N-demethylation and 8-hydroxylation of theophylline is induced.11 Ageing appears to offset the effects of smoking on theophylline metabolism.8

**Importance and management**

An established interaction of clinical importance. Heavy smokers (20 to 40 cigarettes daily) may need much greater theophylline dosage than non-smokers,1 and increased doses are likely for those who chew tobacco or take snuff,9 but not for those who chew nicotine gum.12,14 In patients who stop smoking, a reduction in the theophylline dosage of up to 25 to 33% may be needed after one week,15 but full normalisation of hepatic function appears to take many months or even years.1,2 Investigators of the possible interactions of theophylline with other drugs should take smoking habits into account when selecting their subjects or doses. Note that the effects of cannabis1,16 may be additive with those of tobacco smoking.

**Theophylline + Trimetazidine**

Trimetazidine does not appear to alter the pharmacokinetics of theophylline.

**Clinical evidence, mechanism, importance and management**

In a study in 13 healthy subjects trimetazidine 20 mg twice daily for at least 14 days did not alter the pharmacokinetics of a single 375-mg dose of theophylline.1 These results suggest that treatment with theophylline is unlikely to be altered in patients concurrently treated with trimetazidine, but this needs confirmation in multiple-dose studies.

**Theophylline + Vidarabine**

A single case report describes a woman who had a rise in serum theophylline levels when she took aminophylline oral liquid with vidarabine.

**Clinical evidence, mechanism, importance and management**

A woman taking aminophylline oral liquid developed elevated serum theophylline levels (an increase from 14 mg/L to 24 mg/L) four days after starting to take vidarabine 400 mg daily for herpes zoster.2 She was also being treated with ampicillin, gentamicin, clindamycin and digoxin, for congestive heart failure, chronic pulmonary disease and suspected sepsis. It was suggested that the vidarabine inhibited the metabolism of the theophylline resulting in the raised levels seen. The general significance of this case is uncertain, but it would now seem prudent to bear this interaction in mind if vidarabine is given with aminophylline or theophylline.

**Theophylline + Viloxazine**

Viloxazine increases serum theophylline levels and toxicity may occur.

Theophylline + Zileuton

Zileuton raises theophylline levels and increases the incidence of adverse effects.

Clinical evidence
In a double-blind, crossover study, 13 healthy subjects were given 200 mg of theophylline (Slo-Phyllin) four times daily for 5 days and either zileuton 800 mg twice daily or a placebo. Zileuton caused a 73% rise in the mean steady-state peak serum levels of theophylline when compared to placebo. A study in 8 healthy subjects found that zileuton 800 mg four times daily for 3 days increased the AUC0-24 of theophylline by 47%, increased its maximum serum concentration, and reduced its clearance. An elderly woman hospitalised for respiratory failure and treated with a variety of drugs including theophylline, developed acute theophylline toxicity (a grand mal seizure) 2 days after starting to take zileuton 200 mg daily. Her serum theophylline levels had increased threefold, from about 10 to 28 mg/L, but the levels were reduced when the zileuton was withdrawn. Nausea and vomiting, associated with raised serum theophylline levels, occurred in another patient treated with zileuton. Theophylline was stopped, and then reintroduced at one quarter of the original dose. Theophylline levels subsequently became subtherapeutic when the zileuton was stopped. A further case report in an elderly man describes a marked rise in serum theophylline levels to toxic concentrations (55.3 mg/L) when zileuton, 100 mg then 300 mg daily, was started.

Mechanism
It is suggested that the zileuton competitively antagonises the metabolism of the theophylline by the liver, thereby reducing its clearance and resulting in an increase in its serum levels.

Importance and management
Information seems to be limited to these reports but it would appear to be a clinically important interaction. Theophylline serum levels should be well monitored if zileuton is added, anticipating the need to reduce the dosage.

Theophylline + Terfenadine

Zafirlukast plasma levels are decreased by terfenadine but the clinical significance of this is unclear. Zafirlukast does not increase the levels of terfenadine, and concurrent use does not prolong the QTc interval.

Clinical evidence, mechanism, importance and management
A study in 16 healthy men given zafirlukast 160 mg twice daily for 16 days with terfenadine 60 mg twice daily on days 8 to 16 found that the mean maximum serum levels and AUC of zafirlukast were reduced by 70% and 60%, respectively. There was a small, non-significant reduction in the terfenadine AUC and serum levels. A study in 8 healthy subjects given zafirlukast 160 mg twice daily with terfenadine 60 mg twice daily for 8 days found that the AUC of terfenadine and the QTc interval were not significantly increased with concurrent use, despite the fact that zafirlukast appears to inhibit CYP3A4 in vitro, the major enzyme involved in terfenadine metabolism. The reduction in zafirlukast serum levels would be expected to reduce its antiasthmatic effects, but this needs assessment. If both drugs are given be alert for a reduced response to zafirlukast.

Mechanism
Not fully established but it seems highly likely that zileuton inhibits the metabolism of the theophylline by the cytochrome P450 enzymes (probably the isoenzymes CYP1A2 and CYP3A) so that its serum levels rise.

Importance and management
Information is limited but the interaction appears to be established and of clinical importance. Concurrent use need not be avoided but monitor theophylline levels and reduce the dosage of theophylline as necessary. The report quoted above suggests that a typical asthma patient may initially need the theophylline dosage to be halved, and this dose reduction is recommended by the US manufacturers. Similarly, the dose of theophylline should be reduced if it is given to a patient already taking zileuton, and adjusted according to theophylline levels. This is based on the results of a study in over 1000 patients taking zileuton 600 mg four times daily without apparent problems when this course of action was followed.

Zafirlukast + Aspirin

Aspirin 650 mg four times daily is reported to have resulted in a mean increase in the plasma levels of zafirlukast 40 mg daily of 45%. No further details are available. The clinical importance of this interaction awaits assessment but the manufacturers do not suggest any alteration in the zafirlukast dosage.

Zafirlukast + Macrolides

Zafirlukast plasma levels are decreased by erythromycin, but this does not appear to be clinically important. No interaction has been found between zafirlukast and azithromycin or clarithromycin.

Clinical evidence, mechanism, importance and management
A study in 11 asthmatic patients found that erythromycin 500 mg three times daily for 5 days reduced the mean plasma level of zafirlukast 40 mg by about 40%. This reduction in levels would be expected to reduce its antiasthmatic effects. If these drugs are given concurrently, be alert for a reduced response. However, note that the manufacturers do not suggest any alteration in the zafirlukast dosage.

Zafirlukast is an inhibitor of the cytochrome P450 isozyme CYP3A4 in vitro. However, a study in 12 healthy subjects found that zafirlukast 20 mg twice daily for 12 days did not significantly affect the pharmacokinetics of a single 500-mg dose of azithromycin or clarithromycin. No precautions would seem necessary if zafirlukast is given with azithromycin or clarithromycin.

Zafirlukast + Terfenadine

Zafirlukast plasma levels are decreased by terfenadine but the clinical significance of this is unclear. Zafirlukast does not increase the levels of terfenadine, and concurrent use does not prolong the QTc interval.

Clinical evidence, mechanism, importance and management
A study in 16 healthy men given zafirlukast 160 mg twice daily for 16 days with terfenadine 60 mg twice daily on days 8 to 16 found that the mean maximum serum levels and AUC of zafirlukast were reduced by 70% and 60%, respectively. There was a small, non-significant reduction in the terfenadine AUC and serum levels. A study in 8 healthy subjects given zafirlukast 160 mg twice daily with terfenadine 60 mg twice daily for 8 days found that the AUC of terfenadine and the QTc interval were not significantly increased with concurrent use, despite the fact that zafirlukast appears to inhibit CYP3A4 in vitro, the major enzyme involved in terfenadine metabolism. The reduction in zafirlukast serum levels would be expected to reduce its antiasthmatic effects, but this needs assessment. If both drugs are given be alert for a reduced response to zafirlukast.

The development of the tricyclic antidepressants arose out of work carried out on phenothiazine compounds related to chlorpromazine. The earlier molecules possessed two benzene rings joined by a third ring of carbon atoms, with sometimes a nitrogen, and had antidepressant activity, hence their name. Some of the later antidepressants have one, two or even four rings. “Table 34.1”, (see below) lists the common tricyclic antidepressants, the selective serotonin reuptake inhibitors (SSRIs) and a number of other drugs that are also used for depression.

SSRIs

These antidepressants act on neurones in a similar way to the tricyclics (see below) but they selectively inhibit the reuptake of serotonin (5-hydroxytryptamine or 5-HT). They have fewer antimuscarinic effects and are also less sedative and cardiotoxic.

Tricyclic antidepressants

The tricyclic antidepressants inhibit the activity of the ‘uptake’ mechanism by which some chemical transmitters (serotonin (5-HT) or noradrenaline (norepinephrine)) re-enter nerve endings in the CNS. In this way they raise the concentrations of the chemical transmitter in the receptor area. If depression represents some inadequacy in transmission between the nerves in the brain, increasing the amount of transmitter may go some way towards reversing this by improving transmission.

The tricyclics also have antimuscarinic (sometimes referred to as anticholinergic or atropine-like) activity and can cause dry mouth, blurred vision, constipation, urinary retention and an increase in ocular pressure. Postural hypotension and cardiotoxic effects may also occur, but they are less frequent. CNS adverse effects include sedation, the precipitation of seizures in certain individuals, and extrapyramidal reactions.

Other antidepressant drugs

(a) Nefazodone and Trazodone

Nefazodone is a phenylpiperazine structurally related to trazodone. Both nefazodone and trazodone block the reuptake of serotonin at presynaptic neurones and block α2-adrenoceptors, but have no apparent effect on dopamine. Unlike trazodone, nefazodone blocks the reuptake of noradrenaline. Compared to the tricyclics, neither drug has very significant antimuscarinic effects, but trazodone also has marked sedative properties. Nefazodone is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and therefore it will inhibit the metabolism of drugs by this route. For a list of CYP3A4 substrates see “Table 1.4”, (p.6). Note that, nefazodone has largely been withdrawn due to adverse hepatic effects.

(b) Reboxetine

Reboxetine is a potent inhibitor of noradrenaline reuptake. It has a weak effect on serotonin reuptake and no significant affinity for muscarinic receptors.

(c) Serotonin and noradrenaline reuptake inhibitors (SNRIs)

Antidepressants in this group include duloxetine, milnacipran and venlafaxine. They inhibit both serotonin and noradrenaline reuptake but with differing selectivity. Milnacipran blocks serotonin and noradrenaline reuptake approximately equally, but duloxetine and to a greater extent venlafaxine have selectivity for serotonin. Duloxetine and venlafaxine are reported to weakly inhibit dopamine reuptake. They are also reported to have no significant affinity for histaminergic, muscarinic or adrenergic receptors, and, compared with the tricyclics, appear to lack significant sedative and antimuscarinic effects.

(d) Tetracyclic antidepressants and related drugs

Mianserin and maprotiline are tetracyclic antidepressants, which have actions similar to those of the tricyclic antidepressants. However, while the tetracyclics are more sedating, their antimuscarinic effects are less marked. Maprotiline inhibits the reuptake of noradrenaline (norepinephrine) and has weak affinity for central adrenergic (α1) receptors. Mianserin does not prevent the peripheral reuptake of noradrenaline; it blocks presynaptic adrenergic (α2) receptors and increases the turnover of brain noradrenaline. It is also an antagonist of serotonin receptors in some parts of the brain.

Mirtazapine is a piperazinoazepine and an analogue of mianserin. It is a presynaptic adrenergic α2-antagonist that increases central noradrenergic and serotonergic transmission. It is a potent inhibitor of histamine (H1) receptors and this accounts for its sedative properties. It has little antimuscarinic activity.

---
**Bupropion + Antiepileptics**

Carbamazepine decreases bupropion levels and increases the levels of its active metabolite hydroxybupropion. Phenobarbital and phenytoin are predicted to interact similarly. The concurrent use of bupropion and valproate has led to increased levels of valproate and hydroxybupropion, and hallucinations have been reported in patients taking both drugs. Hypomania has been reported in a patient taking bupropion and lamotrigine.

**Clinical evidence, mechanism, importance and management**

(a) **Carbamazepine, Phenobarbital, Phenytoin**

One study found that carbamazepine at steady-state decreased the maximum plasma levels and AUC of bupropion and two of its metabolites (threohydrobupropion and erythrohydrobupropion) by about 81 to 96%. These two metabolites have only weak potential antidepressant activities. However, the AUC of another metabolite, hydroxybupropion (which has similar potency to the parent compound) was increased by 50% and its maximum plasma levels by 71%. Two patients with bipolar illness have been described who were initially given bupropion 450 mg daily, later increased up to 600 mg daily. They had undetectable bupropion plasma levels while taking carbamazepine but their plasma levels of hydroxybupropion were markedly increased.

What the sum of all these changes is likely to mean is uncertain, but good monitoring for any evidence of reduced efficacy and/or increased toxicity (due to the raised hydroxybupropion) is clearly needed. The same good monitoring would also be appropriate with phenytoin and phenobarbital, which would be expected to interact similarly, but clinical studies appear to be lacking.

(b) **Lamotrigine**

A study in 12 healthy subjects found that bupropion 150 mg twice daily did not affect the pharmacokinetics of a single 100-mg dose of lamotrigine. A 23-year-old patient with a DSM-IV diagnosis of major depression taking bupropion 400 mg daily had an improvement in mood when she was also given lamotrigine 25 mg at night, and there was further improvement in mood, decreased anxiety and increased energy when lamotrigine was increased to 50 mg daily for 3 weeks. However, when the dose of lamotrigine was increased to 75 mg daily she reported decreased sleep, increased energy, mood lability and increased spending, which was diagnosed as hypomania. The symptoms resolved over about 2 weeks when the lamotrigine dose was reduced to 50 mg at bedtime. Antidepressants in high doses or in combination can induce hypomania and in this case the effect was attributed to a potentiation of the effects of bupropion, caused by lamotrigine.

(c) **Sodium valproate**

A study found that the AUC of hydroxybupropion, an active metabolite of bupropion, almost doubled when bupropion was given with valproate at steady-state, but the pharmacokinetics of the parent compound and the two other less active metabolites were unaffected. An increase in valproate levels of almost 30% was seen in another report in one patient. Visual and auditory hallucinations were reported in a patient given bupropion and valproate. The UK manufacturer recommends caution when using drugs which may inhibit bupropion metabolism, such as valproate. As valproate levels may also be increased by bupropion, good monitoring for evidence of increased adverse effects of both drugs would seem appropriate.

**Bupropion + Antiretrovirals**

Ritonavir, efavirenz and nelfinavir inhibit the cytochrome P450 isoenzyme CYP2B6, which is the isoenzyme primarily involved in bupropion metabolism. The potential therefore exists for a drug interaction causing an increase in bupropion concentrations, which may lead to an increased risk of seizures. The US manufacturer of ritonavir predicts that the metabolism of bupropion might possibly be inhibited, leading to increased plasma levels and toxicity, and they recommend caution with a possible decrease in bupropion dose. However, a retrospective study identified 10 HIV-positive patients who had taken bupropion 150 mg once or twice daily together with nelfinavir, ritonavir or efavirenz for 3 weeks to 2 years (median 8 months) without having seizures, but note that the number of patients was small and the 2 patients who received ritonavir were only given 100 mg twice daily.

In contrast, the manufacturers of bupropion report a study in healthy subjects, in which ritonavir 600 mg twice daily for 20 days decreased the AUC and maximum serum levels of bupropion by about 65% and 60%, respectively. The plasma levels of the active metabolites of bupropion were also decreased. This contrasting information suggests that further study is needed. In the meantime, patients given bupropion with ritonavir should be monitored for increased bupropion effects and decreased bupropion effects. It would seem prudent to start bupropion at the lowest recommended dose and titrate to effect.

**Bupropion + Benzodiazepines and related drugs**

Visual hallucinations have been seen in one patient given zolpidem with bupropion. Bupropion is contraindicated during the abrupt withdrawal from any drug known to be associated with seizures on withdrawal, particularly benzodiazepines and related drugs.

**Clinical evidence, mechanism, importance and management**

Visual hallucinations lasting 3 to 4 hours occurred in a 17-year-old boy who had been taking bupropion 450 mg daily for one month and zolpidem 5 to 10 mg daily for about 6 months, when he increased the zolpidem dose to 60 mg. Note that the recommended dose of zolpidem is 10 mg daily and that zolpidem itself can cause psychiatric adverse effects such as hallucinations. Therefore an interaction is not established. Bupropion is contraindicated during abrupt withdrawal from any drug known to be associated with seizures on withdrawal, particularly benzodiazepines and benzodiazepine-like drugs.

**Bupropion + Carbimazole**

An isolated report describes acute liver failure in a patient taking bupropion and carbimazole.
Clinical evidence, mechanism, importance and management

A 41-year-old man treated for hyperthyroidism with carbimazole 15 mg daily and propranolol 10 mg daily for 5 years received a 10-day course of bupropion 150 mg daily to aid smoking cessation. Ten weeks after completing the course of bupropion he was admitted to hospital with severe jaundice, nausea, dyspepsia, lethargy, and epigastric discomfort persisting for 5 days. The only other medication he had taken was paracetamol (acetaminophen) 500 mg to 1 g daily for up to 2 days, about 2 weeks before admission. Both carbimazole and propranolol were discontinued. He developed acute liver failure and a rapid deterioration of renal function, complicated by sepsis and coagulopathy. Liver biopsy showed evidence of non-specific drug-induced acute liver injury. The patient died 19 days after the onset of symptoms. Both bupropion and carbimazole may cause liver damage. In this case the hepatotoxicity was attributed to bupropion or a combined toxic effect of bupropion and carbimazole. The potential for serious hepatotoxicity should be borne in mind if bupropion is given with other hepatotoxic drugs.1

Bupropion + Cimetidine

A randomised, open-label, crossover study in 24 healthy subjects found no evidence of any significant pharmacokinetic interaction between a single 300-mg dose of bupropion (sustained release preparation) and a single 800-mg dose of cimetidine.1 No special precautions would seem to be necessary on concurrent use.

Bupropion + Corticosteroids

A patient taking bupropion had a seizure after being given an intra-articular injection of methylprednisolone.

Clinical evidence, mechanism, importance and management

A case report describes a patient taking bupropion, who experienced a severe, prolonged seizure 24 hours after receiving methylprednisolone 30 mg for subacromial bursitis.1 The author notes that there could be a risk of seizures in patients taking bupropion who are given prophylactic oral steroids.2 This is in line with the manufacturers’ suggestion that systemic steroids could increase the risk of seizures, see ‘Bupropion + Miscellaneous’, p.1206.

Bupropion + Guanfacine

A grand mal seizure in a child, which was attributed to an interaction between bupropion and guanfacine, was later identified as being more probably due to a bupropion overdose.

Clinical evidence, mechanism, importance and management

A 10-year-old girl, being treated for attention deficit hyperactivity disorder, was prescribed increasing doses of bupropion up to 100 mg three times daily, to which guanfacine, initially 500 micrograms twice daily then 500 micrograms three times daily, was added. Ten days later she had a grand mal seizure, which the author of the report attributed to an interaction between the two drugs.1,2 This was challenged in subsequent correspondence.3 Furthermore, 2 years later the author of the original report wrote to say that he had now discovered that the girl had in fact taken 500 mg of bupropion and 5 mg of guanfacine before the seizure took place, so that what happened was much more likely to have been due to an overdose of the bupropion than to an interaction with guanfacine.4 Bupropion is associated with seizures at high doses (see ‘Bupropion + Miscellaneous’, p.1206). There is insufficient evidence to suggest that the concurrent use of these two drugs should be avoided.

Bupropion + MAOIs and related drugs

Bupropion is contraindicated with MAOIs, although there is little clinical evidence of serious problems. Orthostatic hypotension occurred in a patient given bupropion and selegiline, and an isolated report describes hypertension in a patient receiving bupropion and the antibacterial linezolid, which has weak MAO inhibitory activity.

Clinical evidence, mechanism, importance and management

In an uncontrolled study, 10 patients were treated for major affective disorder (8 unipolar, 2 bipolar) with bupropion in daily doses of 225 to 450 mg and an MAOI: isocarboxazid (1 patient), phenelzine (5), tranylcypromine (2), and the MAO-B inhibitor selegiline (2). Four were transferred from the MAOI to bupropion without any washout period, and the other 6 were given both drugs concurrently. No untoward cardiovascular events occurred, except for one patient taking bupropion and selegiline, who experienced orthostatic hypotension. Notable weight loss occurred in two others when transferred from the MAOI to bupropion.1 A Medline search (1962 to 2003) and review of published literature found no documented reports of hypertensive crises or fatalities when a stimulant drug (including bupropion) was cautiously added to an MAOI, although orthostatic hypotension and elevated blood pressure were reported.2

Despite very limited clinical evidence, the manufacturers of bupropion are apparently wary of a possible interaction with MAOIs because of the toxicity seen in studies in animals when phenelzine and bupropion were given concurrently.3 They contraindicate bupropion with MAOIs and recommend that at least 14 days should elapse between stopping irreversible MAOIs and starting bupropion.4,5 This precaution would therefore apply particularly to the older MAOIs (phenelzine, tranylcypromine, isocarboxazid etc). For reversible MAOIs such as moclobemide, the manufacturers advise that a 24-hour period is sufficient.4 Note also, that an isolated report describes severe intermittent intraoperative hypertension possibly due to an interaction between maintenance bupropion and linezolid, which had been started 24 hours previously for treatment of a resistant gram-positive infection.5 Linezolid is known to have weak MAOI properties, and, although concurrent use need not be avoided, this report therefore introduces a note of caution if both drugs are given together.

Bupropion + Methylphenidate

Isolated reports describe grand mal seizures in one patient and myocardial infarction in another, associated with bupropion and methylphenidate.

Clinical evidence, mechanism, importance and management

A 14-year-old boy taking methylphenidate 60 mg daily was additionally given bupropion 200 mg increased to 300 mg daily. The patient experienced grand mal seizures 4 weeks after the dosage increase, but remained seizure-free once the bupropion was discontinued.1 Another report describes acute myocardial infarction in a 16-year-old boy associated with methylphenidate, bupropion and erythromycin. It was proposed that the erythromycin might have caused elevated levels of bupropion leading to a
hyperadrenergic state and this, together with the sympathetic effects of the
methylphenidate, resulted in excessive vasospasm, leading to myocardial
damage.\(^2\)

The report of the myocardial infarction is isolated and of uncertain gen-
significance. Note that the manufacturers of bupropion list stimulants as
drugs that increase the risk of seizures with bupropion (see ‘Bupropion +
Miscellaneous’, below) and this case adds weight to that warning.

---

## Bupropion + Miscellaneous

The manufacturers issue warnings about the concurrent use of
bupropion with alcohol, amantadine, levodopa, drugs that can
lower the convulsive threshold, drugs metabolised by the cyto-
hrome P450 isoenzyme CYP2D6, drugs which affect CYP2B6,
and also the use of nicotine.

### Clinical evidence, mechanism, importance and management

**(a) Alcohol**

The manufacturers report rare adverse neuropsychiatric events or reduced
alcohol tolerance in patients drinking alcohol during bupropion treatment.
They recommend that the consumption of alcohol should be minimised or
avoided.\(^1,2\) For comment on the increased risk of seizures with alcohol see
**(d)**, below.

**(b) Antiparkinsonian drugs**

The manufacturers say that the concurrent use of bupropion and levodopa
or amantadine should be undertaken with caution because limited clinical
data suggest a higher incidence of undesirable effects (nausea, vomiting,
excitement, restlessness, postural tremor) in patients given bupropion with
either drug. Good monitoring is therefore appropriate and patients should
be given small initial bupropion doses, which are increased gradually.\(^1,2\)

**(c) CYP2B6 substrates**

The manufacturers advise caution if bupropion is used with drugs such as
clopidogrel, cyclophosphamide, ifosfamide, orphenadrine, and ticlopi-
dine as bupropion is metabolised to its major metabolite hydroxybupropi-
on by CYP2B6 and these drugs are also metabolised by this isoenzyme.\(^1,2\)
However, there is no evidence to suggest that this is a problem in practice.

**(d) CYP2D6 substrates**

The manufacturers of bupropion predict that it may inhibit the metabolism
of drugs by the cytochrome P450 isoenzyme CYP2D6, which might result
in a rise in their plasma levels. They name haloperidol, risperidone,
thioridazine, flecainide, propafenone. The recommendation is that if
any of these drugs is added to treatment with bupropion, doses at the lower
end of the range should be used. If bupropion is added to existing treat-
ment, decreased dosages should be considered.\(^1,2\) This seems a pruden-
t precaution as bupropion raises the levels of ‘desipramine’, (p.1232), ‘dex-
tromethorphan’, (p.1255), ‘metoprolol’, (p.838), all of which are metabo-
lised by this isoenzyme.

**(e) Drugs and circumstances that can lower the convulsive threshold**

There is a small dose-related risk of seizures with bupropion. At a daily
 dose of 300 mg of the sustained-release formulation the risk is 0.1%,
which increases to 0.4% at a dose of 450 mg of the immediate-release for-
mulation, and increases tenfold between doses of 450 and 600 mg daily.\(^2\)
The manufacturers caution the use of other drugs that lower the convulsive
threshold, the concern being that these drugs might further increase the
risk of seizures. The UK\(^1\) and US\(^2\) manufacturers list antipsychotics, an-
tidepressants (see ‘SSRIs’, (p.1215) and ‘tricyclics’, (p.1232)), ‘systemic
steroids’, (p.1205), and theophylline. The UK manufacturers additionally list
antimalarials, tramadol, quinolones and sedating antihistamines.
A maximum dose of 150 mg of bupropion should be considered for pa-
tients prescribed such drugs.\(^2\) Caution is also urged with regard to circum-
stances that may lower the convulsive threshold, including the use of
anorectics or ‘stimulants’, (p.1205), excessive use of alcohol or seda-
tives, addiction to cocaine or opiates. Bupropion is contraindicated during
abrupt withdrawal from alcohol or any drug known to be associated with
seizures on withdrawal.\(^1,2\)

---

1. Pederson KJ, Kunzler DH, Garbe GI. Acute myocardial ischemia associated with ingestion of

## Bupropion + Pseudoephedrine

An isolated report describes acute myocardial ischaemia associat-
ed with bupropion, nicotine and pseudoephedrine.

### Clinical evidence, mechanism, importance and management

A 21-year-old man presented in a hospital emergency department with se-
vere chest pain, radiating pain into both arms and between the shoulder
blades, diaphoresis and shortness of breath. Initially this was diagnosed as
an acute myocardial infarction, but a later angiogram showed normal cor-
onary arteries and it was concluded that these symptoms were due to acute
myocardial ischaemia apparently brought on by the combined use of pseu-
doeephedrine (9 tablets of 30 mg taken over the previous 3 days), bupropi-
on for smoking cessation and nicotine (he smoked 25 cigarettes daily).
The authors of the report postulate that all these drugs acted on the alpha
receptors of the coronary arteries to cause vasospasm and acute ischaemia.
He had been taking both drugs and erythromycin for 3 days, and had taken
pseudoephedrine on numerous previous occasions without problems. He
recovered fully.\(^1\)

This is an isolated case from which no general conclusions can be drawn,
but some warning might be appropriate for patients who are at risk of cor-
onary ischaemia. For comment on the use of nicotine with bupropion, see
‘Bupropion + Miscellaneous’, above.

## Maprotiline + Hormonal contraceptives or Tobacco

Neither tobacco smoking nor the use of oral contraceptives affect
the levels of maprotiline.

### Clinical evidence, mechanism, importance and management

A study in women showed that, over a 28-day period, the use of oral con-
traceptives did not significantly affect the steady-state blood levels of
maprotiline 75 mg given at night, nor was its therapeutic effectiveness
Maprotiline + Propranolol

Maprotiline toxicity, attributed to the concurrent use of propranolol, has been described in three patients.

Clinical evidence

A patient experienced maprotiline toxicity (dizziness, hypotension, dry mouth, blurred vision, etc.) after taking propranolol 120 mg daily for 2 weeks. His trough maprotiline levels had risen by 40%. The levels fell and the adverse effects disappeared when the propranolol was withdrawn.1 Another patient taking propranolol 120 mg daily began to experience visual hallucinations and psychomotor agitation within a few days of starting to take maprotiline 200 mg daily.2 Another man taking haloperidol, benztrapine, triamterene, hydrochlorothiazide and propranolol became disorientated, agitated and uncooperative, with visual hallucinations and incoherent speech, within a week of starting to take maprotiline 150 mg daily. These symptoms disappeared when all the drugs were withdrawn. Reintroduction of the antihypertensive drugs with haloperidol and desipramine proved effective and uneventful.3

Mechanism

Not understood. A suggested reason is that the propranolol reduces the blood flow to the liver so that the metabolism of the maprotiline is reduced, leading to its accumulation in the body.

Importance and management

Information seems to be limited to the cases cited. The general importance of this interaction is uncertain. The authors of one of the reports4 say that simultaneous use is advisable, but on the basis of just three cases, and with no further information, this seems over-cautious.

Maprotiline + Risperidone

Risperidone appears to increase the plasma levels of maprotiline.

Clinical evidence, mechanism, importance and management

A 39-year-old patient with a schizodpressive disorder taking pipamperone and lorazepam, and taking maprotiline 175 mg daily for a severe depressive episode had plasma levels of maprotiline of 145 and 166 nanograms/mL after 4 and 6 weeks, respectively. After 8 weeks, she was given risperidone to treat acute psychotic symptoms. The dose of risperidone was titrated over 5 days up to 5 mg daily and the dose of pipamperone was increased from 40 to 80 mg at night. She had a rapid remission of the psychotic symptoms and almost complete remission of the depression, but gradually developed antimuscarinic adverse effects. Ten days after starting risperidone and with maprotiline at a dose of 150 mg daily, maprotiline plasma levels had increased to 266 nanograms/mL. The doses of maprotiline and risperidone were reduced to 100 mg and 3 mg daily, respectively, and this reduced the severity of the adverse effects.1

Gradual increases in maprotiline levels over 6 to 7 weeks during concurrent risperidone therapy have been found in 2 other patients. One of the patients was also taking nortriptyline, but its levels were unaltered.1 Maprotiline is mainly metabolised by the cytochrome P450 isozyme CYP2D6. The increased levels of maprotiline may be due to an inhibition of CYP2D6-mediated metabolism by risperidone.1 This interaction is unconfirmed but be aware of the possibility of an interaction if maprotiline adverse effects are troublesome.

Mianserin + Antiepileptics

Plasma levels of mianserin can be markedly reduced by the concurrent use of carbamazepine, phenobarbital or phenytoin.

Clinical evidence

A comparative study in 6 epileptics and 6 healthy subjects showed that phenytoin with either phenobarbital or carbamazepine markedly reduced the plasma levels of a single dose of mianserin.1,2 The mean half-life of mianserin was reduced by 75% (from 16.9 to 4.8 hours) and the AUC was reduced by 86%. Another study in 4 patients found that carbamazepine reduced serum mianserin levels by 70%.3 In another study 12 patients taking mianserin 60 mg daily were also given carbamazepine 400 mg daily for 4 weeks. Average plasma levels of total S-mianserin (the more potent enantiomer) and total R-mianserin were reduced by about 45% in the presence of carbamazepine.4

Mechanism

It seems probable that these antiepileptics increase the metabolism of mianserin by the liver, thereby increasing its loss from the body. Carbamazepine may increase the metabolism of mianserin by cytochrome P450 isozyme CYP3A4.4

Importance and management

Information seems to be limited to these studies, but the interaction appears to be established and of clinical importance. Monitor concurrent use and increase the dosage of mianserin as necessary. One study suggests that the dose of mianserin may need to be approximately doubled if carbamazepine 400 mg daily is added.4

The manufacturers say that two weeks should elapse between taking an MAOI and mirtazapine. Mirtazapine combined with other serotonergic antidepressants may possibly increase the risk of bleeding and/or the serotonin syndrome. SSRIs may increase plasma levels of mirtazapine and there is a report of hypomania associated with combined use. The concurrent use of mirtazapine with amitriptyline may have a minor effect on the levels of both drugs.

Clinical evidence

(a) MAOIs

No adverse interactions have been reported between mirtazapine and the MAOIs but, to be on the safe side, the manufacturers say that the concurrent use of mirtazapine and MAOIs should be avoided both during and within two weeks of stopping treatment.

(b) SNRIs

For mention of the serotonin syndrome and an increased risk of bleeding in patients given mirtazapine and venlafaxine, see ‘SNRIs; Venlafaxine + Antidepressants’, p.1212.

(c) SSRIs

1. Escitalopram. For a report of bleeding associated with the combined use of escitalopram, mirtazapine and venlafaxine, see ‘SNRIs; Venlafaxine + Antidepressants’, p.1212.

2. Fluoxetine. There is an isolated report of the serotonin syndrome in a 75-year-old woman when fluoxetine 20 mg daily was discontinued and mirtazapine 30 mg daily started soon afterwards (exact interval not stated). Symptoms including dizziness, headache, nausea, dry mouth, anxiety, agitation, suicidal ideas and difficulty in walking occurred within hours of the first dose of mirtazapine. Symptoms worsened until mirtazapine was discontinued on day 5, after which an improvement was noticed. Fluoxetine was restarted on day 7.

3. Fluvoxamine. A 26-year-old woman with a 12-year history of anorexia nervosa, taking fluvoxamine 200 mg daily, developed symptoms consistent with the serotonin syndrome (tremors, restlessness, twitching, flushing, diaphoresis, nausea) about 4 days after starting mirtazapine 30 mg daily. A 17-year-old boy taking mirtazapine 30 mg daily experienced increased anxiety when fluvoxamine 100 mg daily was also given. Mirtazapine serum levels were increased threefold. In a second patient taking mirtazapine 15 mg daily, the addition of fluvoxamine 50 mg daily resulted in a fourfold increase in serum mirtazapine concentrations, accompanied by mood improvements.

4. Paroxetine. A study in 21 healthy subjects given mirtazapine 30 mg, paroxetine 40 mg or a combination of both, daily for 9 days, found that paroxetine inhibited the metabolism of mirtazapine (AUC of mirtazapine increased by about 17%). Mirtazapine did not alter the pharmacokinetics of paroxetine. The results of psychometric assessments suggested that concurrent use of mirtazapine and paroxetine did not alter cognitive function, or cause major changes in mood or sleep, compared with the use of either drug alone.

5. Sertraline. A woman taking sertraline 250 mg daily was also given mirtazapine 15 mg daily because of inadequately controlled depression. Within 4 days she developed hypomanic symptoms and she stopped taking the mirtazapine. The hypomania resolved within 3 days but her depression then recurred.

6. Tricyclic antidepressants

In a single-blind, crossover study involving 24 healthy subjects, mirtazapine 15 to 30 mg daily, amitriptyline 25 to 75 mg daily or both drugs were given for periods of 9 days and in addition, 8 subjects received placebo. Amitriptyline increased the maximum plasma levels of mirtazapine, in male subjects only, by 36%. Mirtazapine increased the maximum plasma levels of amitriptyline in male subjects by 23% but in female subjects the maximum plasma levels were decreased by 23%. Other pharmacokinetic parameters and tolerability were not affected by concurrent use.

Mechanism

The cytochrome P450 isoenzyme CYP2D6 is inhibited by fluoxetine and paroxetine and CYP1A2 is inhibited by fluvoxamine. Both of these isoenzymes are involved in the metabolism of mirtazapine, which may explain the raised mirtazapine levels reported.

SNRIs, SSRIs and mirtazapine affect serotonin transmission, which may lead to increased serotonin levels and therefore cause the symptoms described as the serotonin syndrome. For more about the serotonin syndrome see ‘Additive or synergistic interactions’, (p.9).

Importance and management

These isolated reports would seem to suggest that the combined use of mirtazapine and the SSRIs can lead to the serotonin syndrome. However, whether these are cases of the serotonin syndrome has been disputed. Low body weight and a decrease in total body fat may also have contributed in one case. This and other reports of anxiety and hypomania highlight the need for some caution during concurrent use. One manufacturer reported that, from postmarketing experience, it appears that the serotonin syndrome occurs very rarely in patients taking mirtazapine alone or in combination with SSRIs. They recommend that if the combination is required, dosage alterations should be made with caution and patients closely monitored for any signs of excessive serotonin stimulation. Similar caution would also seem appropriate with SNRIs.

Carbamazepine and phenytoin can decrease the plasma levels of mirtazapine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, healthy subjects were given carbamazepine (at steady state) with mirtazapine for 7 days. It was found that carbamazepine (an inducer of cytochrome P450 isoenzyme CYP3A4) decreased the AUC and maximum plasma levels of mirtazapine, by 63% and 44%, respectively, and increased the peak levels of demethylmirtazapine. Another related study found that mirtazapine did not affect the pharmacokinetics of carbamazepine (also a CYP3A4 substrate). A study in 9 healthy subjects given phenytoin 200 mg daily for 17 days, and from day 11, mirtazapine 15 mg daily for 2 days then 30 mg daily for 5 days, found that mirtazapine had no effect on the steady-state pharmacokinetics of phenytoin. In a second associated study, 8 healthy subjects were given mirtazapine 15 mg daily for 2 days then 30 mg daily for 15 days with phenytoin 200 mg daily on days 8 to 17. It was found that phenytoin (an inducer of CYP3A4) decreased the AUC and maximum plasma levels of mirtazapine by 47% and 33%, respectively.

The manufacturers advise that if carbamazepine or other drugs that induce drug metabolism (such as phenytoin) are given with mirtazapine, the mirtazapine dose may have to be increased. Further, if treatment with an inducer is stopped, the mirtazapine dosage may have to be reduced. Although not specifically named, phenobarbital and primidone can also induce CYP3A4, and they therefore may interact similarly. Note that,
Mirtazapine + Antipsychotics

Limited evidence suggests that risperidone does not appear to affect mirtazapine pharmacokinetics. Mirtazapine does not appear to interact to a clinically relevant extent with clozapine, olanzapine or risperidone.

Clinical evidence, mechanism, importance and management

A pilot study in 6 psychiatric patients taking risperidone 1 to 3 mg twice a day for 1 to 4 weeks followed by 2 to 4 weeks of combined treatment with mirtazapine 15 to 30 mg at night, found that mirtazapine did not affect the plasma levels of risperidone or its 9-hydroxy metabolite. Data from another patient suggest that giving risperidone with mirtazapine does not result in clinically relevant changes in the plasma levels of mirtazapine. Concurrent use did not appear to increase the incidence of adverse effects, but the number of patients was limited.1

Another study in 24 schizophrenic patients investigated the effect of adding mirtazapine 30 mg at bedtime, for 6 weeks, to treatment with clozapine (9 patients), risperidone (8), or olanzapine (7). Mirtazapine had a negligible effect on the metabolism of all three drugs and the combination was well tolerated.2

Mirtazapine + Benzodiazepines

The sedative effects of mirtazapine may be increased by the benzodiazepines.

Clinical evidence, mechanism, importance and management

A single-dose study in 12 healthy subjects found that the pharmacokinetics of mirtazapine and diazepam were not affected by concurrent use, but diazepam further impaired the action of mirtazapine on objectively measured skill performance; the combined actions were mostly additive.1 The impairment of psychomotor performance and learning caused by diazepam is increased by mirtazapine and therefore the manufacturers warn that the sedative effects of benzodiazepines in general may be potentiated by concurrent use with mirtazapine.2,3

Mirtazapine + Cimetidine

Cimetidine increases the bioavailability of mirtazapine.

Clinical evidence, mechanism, importance and management

In a double-blind, crossover study in 12 healthy subjects, placebo or cimetidine 800 mg twice daily were given for 14 days. Mirtazapine 30 mg was given at night on days 6 to 12. Concurrent administration of cimetidine with mirtazapine increased the AUC and peak plasma levels of mirtazapine by 54% and 22%, respectively. Trough and average mirtazapine plasma levels, at steady state, were increased by 61% and 54%, respectively, by cimetidine. Mirtazapine did not affect the pharmacokinetics of cimetidine.1 The manufacturers advise that mirtazapine dosage may need to be reduced during concurrent treatment and increased when cimetidine treatment is stopped.2,3

Mirtazapine + Miscellaneous

Pharmacokinetic interactions may occur between mirtazapine and inhibitors or inducers of the cytochrome P450 isoenzyme CYP3A4.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

Ketoconazole is reported to increase the peak plasma levels and AUC of mirtazapine by about 30% and 45%, respectively.1 Mirtazapine is extensively metabolised and the cytochrome P450 isoenzyme CYP3A4 is thought to be responsible for the formation of the N-demethyl and N-oxide metabolites.2 The manufacturers advise caution when potent inhibitors of CYP3A4 such as azole antifungals, protease inhibitors, erythromycin, or nefazodone are given with mirtazapine.1,2

(b) Rifampicin (Rifampin)

The manufacturers advise that if drugs such as rifampicin, that induce drug metabolism, are given with mirtazapine, the mirtazapine dose may have to be increased. Further, if treatment with an inducer is stopped, mirtazapine dosage may have to be reduced.1,2

Nefazodone + Antidepressants

An isolated report describes a woman who developed marked and acute hypotension and weakness when desipramine, fluoxetine and venlafaxine were replaced by nefazodone. Isolated cases describe the serotonin syndrome in patients given nefazodone together, or sequentially, with another serotonergic drug (amitriptyline, paroxetine, St John’s wort, or trazodone). The manufacturer recommended that nefazodone should not be used with an MAOI or within 14 days of discontinuing an MAOI. Note that, due to adverse hepatic effects nefazodone was widely withdrawn from the market.

Clinical evidence, mechanism, importance and management

(a) MAOIs

The manufacturer stated that nefazodone should not be used with an MAOI or within 2 weeks of discontinuing treatment with an MAOI. Conversely at least one week should be allowed after stopping nefazodone before starting an MAOI.1 There appears to be no direct clinical evidence that an adverse interaction occurs.

(b) Reboxetine

Nefazodone may increase the plasma concentrations of reboxetine, see ‘Reboxetine + Antidepressants’, p.1210.

(c) SSRIs

Anecdotal evidence has suggested that patients who are switched from an SSRl to nefazodone may tolerate nefazodone poorly. Nevertheless, in a 12-week, open study involving 26 depressed patients, nefazodone 100 to 600 mg daily was equally well tolerated in the 13 patients who had discontinued an SSRI within 1 to 4 weeks compared with the other 13 patients who had received no antidepressant treatment for the previous 6 months. However, the patients who had recent exposure to an SSRI (within the previous 4 weeks) were given a washout period of 4 to 5 days for short half-life SSRIs or a full week washout period for fluoxetine prior to initiating...
nefazodone. Cases with specific SSRIs are discussed in the subsections below.

1. Fluoxetine. A woman with a one-year history of DSM-IV major depressive disorder and panic disorder was given daily doses of desipramine 75 mg, fluoxetine 20 mg, venlafaxine 37.5 mg, clonazepam 3 mg and valproate 400 mg with no adverse effects, except a dry mouth and sexual difficulties. The first three drugs were stopped and replaced by nefazodone 100 mg twice daily, started about 12 hours later. Within an hour of the first dose she felt very weak and her blood pressure was found to have fallen to only 90/60 mmHg (normally 120/90 mmHg). On waking the next day she had severe weakness, unsteady gait, pale, cool and sweaty skin, and paraesthesia. During the day she took two further 100-mg doses of nefazodone and her condition persisted and worsened with continuing hypotension. The nefazodone was discontinued and by the following day the weakness had improved, disappearing over the next few days. Within a week nefazodone 200 mg daily was reintroduced without problems. The US manufacturer of nefazodone noted that nefazodone did not alter the pharmacokinetics of fluoxetine, but fluoxetine increased the AUC of the metabolites of nefazodone by up to 6-fold. When nefazodone 200 mg twice was given to patients who had been taking fluoxetine for 7 days adverse effects (including headache and nausea) were increased. The manufacturers advised allowing a washout period of at least one week (more may be needed depending on dose and individual patient characteristics) to minimise these effects. It therefore seems likely that fluoxetine was the interacting drug, but it is impossible to rule out a contribution from the other drugs.

2. Paroxetine. A woman was withdrawn from nefazodone after about 6 months of treatment, tapering over the last fortnight to 75 mg every 12 hours. Within a day she started taking paroxetine 20 mg daily and valproic acid, and was admitted the next day with muscle rigidity, uncoordinated muscle tremors, flailing arms and twitching legs, diaphoresis and agitation. This was identified as the serotonin syndrome. Rechallenge with paroxetine 7 days later was uneventful.4

(d) St John’s wort
An elderly patient taking nefazodone 100 mg twice daily, developed symptoms similar to the serotonin syndrome within 3 days of starting to take St John’s wort 300 mg three times daily. The symptoms included nausea, vomiting, and restlessness. She was asked to stop both medications, but continued the St John’s wort and her symptoms gradually improved over a 1-week period.5

(e) Trazodone
A woman taking irbesartan for hypertension was also given nefazodone at an initial dosage of 200 mg daily, followed by 400 mg daily for about 5 weeks. Four days after the dose was increased to 500 mg daily, and trazodone 25 to 50 mg daily was also added as a hypnotic, she was admitted to hospital with a blood pressure of 240/120 mmHg. She was confused, had difficulty concentrating and had numbness on the right side of her lips, nose and right-hand fingers, flushed pruritic skin, nausea, and loose stools. On examination she was restless, hyperreflexic, and diaphoretic. Nefazodone and trazodone were discontinued. She recovered after treatment with labetalol, clonidine, amlodipine and increased irbesartan dosage. Although trazodone is used with other serotonergic drugs, it is important to be aware that this may lead to the potentially fatal ‘serotonin syndrome’, (p.9).

The manufacturers of trazodone say that in vitro drug metabolism studies suggest that there is a potential for drug interactions when trazodone is given with a potent CYP3A4 inhibitor such as nefazodone. There may be substantial increases in trazodone levels, with the potential for adverse effects, and a lower dose of trazodone should be considered.6,7 The UK manufacturer suggests avoidance of the combination where possible.7

(f) Tricyclic antidepressants
1. Amitriptyline. A woman who had been taking amitriptyline 10 mg at night and thioridazine developed the serotonin syndrome after taking half a tablet of nefazodone (dosage unspecified).3

2. Desipramine. The manufacturer of nefazodone reported that desipramine 75 mg daily did not change the pharmacokinetics of nefazodone 150 mg twice daily, but levels of the nefazodone metabolite, meta-chlorophenylpiperazine, were increased by up to 50%. There was no change in the pharmacokinetics of desipramine or its metabolite. No specific dosage adjustments were said to be required on concurrent use.1

Nefazodone + Cimetidine

No changes in the steady-state pharmacokinetics of either cimetidine or nefazodone were seen in a week long study in 18 healthy subjects given cimetidine 300 mg four times daily and nefazodone 200 mg every 12 hours. No special precautions would seem to be necessary if both drugs are used concurrently.1

Reboxetine + Antidepressants

The manufacturer of reboxetine recommends avoiding the concurrent use of potent CYP3A4 inhibitors as reboxetine levels may be increased. They also recommend avoiding the concurrent use of MAOIs, because of the possible risk of hypertensive crises. The concurrent use of fluoxetine and reboxetine does not appear to alter the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A study in 30 healthy subjects given reboxetine 4 mg twice daily and fluoxetine 20 mg daily found no significant changes in the pharmacokinetics of either drug.1

The manufacturer of reboxetine suggests that because fluvoxamine is a potent inhibitor of CYP3A4 it may increase plasma concentrations of reboxetine, and, because of the narrow therapeutic margin of reboxetine, concurrent use should be avoided. However, note that fluvoxamine is more usually considered a potent inhibitor of CYP1A2 and is generally considered a weak inhibitor of CYP3A4.

No data seem to be available about the concurrent use of reboxetine with MAOIs and the manufacturer currently advises the avoidance of MAOIs because of the potential risk of a tyramine-like effect [hypertensive crisis].2

Reboxetine + CYP3A4 inhibitors

Ketoconazole may inhibit the metabolism of reboxetine. The manufacturer therefore advises avoiding the concurrent use of azoles, macrolides and nefazodone.

Clinical evidence, mechanism, importance and management

A study in 11 healthy subjects found that ketoconazole 200 mg daily for 5 days increased the plasma concentrations of a single 4-mg dose of reboxetine, taken on the second day, by about 50%. Although the adverse effect profile of reboxetine was not altered, because reboxetine has a narrow therapeutic index it was concluded that caution should be used and a reduction in reboxetine dosage considered if it is given with ketoconazole.1 The manufacturer recommends that potent inhibitors of CYP3A4, including azoles, macrolides (erythromycin) and nefazodone should not
be given with reboxetine. For a list of clinically significant CYP3A4 inhibitors see ‘Table 1.4’, (p.6).

### Reboxetine + Dextromethorphan

A study in 10 healthy subjects who were of the CYP2D6 extensive metaboliser phenotype (the most commonly found phenotype) found that the pharmacokinetics of reboxetine 8 mg daily were not affected by a single 30-mg dose of dextromethorphan.

### Reboxetine + Miscellaneous

The manufacturer points out the possibility of hypokalaemia if reboxetine is used with potassium-depleting diuretics. Experience with reboxetine in elderly patients suggests it reduces potassium by up to 0.8 mmol/L, starting after 14 weeks of use. They also suggest that the concurrent use of reboxetine and ergot derivatives might result in increased blood pressure although no clinical data are quoted, and the concurrent use of lorazepam results in mild to moderate drowsiness and an orthostatic increase in heart rate, but no pharmacokinetic interaction occurs.

### SNRIs + H2-receptor antagonists

Cimetidine may increase duloxetine and venlafaxine plasma levels, which may lead to an increase in their adverse effects. Famotidine does not appear to interact with duloxetine.

### Clinical evidence, mechanism, importance and management

**(a) Duloxetine**

The metabolism of duloxetine is reduced by cytochrome P450 isoenzyme CYP1A2 inhibitors and it has been suggested that drugs with this effect should be avoided (see ‘fluvoxamine’, (p.1212)). The US manufacturer of duloxetine specifically mentions cimetidine as an inhibitor of this enzyme and therefore if duloxetine is given with cimetidine it would seem prudent to monitor duloxetine plasma levels and adverse effects. Famotidine has no effect on the rate or extent of absorption of a single 40-mg dose of duloxetine, and it may therefore be a suitable alternative to cimetidine in patients taking duloxetine.

**(b) Venlafaxine**

Venlafaxine 800 mg daily for 5 days was found to reduce the oral clearance of venlafaxine 50 mg every 8 hours by 40%, and to increase the AUC by 62% in 18 healthy subjects. It had no effect on the formation or elimination of the major active metabolite of venlafaxine, O-desmethylvenlafaxine (ODV). The total level of venlafaxine with ODV was found to be increased by only 13%. Thus the overall pharmacological activity of the two was only slightly increased by cimetidine and no special precautions would seem to be necessary on concurrent use. However, the manufacturers of venlafaxine suggest that the elderly and those with hepatic impairment may possibly show a more pronounced effect, and such patients should be monitored more closely for venlafaxine adverse effects.

### SNRIs + Propafenone

An isolated report describes psychosis, which occurred when a patient took venlafaxine with propafenone. Duloxetine may increase propafenone levels.

### Clinical evidence, mechanism, importance and management

**(a) Duloxetine**

Duloxetine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2D6 and may increase the levels of drugs metabolised by CYP2D6 such as propafenone. The US manufacturer recommends that the concurrent use of duloxetine and propafenone should be approached with caution.

**(b) Venlafaxine**

A 67-year-old woman with bipolar disorder taking venlafaxine 300 mg daily experienced symptoms of paranoia, visual hallucinations and marked confusion, about 2 weeks after starting propafenone 600 mg daily for intermittent atrial fibrillation. Serum levels of venlafaxine had increased from 85 nanograms/mL to 520 nanograms/mL (upper level of normal range 150 nanograms/mL) and levels of the metabolite O-desmethylvenlafaxine had increased but were still within normal ranges. Venlafaxine was stopped for a few days then restarted at the lower dose of 75 mg daily and her mental condition (diagnosed as organic psychosis) improved. However, as she also had orthostatic hypotension her propafenone dosage was subsequently reduced to 300 mg daily, which necessitated dosage adjustments of venlafaxine because of a marked drop in serum level. When propafenone was again increased to 600 mg daily the venlafaxine had to be reduced to 50 mg daily. The reasons for the interaction are not known, but venlafaxine is partly metabolised by CYP2D6 and propafenone may compete for this metabolic pathway. Information is limited to this single case report, and therefore its general significance is unclear.

### SNRIs + St John’s wort (Hypericum perforatum)

The serotonin syndrome has been reported in one patient taking venlafaxine and St John’s wort.

### Clinical evidence, mechanism, importance and management

An interaction between venlafaxine and St John’s wort (Hypericum perforatum) was reported to the Centre Régional de Pharmacovigilance de Marseille involving a 32-year-old man who had been taking venlafaxine 250 mg daily for several months. He started taking St John’s wort at a dose of 200 drops 3 times daily (usual dose up to 160 drops daily) and on the third day felt faint and anxious, and had symptoms of diaphoresis, shivering and tachycardia. The St John’s wort was stopped and his symptoms resolved in 3 days without altering the dose of venlafaxine. A search of Health Canada’s database of spontaneous adverse reactions for the period 1998 to 2003 also found one case of suspected serotonin syndrome as a result of an interaction between venlafaxine and St John’s wort. Duloxetine would be expected to interact similarly. The manufacturers of both duloxetine and venlafaxine generally advise caution if they are given with drugs that affect the serotonergic neurotransmitter systems.

The manufacturers of duloxetine contraindicate the concurrent use of MAOIs because of the theoretical risk of the serotonin syndrome. Similarly they recommend caution with other serotonergic drugs, including the SSRIs, venlafaxine, and tryptophan. Fluvoxamine should not be used with duloxetine, because it markedly increases duloxetine levels. Low-dose paroxetine caused a modest increase in the duloxetine AUC, but fluoxetine is predicted to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturer advises caution if duloxetine is used with SSRIs (see below), ‘tricyclic antidepressants’, (p.1240), ‘St John’s wort’, (p.1224), venlafaxine, or tryptophan, because the concurrent use of more than one serotonergic drug has rarely resulted in ‘the serotonin syndrome’, (p.9).1,2

(a) SSRIs

1. Fluvoxamine. Fluvoxamine 100 mg daily increased the AUC of duloxetine five- to sixfold, and decreased its clearance by about 77% in 14 healthy subjects.1,3 Similar increases in duloxetine plasma levels were found in 15 healthy subjects who were given fluvoxamine 50 to 100 mg daily and duloxetine 40 mg twice daily.5 Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, by which duloxetine is, in part, metabolised.1 Therefore concurrent use raises duloxetine levels. Although the clinical relevance of the increases in duloxetine levels have not been assessed, the manufacturer considers that the rise with fluvoxamine is so marked that the combination should be avoided.1,3 The UK manufacturers specifically contraindicate concurrent use.1 Other SSRIs have minimal effects on this isoenzyme, and would therefore not be expected to interact by this route, but see also paroxetine, below.

2. Paroxetine. The concurrent use of paroxetine 20 mg daily and duloxetine 40 mg daily increased the AUC of duloxetine at steady state by about 60% in healthy subjects.5 Paroxetine is an inhibitor of CYP2D6, which has a role in duloxetine metabolism. Therefore concurrent use raises duloxetine levels. The rise in duloxetine levels with paroxetine 20 mg daily is probably not clinically relevant, but the manufacturer notes that greater increases would be expected with higher doses.3,5 Caution is warranted. Other SSRIs (notably fluoxetine) also inhibit this isoenzyme, and would therefore be expected to interact similarly.

(b) MAOIs

The manufacturers contraindicate the use of duloxetine with non-selective irreversible MAOIs, and for 14 days after discontinuing an MAOI, and at least 5 days should be allowed after stopping duloxetine before starting an MAOI. This is because of the possible risk of serotonin syndrome.1,3 Although the risk would be lower with selective, reversible MAOIs such as moclobemide, the manufacturer still says concurrent use is not recommended.1,2

Ciprofloxacin, enoxacin and quinidine are predicted to raise flecainide and thioridazine. Due to the theoretical risk of serotonin syndrome, the manufacturers of duloxetine recommend caution with other serotonergic drugs or other CNS depressants. The pharmacokinetics of duloxetine were not affected by antacids.

Clinical evidence, mechanism, importance and management

(a) Antacids

Aluminum/magnesium-containing antacids had no effect on the rate or extent of absorption of a single 40-mg dose of duloxetine.1,3 No special precautions appear to be necessary on concurrent use.

(b) CYP1A2

1. Inducers. Population pharmacokinetic studies have shown that smokers have almost 50% lower plasma concentrations of duloxetine, when compared with non-smokers.4 The clinical significance of this finding is unclear.

2. Inhibitors. ‘Fluvoxamine’, (above), a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, markedly increases duloxetine levels. The manufacturers predict that some quinolones (they name ciprofloxacin and enoxacin) will have the same effect and suggest that their concurrent use with duloxetine should be avoided.1,3 For a list of clinically significant CYP1A2 inhibitors, see ‘Table 1.2’, (p.4).

(c) CYP2D6

1. Inhibitors. Paroxetine, an inhibitor of the cytochrome P450 isoenzyme CYP2D6, increases duloxetine levels. The manufacturer suggests that other CYP2D6 inhibitors will interact similarly, and specifically names quinidine.3 For a list of clinically significant CYP2D6 inhibitors, see ‘Table 1.3’, (p.6).

2. Substrates. Duloxetine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2D6. The manufacturers advise caution if duloxetine is given with drugs that are predominantly metabolised by CYP2D6 and have a narrow therapeutic index,1,3 including flecainide, and thioridazine which is contraindicated in the US because of the risk of arrhythmias with elevated levels of this drug.4 This seems prudent as the CYP2D6 inhibitory effects of duloxetine have been shown to be modest (see ‘tolterodine’, (p.1289) and ‘desipramine’, (p.1240)), and changes of this size may be clinically significant with narrow therapeutic index drugs.

(d) Serotonergic drugs

Because the concurrent use of more than one serotonergic drug has rarely resulted in ‘the serotonin syndrome’, (p.9), the manufacturer advises caution if duloxetine is used with ‘tricyclic antidepressants’, (p.1240), or other ‘antidepressants’, (above), triptans, tramadol, and pethidine.1,2

SNRIs; Venlafaxine + Antidepressants

Bupropion may increase venlafaxine plasma levels. Antimuscarinic adverse effects can develop in patients taking fluoxetine and venlafaxine. Venlafaxine combined with other serotonergic antidepressants may increase the risk of bleeding and/or the serotonin syndrome. The serotonin syndrome has also been reported in patients taking venlafaxine with mirtazapine or trazodone; some of these patients were also taking other serotonergic drugs.

Clinical evidence and mechanism

(a) Bupropion

Bupropion was found to increase venlafaxine plasma levels and decrease the levels of the metabolite, O-desmethylvenlafaxine, in 7 patients who had been given venlafaxine alone for a minimum of 6 weeks and then with bupropion SR 150 mg daily for a further 8 weeks.1 For a report of worsening symptoms of the serotonin syndrome when venlafaxine was given with bupropion and sertraline, see ‘SSRIs + Bupropion’, p.1215.

(b) MAOIs

For reports of the serotonin syndrome with venlafaxine and MAOIs, see ‘MAOIs or RIMAs + Venlafaxine’, p.1156.
1. Antimuscarinic adverse effects. A woman taking fluoxetine 20 mg and clonazepam 1 mg daily developed blurred vision, dry mouth, constipation, dizziness, insomnia and a hand tremor within a week of starting to take venlafaxine 37.5 mg daily. These symptoms worsened by the second week and persisted until the venlafaxine was stopped.4,5 Four patients (aged 21, 24, 51 and 70) taking fluoxetine developed antimuscarinic adverse effects (constipation, blurred vision, urinary retention and dry mouth) within a week of starting venlafaxine, which persisted until the venlafaxine was stopped.6 A 61-year-old man taking fluoxetine 20 mg daily had extreme difficulty in urinating within 2 days of starting to take venlafaxine 37.5 mg daily. The effect became intolerable after 10 days but no other obvious antimuscarinic adverse effects (blurred vision, constipation, dry mouth, tachycardia) were seen. This patient had some prostate enlargement and had previously had some moderate urinary problems while taking fluoxetine and nortriptyline.5,7 One possible explanation is that fluoxetine inhibits the cytochrome P450 isoenzyme CYP2D6, which is concerned with the metabolism of venlafaxine, leading to an increase in its serum levels and in its usually minimal antimuscarinic adverse effects.4,5 An alternative explanation is that these adverse effects are due to an adrenergic mechanism.7

2. Haemorrhages. A 60-year-old man experienced haemorrhages from his nose and rectum one week after venlafaxine 150 mg daily and mirtazapine 15 mg daily were added to treatment with escitalopram 20 mg daily. The bleeding progressively worsened during the following 3 weeks and then the patient reduced the dosages to escitalopram 15 mg, mirtazapine 7.5 mg and venlafaxine 100 mg daily, and the bleeding decreased over the following week. He continued weekly tapering of the medications and the bleeding progressively decreased until it stopped when the doses were escitalopram 5 mg, mirtazapine 7.5 mg and venlafaxine 37.5 mg daily. Previous treatments with these three drugs used alone had not caused haemorrhages and it was suggested that the bleeding was due to the combined drugs causing high levels of serotonin.8

3. Serotonin syndrome. A 39-year-old woman with depression and panic attacks was taking cimetidine, trazodone, clonazepam and fluoxetine. With 24 hours of abruptly stopping clonazepam and fluoxetine and starting lorazepam and venlafaxine, she developed the serotonin syndrome (diaphoresis, tremors, slurred speech, myoclonus, restlessness and diarrhoea).9 A 21-year-old woman whose long-term treatment with paroxetine was stopped a week before starting venlafaxine (37.5 mg daily for 5 days then 75 mg daily for 2 days) developed vomiting, dizziness, incoordination, anxiety and electric shock sensations in her arms and legs within 3 days of starting venlafaxine. She stopped venlafaxine after 7 days of treatment, but symptoms persisted for 5 days until she was treated with cyproheptadine.10 A 75-year-old man developed the serotonin syndrome after discontinuing sertraline and starting venlafaxine 48 hours later, although the onset of symptoms did not develop until after 14 days of therapy with venlafaxine. The venlafaxine was discontinued and the symptoms subsided over a 6-day period. However, 2 weeks later amitriptyline was introduced and a recurrence of symptoms was seen over the following 48 hours. The author commented that any drug with serotonergic activity might potentially cause a serotonin syndrome when serotonin transmission has been enhanced by concomitant or recently withdrawn serotonergic drugs.11 Other reports of the serotonin syndrome have been described with venlafaxine and ‘amitriptyline’, (p.1240), and ‘sertraline and bupropion’, (p.1215).

(f) Tricyclic antidepressants

For reports of increased antimuscarinic effects and the serotonin syndrome, see ‘Tricyclic antidepressants + SNRIs; Venlafaxine’, p.1240.

Importance and management

Information about the adverse antimuscarinic adverse effects due to an interaction between fluoxetine and venlafaxine seems to be limited to the reports cited, all by the same author. The incidence is not known, but if venlafaxine and fluoxetine are given concurrently, be alert for any evidence of increased antimuscarinic adverse effects (such as dry mouth, blurred vision and urinary retention). It may be necessary to withdraw one or other of the two drugs.

Also note that the development of the serotonin syndrome has been attributed to the sequential use of an SSRI (fluoxetine, paroxetine, or sertraline) and venlafaxine. It has also occurred with concurrent use of venlafaxine and mirtazapine or trazodone. The manufacturers of venlafaxine caution its use with other drugs that affect serotonergic transmission, such as the SSRIs,2,3,4 because of the potential risks of the serotonin syndrome. For more about the serotonin syndrome see ‘Additive or synergistic interactions’, (p.9).
chromosome P450 isoenzyme CYP2D6. The general significance of this report is unclear.

An isolated case of the serotonin syndrome has been attributed to the concurrent use of venlafaxine and co-amoxiclav.

Clinical evidence, mechanism, importance and management
A 56-year-old man taking venlafaxine 37.5 mg twice daily for 10 months was given a course of co-amoxiclav (amoxicillin with clavulanate) 375 mg three times daily to treat gingivitis and a dental abscess. Within 3 hours of a dose of co-amoxiclav he developed tingling in the tip of his tongue, intense paraesthesia in the fingers, severe abdominal cramps, pro-fuse diarrhea, cold sweats, tremor and uncontrollable shivering. He was also agitated and frightened, but not confused. The symptoms lasted for 6 hours and were initially assumed to be due to gastroenteritis. However, 2 months later while still taking venlafaxine, he developed identical symp-toms after a single dose of co-amoxiclav, which was then diagnosed as the serotonin syndrome. The patient had taken co-amoxiclav without problem when not taking venlafaxine and after the second episode continued ven-lafaxine without further episodes of the serotonin syndrome. Venlafaxine is metabolised mainly by the cytochrome P450 isoenzyme CYP2D6, but co-amoxiclav is not a substrate for this isoenzyme and its ability to inhibit CYP2D6 is not known. It is probable that many patients have received both venlafaxine and co-amoxiclav without adverse effects, so the general importance of this isolated report is unknown, but it seems likely to be small.1

An isolated case of the serotonin syndrome has been attributed to the concurrent use of dexamfetamine and venlafaxine.

Clinical evidence, mechanism, importance and management
A 32-year-old patient taking dexamfetamine 5 mg three times daily for attention deficit hyperactivity disorder (ADHD) presented with marked agitation, anxiety, shivering and tremor 2 weeks after also starting to take venlafaxine 75 mg to 150 mg daily. Other symptoms included generalised hypertonia, hyperreflexia, frequent myoclonic jerking, tonic spasm of the orbicularis oris muscle, and sinus tachycardia. His symptoms resolved completely when both drugs were withdrawn and cyprohepta-dine, to a total dose of 32 mg over 3 hours, was given. Dexamfetamine was restarted after 3 days. It was suggested that the combination of serot-onin re-uptake blockade and either presynaptic release of serotonin or monoamine oxidase inhibition by dexamfetamine could cause increased serotonin in the CNS. Caution is advised when dexamfetamine is given with venlafaxine.1 For more information about the serotonin syndrome, see 'Additive or synergistic interactions'. (p.9).

An isolated case of the serotonin syndrome has been attributed to the concurrent use of metoclopramide and venlafaxine.

Clinical evidence, mechanism, importance and management
A 32-year-old woman with intermittent depression took jujube 500 mg daily (sour date nut; Ziziphus jujuba), prescribed by a traditional Chinese healer, for several weeks, with minor improvement. She was then prescribed venlafaxine 37.5 mg daily by a psychiatrist, but approximately one hour after taking the first dose of venlafaxine together with the jujube she became agitated, restless, nauseated, dizzy and ataxic, and subsequently collapsed. She showed symptoms of a severe acute se-rotonin reaction with some anaphylactic features, which improved over the following 8 hours. She stopped taking the jujube and subsequently took venlafaxine 150 mg daily for 1 month without adverse effects.1 This highlights the need for physicians to ask patients about the use of herbal remedies and to advise their discontinuation before prescribing antide-presant drugs if there is any possibility of an interaction.

An isolated case of the serotonin syndrome has been attributed to the concurrent use of venlafaxine and miscellaneous.

Clinical evidence, mechanism, importance and management
Theoretically the metabolism of venlafaxine may be inhibited by CYP2D6 inhibitors or substrates such as diphenhydramine, melperone, quinidine or thioridazine. CYP3A4 inhibitors such as ketoconazole may also have some effect. An isolated case describes a hypertensive crisis associated with venlafaxine and dis-sufiram. The manufacturers predict that the use of triptans with venlafaxine may have additive effects on serotonin, which could lead to the serotonin syndrome.
metabolisers was erratic with 3 out of 6 displaying marked increases in AUC (81%, 126% and 206%, respectively) whilst the other 3 showed little or no change.3

(c) Disulfiram

An isolated report describes a hypertensive crisis associated with a low dose of venlafaxine (75 mg daily). It was thought that the concurrent use of disulfiram might have increased the toxicity of venlafaxine by interfering with its metabolism via CYP3A4. However disulfiram predominantly inhibits CYP2E1 and has not been reported to significantly affect CYP3A4. Note that disulfiram may provoke hypertension through its interaction with alcohol; however the authors state they found no evidence of a reaction with alcohol in this patient.3 This is an isolated and unexplained case, which is of unknown general significance.

(d) Triptans

The manufacturers caution the use of drugs that affect serotonin transmission, such as the triptans.1,2 3,4 This is because of the possible risks of the serotonin syndrome. For more about the serotonin syndrome see ‘Additive or synergistic interactions’, (p.9). This interaction has been seen, rarely, to occur with a number of other serotonin drugs and venlafaxine, which gives weight to this prediction.

SNRIs; Venlafaxine + Tramadol

Two cases of the serotonin syndrome have been reported when tramadol was given with venlafaxine; one patient was also receiving mirtazapine. Fatal seizures occurred in an alcoholic man receiving tramadol, venlafaxine, quetiapine and trazodone.

Clinical evidence, mechanism, importance and management

A 47-year-old man who had been stable taking venlafaxine 300 mg daily and mirtazapine 30 mg daily for 4 months was given tramadol, titrated to 300 mg daily over 4 weeks, without adverse effects. However, approximately 7 weeks after increasing the dose of tramadol to 400 mg daily he experienced agitation, confusion, severe shivering, diaphoresis, myoclonus, hyperreflexia, mydriasis, and tachycardia. His symptoms resolved over 36 hours after all medications were discontinued and did not recur when venlafaxine and mirtazapine were restarted without tramadol.1 A 65-year-old woman who had been taking venlafaxine 100 mg daily for 3 weeks, developed symptoms of the serotonin syndrome 3 days after tramadol 300 mg daily was added. The symptoms resolved completely 3 days after venlafaxine withdrawal, when tramadol was also withdrawn. No symptoms occurred on rechallenge with venlafaxine alone, 2 weeks later.2 A 36-year-old alcoholic died after developing seizures while taking tramadol several drugs, including venlafaxine, tramzodone and quetiapine, all of which interact with the neurotransmitter serotonin. It was thought that the combination of these drugs and alcohol withdrawal lowered the seizure threshold.3

SSRIs + Azoles

Anorexia developed in a patient taking fluoxetine when itraconazole was started, and it disappeared when the itraconazole was stopped. The pharmacokinetics of citalopram in healthy subjects were not affected by ketoconazole. The clearance of escitalopram was not affected by ketoconazole in an in vitro study.

Clinical evidence, mechanism, importance and management

(a) Citalopram or Escitalopram

In a double-blind, placebo-controlled, crossover study in 18 healthy subjects, a single 200-mg dose of ketoconazole did not affect the pharmacokinetics of citalopram 40 mg.1 Ketoconazole is a potent inhibitor of cytochrome P450 isoenzyme CYP3A4, which, in part, metabolises citalopram, but as several other cytochrome P450 isoenzymes are also involved in citalopram metabolism it would seem that inhibition of only one pathway does not result in clinically significant effects. Similarly, escitalopram is metabolised by CYP3A4, CYP2C19, and CYP2D6, and it has been suggested that its clearance is also unlikely to be affected by impaired activity of only one CYP isofrom.2

(b) Fluoxetine

A man taking fluoxetine 20 mg daily, diazepam and several anti-asthma drugs (salbutamol (albuterol), salmeterol, budesonide, theophylline) was given itraconazole 200 mg daily for allergic bronchopulmonary aspergillosis. Within 1 to 2 days he developed anorexia without nausea. He stopped the itraconazole after 1 day, and the anorexia resolved 1 to 2 days later. The author of the report suggested that itraconazole, a potent enzyme inhibitor, increased the levels of the fluoxetine metabolite, norfluoxetine, which resulted in the anorexia.3 Anorexia is a recognised adverse effect of fluoxetine. However, drug levels were not taken, so this suggestion has not been confirmed.

This report and the conclusions reached are uncertain, but they draw attention to the possibility of an interaction between fluoxetine and itraconazole. Consider this interaction if fluoxetine adverse effects are troublesome.

SSRIs + Bupropion

There are isolated reports of psychosis, mania and seizures associated with the use of bupropion and fluoxetine and an isolated report of the serotonin syndrome with bupropion and sertraline. Hypersexuality has also been reported with bupropion and fluoxetine.

Clinical evidence

(a) Fluoxetine

The day after stopping fluoxetine 60 mg daily, a 41-year-old man was started taking 75 mg and later 100 mg of bupropion three times daily. After 10 days he became edgy and anxious and after 12 days he developed myoclonus. After 14 days he became severely agitated and psychotic, with delirium and hallucinations. His behaviour returned to normal 6 days after the bupropion was stopped.4 Another patient taking lithium carbonate for bipolar disorder developed anxiety, panic and eventually mania a little over a week after stopping fluoxetine and starting bupropion.2 A further patient developed a grand mal seizure after being given fluoxetine and bupropion 300 mg daily.3

An isolated report describes a fatal multiple drug intoxication involving citalopram and cocaine. Animal studies have suggested that SSRIs may potentiate the pro-convulsive effects of cocaine.

Clinical evidence, mechanism, importance and management

An isolated report describes a fatal multiple drug intoxication involving citalopram and cocaine. It was suggested that SSRIs and cocaine bind to the same receptor site and their concurrent use may have an additive effect through inhibition of serotonin reuptake. The patient also took other drugs including omeprazole, which may have further potentiated the effects of citalopram.

A study in animals suggested that most SSRIs potentiate cocaine-induced convulsions, although sertraline appeared to have no effect on convulsions or lethality.

SSRIs + Cyproheptadine

Several reports suggest that cyproheptadine can oppose the antidepressant effects of fluoxetine, and another describes the same effect with paroxetine.

Clinical evidence

(a) Fluoxetine

Three depressed men complained of anorgasmia when taking fluoxetine. When this was treated with cyproheptadine their depressive symptoms returned, decreasing again when cyproheptadine was stopped. Two women also complained of anorgasmia within 1 to 3 months of starting to take fluoxetine 40 to 60 mg daily for bulimia nervosa. When cyproheptadine was added to treat this sexual dysfunction, the urge to binge on food returned in both of them and one experienced increased depression. These symptoms resolved 4 to 7 days after stopping cyproheptadine.

A woman successfully treated with fluoxetine 40 mg daily showed a re-emergence of her depressive symptoms on two occasions within 36 hours of starting to take cyproheptadine. In a further case, a woman who responded well to fluoxetine 20 mg daily for depression had a recurrence of her depression after she began to take cyproheptadine for migraine. Increasing the dose of fluoxetine to 40 mg daily controlled the depressive symptoms while cyproheptadine was continued for migraine.

In contrast, no exacerbation of depression was seen in a study in which both cyproheptadine and fluoxetine were used in 2 patients.

(b) Paroxetine

A woman taking paroxetine 20 mg daily for depression relapsed and worsened, and developed confusion and psychotic symptoms, within 2 days of starting to take cyproheptadine 2 mg twice daily for the treatment of anorgasmia. Psychotic symptoms resolved 2 days after stopping cyproheptadine. However, cyproheptadine (8 mg followed by 12 mg in 3 divided doses over 24 hours) seemed to have little effect on the course of the serotonin antagonist caused by a massive overdose of paroxetine (3.6 g) taken with alcohol. It was thought that the dosing of cyproheptadine might have been insufficient for such a large overdose. The patient recovered over the next 6 days with supportive measures.

Mechanism

Although the mechanism is not fully understood, it has been suggested that because cyproheptadine is a serotonin antagonist it blocks or opposes the serotonergic effects of these SSRIs.

Importance and management

Direct information about this interaction appears to be limited to these studies although cyproheptadine has also been found to oppose the antidepressant effects of MAOIs (see ‘MAOIs or RIMAs + Antihistamines; Cyproheptadine’, p.1131). One study suggests that not every patient is affected.

If concurrent use is thought appropriate, the outcome should be very well monitored for evidence of a reduced antidepressant response.

SSRIs + Cocaine

An isolated report describes a fatal multiple drug intoxication involving citalopram and cocaine. Animal studies have suggested that SSRIs may potentiate the pro-convulsive effects of cocaine.

Mechanism

Several mechanisms have been proposed. Bupropion inhibits the cytochrome P450 isoenzyme CYP2D6, which may interfere with the metabolism of some SSRIs, causing an increase in plasma levels and increased toxicity. However, a small study found no statistically significant changes in plasma levels of fluoxetine or paroxetine when combined with bupropion.

An in vitro study demonstrated that several SSRIs (paroxetine, sertraline, norfluoxetine, and fluvoxamine) could inhibit CYP2B6, the isoenzyme involved in bupropion hydroxylation, and in one of the cases described above it was suggested that residual fluoxetine may have inhibited the metabolism of bupropion, leading to toxic levels. A pharmacodynamic mechanism has also been proposed. Bupropion can cause seizures and antidepressants may further lower the seizure threshold, see ‘Bupropion + Miscellaneous’, p.1206.

Importance and management

Information is very limited but these reports suggest that if concurrent or sequential use is thought appropriate, the outcome should be well monitored and reduced doses should be considered. The UK and US manufacturers recommend that drugs that are metabolised by CYP2D6 should be given with bupropion with caution and initiated at the lower end of the dose range. If bupropion is added to the treatment of a patient already taking a drug metabolised by CYP2D6, the need to decrease the dose of this drug should be considered. The UK manufacturers specifically name paroxetine and the US manufacturers additionally name fluoxetine and sertraline. In addition, the manufacturers advise extreme caution if bupropion is given with antidepressants that lower seizure threshold and recommend reducing the dose of bupropion to a maximum of 150 mg daily.

Three reports describe the development of a serotonin-like syndrome in two patients taking paroxetine and one taking citalopram and nefazodone, when they were given dextromethorphan. Another report describes hallucinations in a woman taking fluoxetine and dextromethorphan.

Clinical evidence

(a) Citalopram

A man who had been taking citalopram 30 mg, nefazodone 600 mg and long-acting oxycodeone 10 mg at bedtime without problems, started taking a cough syrup containing dextromethorphan and within a day he began to experience fatigue, lethargy, jitters and headache. He stopped taking the dextromethorphan and his symptoms gradually disappeared over several hours.1

(b) Fluoxetine

A woman who had been taking fluoxetine 20 mg daily for 17 days took about 10 mL of a cough syrup containing dextromethorphan, and a further dose the next morning, with the next dose of fluoxetine. Within 2 hours vivid hallucinations developed (bright colours, distortions of shapes and sizes), which lasted 6 to 8 hours. The patient said they were similar to her past experience with LSD 12 years earlier.2 However, in a report of an extensive metabolic study3 in which depressed patients taking fluoxetine were given a single 30-mg dose of dextromethorphan, no mention was made of adverse effects.3

(c) Paroxetine

A man with multiple medical problems was admitted to hospital as an emergency, mainly because he was vomiting blood. He was taking diazepam, diltiazem, glyceryl trinitrate, paroxetine, piroxicam, ranitidine and long-acting oxycodone 10 mg at bedtime without problems, started taking a cough syrup containing dextromethorphan and within a day he began to experience fatigue, lethargy, jitters and headache. He stopped taking the dextromethorphan and his symptoms gradually disappeared over several hours.1

Mechanism

Not understood. The symptoms that developed with citalopram or paroxetine and dextromethorphan were attributed by the authors of the reports to the serotonin syndrome, caused by the additive effects of the SSRIs and dextromethorphan on serotonin transmission. It has also been suggested that paroxetine inhibited the cytochrome P450 isoenzyme CYP2D6, by which dextromethorphan is metabolised, resulting in increased dextromethorphan levels.2,3 Fluoxetine also inhibits CYP2D6.4

Importance and management

These seem to be, so far, the only reports of the serotonin syndrome being attributed to an interaction between an SSRI and dextromethorphan. However, it has been suggested that the incidence of mild serotonin excess (as seen in with citalopram) may be more common than is known.1 The general importance of this apparent interaction is therefore very uncertain. The SSRIs are now very widely prescribed and dextromethorphan is a relatively common ingredient of non-prescription medicines. More study is therefore needed to establish this apparent interaction, but in the meantime it would seem prudent for patients taking citalopram, fluoxetine, or paroxetine to be cautious using dextromethorphan-containing products because the risks of the serotonin syndrome, which, if it occurs, can be serious. Concurrent use should be well monitored. It is not clear whether other SSRIs would interact with dextromethorphan similarly, but it has been predicted that sertraline and fluvoxamine are less likely to do so.5 This prediction has been challenged.6 The outcome will largely depend on the mechanism of this interaction, as sertraline and fluvoxamine do not usually have clinically significant effects on CYP2D6. For more information about the serotonin syndrome, see ‘Additive or synergistic interactions’ (p.9).

SSRIs + Grapefruit juice

Excessive consumption of grapefruit caused symptoms similar to the serotonin syndrome in a patient taking fluoxetine and trazodone.

Grapefruit juice appears to raise fluvoxamine levels, which resulted in adverse effects in one patient. Sertraline plasma levels are also increased by grapefruit juice.

Clinical evidence

A 57-year-old HIV-positive man had been receiving indinavir, stavudine and lamivudine, as well as other medications including fluoxetine 20 mg daily and trazodone 200 mg daily. He complained of dizziness, mild confusion, diarrhoea, visual changes, and a general feeling of being “out of sorts” for approximately one month. On further questioning it was found that the patient had been having one grapefruit each morning but had increased his consumption to 3 per day. His symptoms resolved when he stopped eating grapefruit.1

A randomised, placebo-controlled, crossover study in 10 healthy subjects found that 250 mL of grapefruit juice three times daily for 6 days increased the AUC of a single 75-mg dose of fluvoxamine by 60% and increased the maximum plasma levels by 33%.2 A 75-year-old woman taking fluvoxamine 150 mg at night experienced palpitations when on holiday in Florida, which stopped when she returned home. The only change identified was that she drank grapefruit juice daily while in Florida. She had previously experienced palpitations when taking a higher dose of fluvoxamine (200 mg at night).3

A study in 5 patients taking sertraline 50 to 75 mg daily found that the concurrent use of grapefruit juice for one week increased serum trough levels by almost 50%.4

Mechanism

Grapefruit juice is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and sertraline is partially metabolised by this enzyme. Therefore grapefruit juice would be expected to reduce the metabolism of sertraline. This has been demonstrated in vitro; grapefruit juice inhibited the formation of desmethylsertraline in a dose-dependent manner.2 The other SSRIs mentioned above are not significantly affected by CYP3A4, but grapefruit juice also inhibits other isoenzymes that could affect the metabolism of SSRIs especially if the patient is also a poor metaboliser of CYP2D6.5,6

Importance and management

There are very few reports of clinically significant interaction between grapefruit and SSRIs, but the possibility of an interaction should be borne in mind especially if unusual amounts of grapefruit have been consumed.1

SSRIs + H₂-receptor antagonists

Citalopram, escitalopram, paroxetine and sertraline levels are moderately increased by cimetidine but the only clinically relevant effect appears to be a slight increase in adverse effects with sertraline.

Clinical evidence

(a) Citalopram

Twelve healthy subjects were given citalopram 40 mg daily for 21 days and then for the next 8 days they were also given cimetidine 400 mg twice daily. The cimetidine caused a 29% decrease in the oral clearance of the citalopram, a 39% rise in its maximum serum levels and a 43% increase in its AUC. Some changes in the renal clearance of the citalopram metabolites were also seen.¹

(b) Escitalopram

Cimetidine 400 mg twice daily increased the mean plasma level of escitalopram by about 70%. There was also a 22% increase in the maximum plasma level of citalopram, but this was not considered to be clinically significant.²

(c) Paroxetine

Cimetidine 200 mg four times daily for 8 days did not affect the mean pharmacokinetic values or bioavailability of a single 30-mg dose of paroxetine in 10 healthy subjects. However, 2 subjects had AUC increases of 55% and 81%, respectively, while taking cimetidine and 4 others also had some minor increases.³ Another study in 11 healthy subjects found that cimetidine 300 mg three times a day increased the AUC of paroxetine 30 mg daily by 50% after 1 week of concurrent use.⁴

(d) Sertraline

In a randomised, two-way, crossover study, 12 healthy subjects were given a single 100-mg oral dose of sertraline after taking either cimetidine 800 mg or a placebo at bedtime for 7 days. Cimetidine increased the AUC of sertraline by 50%, the maximum serum levels of sertraline by 24%, and the half-life by 26%.⁵ There was a small increase in sertraline adverse effects (not specified) while taking the cimetidine.⁵

Mechanism

The apparent reason for all these changes is that cimetidine inhibits the activity of cytochrome P450 so that the metabolism of the SSRIs is reduced, and as a result their serum levels rise.

Importance and management

The authors of the citalopram study say that while cimetidine certainly causes an increase in the serum levels of citalopram, the extent is only moderate and because the drug is well tolerated and there are very considerable pharmacokinetic variations between individual subjects, they consider that there is no need to reduce the citalopram dosage.⁷ This advice is most likely applicable to escitalopram, the S-isomer of citalopram. However, the manufacturer of escitalopram suggests caution, and advises that a reduction in the dose of escitalopram may be necessary (based on monitoring of adverse effects) during concurrent treatment.⁷

Information on the concurrent use of cimetidine and paroxetine or sertraline seems to be limited and the clinical significance of the changes in clearance is not known. However, it would be prudent to monitor the outcome for excessive adverse effects (dry mouth, nausea, diarrhoea, dyspepsia, tremor, ejaculatory delay, sweating) if cimetidine is used with either of these SSRIs and reduce the sertraline or paroxetine dosage if necessary. If the suggested mechanism of interaction is true, one of the other H₂-receptor antagonists that lack enzyme inhibitory activity, such as ranitidine or famotidine, might be a non-interacting alternative for cimetidine. This needs confirmation.

SSRIs + Herbal medicines

A man taking fluoxetine experienced symptoms of the serotonin syndrome after ingesting the psychoactive beverage ayahuasca, which contains monoamine oxidase-inhibiting harmala alkaloids. The Japanese herbal medicine Gorei-san does not appear to interact with fluvoxamine or paroxetine.

Clinical evidence, mechanism, importance and management

A 36-year-old man who was receiving fluoxetine 20 mg daily for mild depression participated in a religious ceremony using ayahuasca (also known as caapi, dainme, hoasca, natema, yage) which is a psychoactive beverage characteristically containing harmala alkaloids (primarily harmine and harmaline) derived from the vine Banisteriopsis caapi. One hour after ingesting 100 mL of ayahuasca he experienced tremors, sweating, shivering and confusion. His condition deteriorated over the next few hours with gross motor tremors and severe nausea and vomiting, but he rapidly recovered four hours after ingestion of the ayahuasca, with no treatment. The harmala alkaloids are capable of blocking the enzymatic activity of MAO for several hours, and consequently inhibit the metabolic breakdown of neurotransmitters. There is, therefore, the potential for the serotonin syndrome with SSRIs and ayahuasca.¹

For reports of the serotonin syndrome and other adverse effects when St John’s wort was taken together with SSRIs, see ‘SSRIs + St John’s wort (Hypericum perforatum)’, p.1224.

An efficacy study in 20 patients taking fluvoxamine (19 patients) or paroxetine (1 patient) reported that the addition of the Japanese herbal medicine Gorei-san (TJ-17), which is composed of 5 herbs (Alismatis rhizoma, Atractyloides lanceae rhizoma, Polyporus, Hoelen, and Cinnamomi cortex), caused no additional adverse events.² However, note that this study was not specifically looking at drug interactions and therefore only gives a broad indication that concurrent use is safe and effective.

SSRIs + 5-HT₃-receptor antagonists

Symptoms similar to the serotonin syndrome have been reported in two patients receiving paroxetine and ondansetron or sertraline and dolasetron.

Clinical evidence, mechanism, importance and management

A possible case of the serotonin syndrome (or possibly neuroleptic malignant syndrome) was reported in a 49-year-old woman who developed postoperative delirium. She had been taking paroxetine 30 mg daily up to 2 days before surgery and was given ondansetron 4 mg during surgery and morphine during and after surgery. Approximately one hour after leaving theatre she became agitated and confused. She also displayed uncontrolled limb movements, brisk reflexes, ankle clonus, abnormal ocular function, hypertension, pyrexia, and raised creatinine kinase levels. The delirium did not respond to naloxone, diazepam or flumazenil and lasted for nearly 2 days. Several explanations involving the disruption of...
serotonergic and/or dopaminergic transmission were suggested.\textsuperscript{1} There has been some debate about whether inhibition of CYP2D6 was another possible mechanism, but this seems unlikely.\textsuperscript{1,2}

Similarly, a 49-year-old woman, who had been receiving 
sertraline for some time without incident was premedicated with 
dolasetron 100 mg before receiving her first cycle of adjuvant chemotherapy for breast cancer. Shortly afterwards she developed symptoms of profound agitation and elation, but with an overwhelming desire to commit suicide and was disoriented. The symptoms resolved within hours without pharmacological intervention. Three weeks later she received the same medications except ondansetron was substituted for dolasetron and she experienced no adverse effects. The author concluded that a variant of the serotonin syndrome may rarely be seen when 5-HT3-receptor antagonists and SSRIs are given together, and clinicians should consider this possibility if these adverse effects occur.\textsuperscript{3}

SSRIs + Interferons

The antidepressant effects of paroxetine and trazodone may be reversed by interferon.

Clinical evidence, mechanism, importance and management

A 31-year-old woman, whose mood and other depressive symptoms improved during treatment with paroxetine 50 mg daily and trazodone 50 mg at night, was later found to have essential thrombocythaemia. After unsuccessful treatment with dipyridamole, she was given interferon alfa, stabilised at 3 million units 3 times weekly. After 3 months her depressive symptoms returned, and worsened over a period of 6 months, despite increased doses of trazodone and cognitive therapy. Interferon alfa was discontinued and replaced by hydroxybocamidene, and then anagrelide. After a good response to a course of ECT, her depressive symptoms were controlled by paroxetine 50 mg daily and trazodone 150 mg at night.\textsuperscript{1}

Interferon is associated with a risk of depression, but in this case it appeared to reverse the antidepressant response. It was suggested that this might have been due to the capacity of interferon to impair serotonin synthesis, by inducing enzymes that degrade the serotonin precursor tryptophan. If this mechanism is true then all SSRIs have the potential to interact. Bear the possibility of an interaction in mind if the response to an SSRI is poor in a patient given interferon.

SSRIs + Lysergide (LSD)

Three patients with a history of lysergide (LSD) abuse experienced the new onset or worsening of the LSD flashback syndrome when given fluoxetine, paroxetine or sertraline. Grand mal convulsions occurred when one patient taking LSD was given fluoxetine. In contrast, one study found that SSRIs reduced or eliminated the subjective responses to LSD.

Clinical evidence

An 18-year-old girl with depression, panic and anxiety disorders, and with a long history of illicit drug abuse experienced a 15-hour LSD flashback within 2 days of starting to take sertraline 50 mg daily. Another flashback lasting a day occurred when the sertraline was replaced by paroxetine. No further flashbacks occurred when the SSRIs were stopped. A 17-year-old boy with depression, also with a long history of illicit drug abuse (including LSD), began to experience LSD flashbacks 2 weeks after starting to take paroxetine. His father, a chronic drug abuser, had taken both fluoxetine and paroxetine for depression and had also reported new onset of a flashback syndrome.\textsuperscript{1} An isolated report describes grand mal convulsions in a patient while taking fluoxetine, tentatively attributed to the concurrent abuse of LSD.\textsuperscript{2} In contrast, a retrospective study found that 28 of 32 subjects (88%) who took LSD and who had taken an SSRI (fluoxetine, paroxetine or sertraline) or trazodone for more than 3 weeks had a subjective decrease or virtual elimination of their responses to LSD. However, another subject who had taken fluoxetine for only one week had an increased response to LSD.\textsuperscript{3}

Mechanism

Not understood. Lysergide increases serotonin in the brain, and one suggestion is that when the serotonin re-uptake is blocked in the brain, there is an increased stimulation of 5-HT\textsubscript{1} and 5-HT\textsubscript{2} receptors.\textsuperscript{1} Changes in brain catecholamine systems may also be involved.\textsuperscript{3}

Importance and management

Information is very limited and conflicting. The authors of the first report suggest that patients who are given SSRIs should be warned about the possibility of flashback or hallucinations if they have a known history of LSD abuse.

SSRIs + Macrolides

An isolated case report describes apparent acute fluoxetine toxicity in a man brought about by the use of clarithromycin. Another isolated report describes the development of what is thought to be the serotonin syndrome in a 12-year-old boy taking sertraline and erythromycin.

Clinical evidence

(a) Fluoxetine

A 53-year-old man taking fluoxetine 80 mg and nitrazepam 10 mg at bedtime for depression and insomnia, was given clarithromycin 250 mg twice daily for a respiratory infection. Within a day he started to become increasingly confused and after 3 days was admitted to hospital with a diagnosis of psychosis and delirium. When no organic cause for the delirium could be found, all his medications were stopped, and erythromycin was started. His mental state returned to normal after 36 hours. Once the antibacterial course had finished, the fluoxetine and nitrazepam were restarted and no further problems occurred.\textsuperscript{1}

(b) Sertraline

A 12-year-old boy with severe obsessive-compulsive disorder and simple phobia, responded to sertraline 12.5 mg daily, titrated over 12 weeks to 37.5 mg daily. He began to feel mildly nervous within 4 days of starting to take erythromycin 400 mg daily for an infection. Over the next 10 days his nervousness grew, culminating in panic, restlessness, irritability, agitation, paraesthesias, tremulousness, decreased concentration and confusion. The symptoms abated within 72 hours of stopping both drugs.\textsuperscript{2}

Mechanism

The authors attribute what was seen to fluoxetine toxicity in the first case, and to the serotonin syndrome in the second case. They postulated that erythromycin (a known and potent inhibitor of cytochrome P450 isoenzyme CYP3A4) and the related macrolide clarithromycin, reduced the metabolism of the SSRIs, thereby raising their serum levels and precipitating the observed toxicity.\textsuperscript{1,2}

Importance and management

These are isolated reports and their general importance is unknown. Nor is it unequivocally established that the second case was the serotonin syn-
drome and not an idiosyncratic reaction. Nevertheless, be aware of these cases when using macrolides with fluoxetine or sertraline.

**SSRIs + Metoclopramide**

There are two reports of the serotonin syndrome in patients taking sertraline when metoclopramide was added. Extrapyramidal symptoms have occurred in patients given fluoxetine, fluvoxamine or sertraline with metoclopramide.

**Clinical evidence**

(a) Extrapyramidal symptoms

Two patients developed extrapyramidal symptoms while taking fluoxetine and metoclopramide.1,2

A 14-year-old boy receiving fluvoxamine 50 mg daily for anorexia nervosa was, after day 7, given metoclopramide 10 mg three times daily. On the third day of concurrent use he developed acute movement disorders including acute dystonia, jaw rigidity, horizontal nystagmus, uncontrolled tongue movements and dysarthria. The boy had taken the same dose of metoclopramide alone on other occasions without experiencing extrapyramidal reactions. A pharmacokinetic interaction was considered unlikely since both drugs use different metabolic pathways.3

In another report a woman with gastro-oesophageal reflux, controlled with metoclopramide 15 mg four times daily, developed symptoms consistent with a mandibular dystonia (periauricular pain, jaw tightness, the sensation of her teeth clenching and grinding) 2 days after starting sertraline 50 mg daily. A 50-mg dose of diphenhydramine resolved the problem within 30 minutes, but the same symptoms recurred the next day, 8 hours after taking sertraline. The symptoms were relieved by 2 mg of oral benztropine.4

A regional pharmaco vigilance centre in France reported 37 cases of extrapyramidal adverse effects linked to concurrent use of an SSRI and a neuroleptic (said to be metoclopramide in 4 cases).5

(b) Serotonin syndrome

A patient who had been taking sertraline 100 mg daily started taking metoclopramide 10 mg four times daily for nausea. After 24 hours his symptoms had worsened and he developed malaise, cardiac arrhythmia, visual hallucinations, diaphoresis, sialosis, hypertreflexia, and tremor. The serotonin syndrome was diagnosed and his symptoms improved with cyproheptadine.6 Another patient taking sertraline 100 mg daily for depression over an 18-month period developed agitation, dysarthria, diaphoresis, and a movement disorder within 2 hours of receiving a single 10-mg intravenous dose of metoclopramide. The symptoms, diagnosed as the serotonin syndrome with serious extrapyramidal movement disorder, resolved within 6 hours of treatment with diazepam.7

**Mechanism**

Both SSRIs and metoclopramide can cause extrapyramidal reactions; metoclopramide by blocking dopamine D2 receptors in the basal ganglia, and SSRIs by inhibition of dopamine neurotransmission.3,4 Metoclopramide has also been reported to have intermediate affinity to certain serotonin receptors.8

**Importance and management**

Information seems to be limited to these reports, but they highlight the fact that care should be taken if two drugs with the potential to cause the same adverse effects are used together.

---

### SSRIs + NNRTIs

A case of the serotonin syndrome occurred in a woman taking fluoxetine when efavirenz was added. Nevirapine decreased fluoxetine plasma levels, but fluvoxamine increased nevirapine levels.

**Clinical evidence, mechanism, importance and management**

(a) Efavirenz

A case of serotonin syndrome in a woman taking fluoxetine coincided with the start of a new antiretroviral regimen including efavirenz. Symptoms resolved when the fluoxetine dose was halved. It was suggested that efavirenz inhibited the metabolism of fluoxetine.9 Until further information is available, caution may be warranted if both drugs are given.

(b) Nevirapine

A study involving 60 HIV-positive patients taking a nevirapine-containing regimen found that fluoxetine had no influence on the pharmacokinetics of nevirapine, but nevirapine significantly lowered the combined plasma levels of fluoxetine and norfluoxetine.10 If nevirapine is given with fluoxetine, the clinical response to fluoxetine should be monitored and the dosage increased if necessary. In the same study the concurrent use of fluvoxamine resulted in a significant 34% reduction in the apparent clearance of fluoxetine, and this appeared to be dependent on the dose of fluvoxamine. The pharmacokinetics of fluvoxamine were not affected.11 If both drugs are given be aware that fluvoxamine could be a cause of increased nevirapine adverse effects.

### SSRIs + Opioids

Symptoms of the serotonin syndrome have been reported with opioids including hydromorphone, oxycodone, pentazocine, pethidine and tramadol and possibly morphine when given with various SSRIs. Seizures have been seen when dextropropoxyphene was given with an SSRI. Fluoxetine has slightly reduced the analgesic effects of morphine and oxycodone. Buprenorphine metabolism is inhibited by fluvoxamine *in vitro*, but this is probably not clinically relevant.

**Clinical evidence**

(a) Buprenorphine

Fluvoxamine inhibited the metabolism of buprenorphine *in vitro*, but the inhibition was not thought sufficient to be clinically significant.1

Fluoxetine did not inhibit buprenorphine dealkylation *in vitro*, although norfluoxetine did so, but this was also thought unlikely to be significant *in vivo*.1

(b) Dextropropoxyphene

Ten of 32 cases of seizures or myoclonus associated with antidepressant treatment reported to the Swedish Adverse Drug Reactions Advisory Committee involved SSRIs (*fluvoxamine* 6, *citalopram* 2, *paroxetine* 2). An important risk factor appeared to be concurrent treatment with other drugs, such as dextropropoxyphene (2 cases), that decrease the seizure threshold.2

(c) Hydrocodone

Visual hallucinations occurred in a 90-year-old woman taking hydrocode done when her antidepressant was changed from *citalopram* 10 mg daily to *escitalopram* 10 mg daily. The hallucinations stopped after her hydrocode done was discontinued because of improvement in pain control. The patient had previously taken *paroxetine* and the same dose of hydrocode done, without experiencing hallucinations or other serotonin-related symptoms.3
An 81-year-old woman who had been taking fluoxetine 20 mg daily along with other medications for several years developed abnormal movements, confusion, incoherent speech, sweating, facial redness, tremor, hyperreflexia and muscle spasms 2 days after starting to take hydromorphone 12 mg daily. The symptoms resolved within 2 weeks of stopping the fluoxetine (the hydromorphone was continued).4

(e) Methadone

The SSRIs, particularly fluvoxamine, can raise methadone levels. See ‘SSRIs + Opioids; Methadone’, below.

(f) Morphine

A double-blind, placebo-controlled study in 35 patients found that the preoperative use of fluoxetine 10 mg daily for 7 days reduced the analgesic effect of intravenous morphine given for postoperative dental pain.5 In contrast, a double-blind, crossover study in 15 healthy subjects found that a single 60-mg dose of fluoxetine slightly improved (by 3 to 8%) the analgesic effect (as assessed by dental electrical stimulation) of morphine sulfate in doses tailored to produce and maintain steady-state plasma levels of 15, 30, and 60 nanograms/mL for 60 minutes. Plasma levels of morphine were not affected by fluoxetine, and morphine was found not to affect plasma levels of fluoxetine or norfluoxetine. The subjects experienced less nausea and drowsiness, but the psychomotor and respiratory depressant effects of morphine were not altered.6

A patient experienced postoperative delirium which lasted for nearly 2 days and included agitation, confusion, uncontrolled limb movements, abnormal ocular function, hypertension, pyrexia, brisk reflexes, ankle clonus and raised creatinine kinase. She had been taking paroxetine before surgery and during surgery she was given morphine and ondansetron.7

(g) Oxycodeone

A man with advanced multiple sclerosis found that when he began to take fluoxetine 20 mg daily for depression he needed to increase his analgesic dosage of oxycodone (for painful muscle spasms) about fourfold, from 45 to 75 mg daily to about 250 to 275 mg daily.8

A bone-marrow transplant recipient taking, amongst other drugs, sertraline 50 mg daily, cisclosporin 75 mg daily, and oxycodone 10 mg as needed, developed severe tremors and visual hallucinations. This coincided with him taking oxycodone 200 mg over 48 hours for severe pain. An adverse reaction to cisclosporin was initially suspected (although serum levels were not high), and this was temporarily discontinued along with the oxycodone. The visual hallucinations decreased but the tremors continued, and did not lessen until sertraline was discontinued and cyproheptadine given. It was concluded that the patient was experiencing a form of the serotonin syndrome as a result of markedly increased opioid use while taking an SSRI.9 Two other cases describe probable serotonin syndrome in elderly patients receiving either sertraline or citalopram together with extended-release oxycodone. In both cases symptoms of the serotonin syndrome (agitation, increased muscle tone, ataxia, tremor and/or myoclonic jerks) occurred after increasing the opioid dose.10 Another case of severe serotoninic symptoms including confusion, nausea, fever, shivering, agitation, clonus, hyperreflexia, hypertonia, and tachycardia occurred in a 70-year-old woman taking fluvoxamine 200 mg daily when she started taking oxycodone 40 mg twice daily. Discontinuation of these two drugs resulted in resolution of her symptoms over 48 hours.11

(h) Pentazocine

A double-blind, placebo-controlled study in 35 patients has shown that oral fluoxetine 10 mg daily for 7 days preoperatively did not reduce the analgesic effects of pentazocine 45 mg given intravenously for postoperative dental pain.5

A man who had been taking fluoxetine 20 mg daily, later increased to 40 mg daily, was given a single 100-mg oral dose of pentazocine (Talwin Nx containing pentazocine 50 mg and naloxone 500 micrograms) for a severe headache. Within 30 minutes he complained of lightheadedness, anxiety, nausea and paraesthesias of the hands. He was diaphoretic, flushed, and atactic, and had a mild tremor of his arms. His blood pressure was 178/114 mmHg, pulse 62 bpm and respiration 16 breaths per minute. He was given intramuscular diphenhydramine 50 mg and recovered over the following 4 hours.11

(i) Pethidine (Meperidine)

A 43-year-old man who had been taking fluoxetine approximately every other day experienced symptoms of the serotonin syndrome immediately after receiving pethidine 50 mg intravenously for an endoscopic procedure.11

(j) Tramadol

The serotonin syndrome has occurred in a number of patients taking SSRIs with tramadol. See ‘SSRIs + Opioids; Tramadol’, p.1222.

Mechanism

Fluoxetine inhibits the activity of the cytochrome P450 540 isoenzyme CYP2D6 within the liver so that the metabolism of oxycodone to an active metabolite oxymorphine is reduced. The metabolism of hydrocodone and similar opioids may also be affected by CYP2D6 inhibitors, see ‘Opioids; Codeine and related drugs + Quinidine’, p.184. Buprenorphine and morphine are not metabolised by CYP2D6, so their metabolism would not be expected to be affected by fluoxetine. Buprenorphine is metabolised by CYP3A4 and so fluvoxamine might be expected to inhibit its metabolism to some extent.

Dextropropoxyphene may have inhibited the metabolism of the SSRIs leading to an increase in seizures. It has been suggested that the reason for the reduced morphine analgesia may have to do with the initial effects of SSRIs on serotonin neurotransmission.6 The serotonin syndrome seems to develop unpredictably in some patients given two or more serotoninergic drugs, in this case, opioids and SSRIs.

Importance and management

Adverse interactions between SSRIs and opioids seem rare (although see ‘methadone’, below) and there is little to suggest that they cannot be used together safely and effectively. The evidence suggesting that fluoxetine may decrease morphine or oxycodone analgesia is limited and insufficient to suggest any change in practice. However, if a patient does not seem to respond well to either of these opioids consider an interaction as a possible cause. Buprenorphine metabolism might be slightly reduced by fluvoxamine, but this does not appear to be clinically relevant.

The incidence of serotonin syndrome-like reactions with opioids and SSRIs is fairly rare (although see ‘tramadol’, p.1222); however, the possibility of ‘the serotonin syndrome’, (p.9), should be considered in patients experiencing altered mental status, autonomic dysfunction and neuromuscular adverse effects while receiving these drugs.

SSRIs + Opioids; Methadone

Methadone serum levels may rise if fluvoxamine is added, sometimes resulting in increased adverse effects. Sertraline, paroxetine, and possibly fluoxetine, may also modestly increase methadone levels.
Clinical evidence

(a) Fluoxetine

Methadone 30 to 100 mg daily, and fluoxetine 20 mg daily were given to
9 patients (two of them were also taking fluvoxamine). Although there
were possible compliance problems with some of the patients, the metha-
done plasma/dose ratio of the group as a whole was not altered by the ad-
dition of the fluoxetine. This is consistent with the results of two other
studies, which found that fluoxetine did not appear to alter the plasma
methadone levels of patients treated for cocaine dependence. However,
the plasma samples for 7 of the 9 patients in the first study were sub-
sequently analysed again to measure the S- and R-enantiomers of methadone
separately. This analysis revealed that fluoxetine 20 mg daily modestly
increased the levels-to-dose ratio of the active R-methadone (by 33%)
without significantly changing either the total or inactive S-methadone
level-to-dose ratios. Moreover, a patient taking methadone developed
opioid toxicity when given ciprofloxacin and fluoxetine, see ‘Opioids; Methadone + Ciprofloxacin’, p.189.

(b) Fluvoxamine

Five patients taking maintenance doses of methadone were given fluvo-
xa mine. Two of them had an increase of about 20% in the methadone pla-
ma/dose ratio, while the other 3 showed 40 to 100% rises (suggesting
increased methadone levels). One of them developed asthma, marked
drowsiness and nausea, which disappeared when both drug dosages were
reduced. A subsequent analysis of the enantiomers of methadone reve-
A recent study in 1222 Chapter 34

SSRIs + Opioids; Tramadol

Tramadol should be used with caution with SSRIs because of the
increased risk of seizures. Several reports describe the develop-
ment of the serotonin syndrome in patients taking SSRIs with tra-
mdol. Another patient developed hallucinations with tramadol and
paroxetine.

Clinical evidence

(a) Seizures

The CSM in the UK has published 27 reports of convulsions and one of
worsening epilepsy with tramadol, a reporting rate of 1 in 7000 patients.
Some of the patients were given doses well in excess of those recommend-
ed, and some were taking SSRIs (5 patients) or ‘tricyclic antidepressants’,
both of which are known to reduce the convulsive threshold. Similarly,
of 124 seizure cases associated with tramadol reported to the FDA in the US, 20 included the concurrent use of SSRIs.

(b) Serotonin syndrome

The Australian Adverse Drug Reaction Advisory Committee has stated
that tramadol may cause the serotonin syndrome, particularly when it is
used at high doses or in combination with other drugs increasing serotonin
levels; of 20 reported cases of the serotonin syndrome associated with tra-
rdol, 16 were taking potentially interacting medicines including SSRIs.
Cases of the serotonin syndrome with specific SSRIs are discussed below.

1. Citalopram. A 70-year-old woman who had been taking citalopram
10 mg daily for 3 years developed tremors, restlessness, fever, confusion, and
visual hallucinations after starting to take tramadol 50 mg daily for pain
relief following an operation. Her symptoms stopped after tramadol was
stopped. However, she continued to take citalopram and one year later she
developed identical symptoms after taking tramadol 20 mg daily. Cita-
lopr am is metabolised by the cytochrome P450 enzyme CYP2C19 and
tramadol is O-demethylated by CYP2D6 and the patient was found to be
deficient in both CYP2C19 and CYP2D6, suggesting that her metabolis-
capacity of both pathways was reduced.

2. Fluoxetine. A woman who had been taking fluoxetine 20 mg daily for 3
years developed what was eventually diagnosed as the serotonin syn-
Rene syndrome. A month previously she had started to take tramadol 50 mg
four times daily, increased after a fortnight to 100 mg four times daily.
Ten days before hospitalisation she had developed a tremor of the right
hand and face, and in hospital she showed agitation, marked facial blepha-
rapasm, some sweating and pyrexia, and stuttering. The symptoms began
to subside 7 days after both drugs were stopped, and after 2 months she
had recovered fully.

Mechanism

Fluvoxamine, and to a lesser extent fluoxetine, paroxetine, and sertraline,
can inhibit the liver metabolism of the methadone (possibly by the cyto-
chome P450 isoenzymes CYP3A4, CYP2D6, and/or CYP1A2) thereby allowing it to accumulate in the body.

Importance and management

Information is limited, but it indicates that the effects of starting or stop-
ning fluvoxamine should be monitored in patients taking methadone, be-
ing alert for the need to adjust the methadone dosage. Although the
increase in methadone levels with sertraline and paroxetine, and possibly
also fluoxetine, is unlikely to have clinical effects in most patients, the
possibility should be borne in mind, especially if high doses of methadone
are being used. Note that methadone can prolong the QT-interval in high
doses, see ‘drugs that prolong the QT-interval’, (p.257).
3. Paroxetine. A man who had been taking paroxetine 20 mg daily for 4 months without problems developed shivering, diaphoresis and myoclonus and became subcomatose within 12 hours of taking tramadol 100 mg. This was diagnosed as the serotonin syndrome. Tramadol was stopped, the paroxetine dosage halved and he became conscious within a day. The other symptoms gradually disappeared over the next week.9 A 78-year-old woman taking paroxetine 20 mg daily developed nausea, diaphoresis and irritability 3 days after starting tramadol 50 mg three times a day. The next day she developed muscular weakness and confusion, and was found to have a temperature of about 38.2°C and a pulse rate of 110 bpm. She recovered when the drugs were withdrawn. Similar symptoms occurred in another elderly woman taking paroxetine 10 mg daily within 2 days of starting tramadol 50 mg four times daily. Both women were later able to continue taking paroxetine alone without problems.7

Four cases of serotonin syndrome have been attributed to the concomitant use of fluoxetine and ritonavir. The concurrent use of escitalopram and ritonavir do not appear to affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a single-dose study involving 18 healthy subjects, no significant pharmacokinetic interaction was seen when ritonavir was given with escitalopram.1

Ritonavir 600 mg was given to 16 healthy subjects before and after 8 days of treatment with fluoxetine 30 mg twice daily. The maximum plasma levels of ritonavir were unaffected, but its AUC rose by 19%. These changes were not considered large enough to warrant changing the dose of ritonavir.2 The study was criticised for not achieving steady state before assessing the pharmacokinetics and thus possibly underestimating the interaction.3 However, the authors point out that fluoxetine levels were equivalent to those seen at steady state, and multiple dosing of ritonavir is likely to induce its own metabolism, so if anything, the interaction would be lessened at steady state.4

The UK manufacturers of ritonavir predict that it may raise the levels of SSRIs (fluoxetine, paroxetine, sertraline) due to the inhibitory effect of ritonavir on the cytochrome P450 isoforms CYP2C6 and CYP2D6.5 The US manufacturers do not mention any specific SSRIs.6 Both manufacturers suggest careful monitoring of adverse effects when these drugs are used with ritonavir; a dose reduction of the SSRI may be required.5,6

Two cases of serotonin syndrome were attributed to adding ritonavir to established fluoxetine treatment. In one patient this was managed by halving the fluoxetine dose, and in the other ritonavir was withdrawn. Other cases of the serotonin syndrome have been seen in patients taking ritonavir or indinavir with fluoxetine. One involved the additional use of ‘trazodone’, (p.1229), and the other involved large quantities of ‘grapefruit’, (p.1217).

In two isolated cases rifampicin decreased the efficacy of citalopram and sertraline.

**Clinical evidence**

A 34-year-old man, with a long-standing history of anxiety disorder being treated with sertraline 200 mg at bedtime, reported that the medication was no longer working well. He was experiencing a significant amount of anxiety, excessive worry, and poor energy. He additionally reported feeling “spaced out,” and having dizziness exacerbated by movement, lethargy, and insomnia. He had started taking rifampicin 300 mg twice daily and co-trimoxazole 7 days earlier and it was found that his sertraline and N-desmethyldesmethylsertraline levels were only 39% and 46%, respectively, of the levels achieved when he was not taking rifampicin and co-trimoxazole. He later experienced similar symptoms when the sertraline dose was tapered so that paroxetine could be substituted. Similarly, a 55-year-old man taking citalopram 40 to 60 mg daily reported a decrease in therapeutic efficacy (increased crying and panic attacks) after starting rifampicin 600 mg twice daily. His condition improved when the rifampicin was stopped.

**Mechanism**

Both sertraline and citalopram are metabolised by cytochrome P450 isoenzymes including CYP3A4 and rifampicin is a potent inducer of the hepatic CYP450 system, particularly CYP3A4. It would therefore appear that rifampicin induced the metabolism of these two drugs resulting in decreased plasma levels.

**Importance and management**

There seem to be very few reports of this interaction, but rifampicin is a potent enzyme inducer and so clinicians should be aware that rifampicin may reduce citalopram or sertraline plasma levels leading to decreased efficacy or symptoms of SSRIs withdrawal. In theory, rifampicin could affect other SSRIs metabolised via other cytochrome P450 isoenzymes, but there appear to be no reports of this. The UK manufacturer of paroxetine suggests that no initial dosage adjustment is considered necessary when paroxetine is given with enzyme inducing drugs such as rifampicin. Any subsequent dosage adjustment should be guided by clinical effect (tolerability and efficacy). Until more is known this would seem to be a sensible approach with rifampicin and any SSRI.

---

**SSRIs + St John’s wort (Hypericum perforatum)**

Several patients taking sertraline developed symptoms diagnosed as the serotonin syndrome after also taking St John’s wort. Another patient taking St John’s wort developed severe agitation after taking a single dose of paroxetine. Isolated cases of mania have also been reported when SSRIs were taken with St John’s wort.

**Clinical evidence**

(a) Fluoxetine

For a report of hypomania when St John’s wort and Ginkgo biloba were added to treatment with fluoxetine and buspirone, see ‘Buspirone + Herbal medicines’, p.741.

(b) Paroxetine

In one report, a woman stopped taking paroxetine 40 mg daily after 8 months, and 10 days later started to take 600 mg of St John’s wort powder daily. No problems occurred until the next night when she took a single 20-mg dose of paroxetine because she thought it might help her sleep. The following day at noon she was found still to be in bed, rousable but incoherent, groggy and slow moving and almost unable to get out of bed. Two hours later she still complained of nausea, weakness and fatigue, but her vital signs and mental status were normal. Within 24 hours all symptoms had resolved.

(c) Sertraline

Four elderly patients taking sertraline developed symptoms characteristic of the serotonin syndrome within 2 to 4 days of also taking St John’s wort 300 mg, either two or three times daily. The symptoms included dizziness, nausea, vomiting, headache, anxiety, confusion, restlessness, and irritability. Two of them were treated with oral cyproheptadine 4 mg either two or three times daily, and the symptoms of all of them resolved within a week. They later resumed treatment with sertraline without problems. A search of Health Canada’s database of spontaneous adverse reactions from 1998 to 2003 found 2 cases of suspected serotonin syndrome as a result of an interaction between sertraline and St John’s wort.

Mania developed in a 28-year-old man, who continued to take St John’s wort against medical advice whilst also receiving sertraline 50 mg daily for depression; he was also receiving testosterone replacement post-orchidectomy.
Mechanism

A pharmacodynamic interaction may occur between St John’s wort and SSRIs because they can both inhibit the reuptake of 5-hydroxytryptamine (serotonin). The serotonin syndrome has been seen with St John’s wort alone, and so additive serotonergic effects appear to be the explanation for what occurred in the cases described here.

Importance and management

Information appears to be limited to these reports, but interactions between SSRIs and St John’s wort would seem to be established. The incidence is not known but it is probably small, nevertheless because of the potential severity of the reaction it would seem prudent to avoid concurrent use. The advice of the CSM in the UK is that St John’s wort should be stopped if patients are taking any SSRI because of the risk of increased serotonergic effects and an increased incidence of adverse reactions.7

In contrast, beneficial augmentation of effects has been reported with methylphenidate and SSRIs (fluoxetine, paroxetine, sertraline) without significant adverse effects.7,8

An isolated report describes a tonic-clonic seizure in a 13-year-old boy after he had been taking sertraline 25 to 50 mg daily and methylphenidate 80 mg daily for about 2 weeks. He had been receiving methylphenidate without significant adverse effects for about 10 months before the seizure and following discontinuation of the sertraline experienced no further seizures.6

Information appears to be limited to these reports, but interactions between SSRIs and St John’s wort would seem to be established. The incidence is not known but it is probably small, nevertheless because of the potential severity of the reaction it would seem prudent to avoid concurrent use. The advice of the CSM in the UK is that St John’s wort should be stopped if patients are taking any SSRI because of the risk of increased serotonergic effects and an increased incidence of adverse reactions.7

Serotonin syndrome is a potentially life-threatening condition that can occur when drugs that affect serotonin levels are taken together. It can cause symptoms such as fever, perspiration, dilated pupils, arrhythmias, and rhabdomyolysis, and can be caused by a variety of drugs, including SSRIs and St John’s wort.

SSRIs + Sympathomimetics

Isolated reports describe delirium in one patient and a seizure in another when methylphenidate was taken with sertraline. Schizophrenia and symptoms of amphetamine toxicity have also been reported in two patients taking amphetamine and fluoxetine. There is an isolated report of the serotonin syndrome associated with concurrent citalopram and dexamfetamine and another associated with sertraline and etilefrine. There is also a report of adverse effects associated with fluoxetine and phenylpropanolamine.

Clinical evidence, mechanism, importance and management

(a) Amphetamines

1. Amphetamine. A man who had taken a small, unspecified, but previously tolerated dose of amphetamine developed signs of amphetamine overdose (restlessness, agitation, hyperventilation, etc.) while taking fluoxetine 60 mg daily. Another man taking fluoxetine 20 mg daily developed symptoms of schizophrenia after taking two unspecified doses of amphetamine.1

It was suggested that this occurred because fluoxetine inhibits the cytochrome P450 isoenzyme CYP2D6, which is involved in the metabolism of amphetamine, thereby increasing amphetamine levels.2 The general importance of these apparent interactions is uncertain.

2. Dexamphetamine. A patient who experienced the serotonin syndrome with concurrent ‘venlafaxine’, p.1214 and dexamphetamine had a second episode when citalopram was given with the dexamphetamine.3

3. Ecstasy (MDMA, methylenedioxymethamphetamine). For comments on the effects of SSRIs on the metabolism of ecstasy and the possibility of increased serotonin effects, see ‘Amphetamines and related drugs + SSRIs’, p.201.

(b) Etilefrine

A case of the serotonin syndrome was reported due to an interaction between sertraline and etilefrine.4

(c) Methylphenidate

A 55-year-old man with major depression was prescribed sertraline 50 mg daily without response. Three months later the dose was increased to 100 mg daily and methylphenidate 2.5 mg daily was started. His symptoms improved and the dose of methylphenidate was increased to 2.5 mg twice daily and then 5 mg twice daily. After several days at the higher dose, the patient experienced visual hallucinations and confusion. The methylphenidate was discontinued and a day later the psychosis resolved. He was maintained on sertraline 100 mg daily and his mood and motivation remained good.5

SSRIs + Tobacco

Smoking does not appear to alter citalopram pharmacokinetics, and has only modest effects on fluvoxamine pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Citalopram

In a pharmacokinetic study involving 44 adolescent patients (under 21 years of age), there was considerable inter-individual variation in serum levels of citalopram and its metabolites at all doses studied. However, smoking did appear to influence the disposition of citalopram.1 The clinical significance of this is unknown and more study is required.

(b) Fluvoxamine

A comparative study in 12 smokers and 12 non-smokers given single 50-mg oral doses of fluvoxamine found that smoking reduced the fluvoxamine AUC and the maximum serum levels by about 30%.2 However, a study in Japanese patients found no significant difference in steady-state plasma levels of fluvoxamine and its metabolite (fluvoxamine acid) between 34 non-smokers and 15 smokers.3 This suggests that the overall pharmacokinetic effect of smoking is probably minimal, although the effects of a sudden withdrawal from heavy smoking has not been investigated.

SSRIs + Tryptophan

Central and peripheral toxicity developed in five patients taking fluoxetine when they were given tryptophan. On theoretical grounds an adverse reaction seems possible between fluvoxamine (and probably other SSRIs) and tryptophan or oxitriptan.
Clinical evidence

(a) Fluoxetine

The concurrent use of tryptophan with fluoxetine 20 mg daily has been reported to be tolerated. A more recent placebo-controlled, double-blind study involving 30 patients with depression found that the use of tryptophan 2 g daily during the initial phase of treatment with fluoxetine 20 mg daily was beneficial and well-tolerated, but problems have been seen when higher doses of both drugs have been given together. Five patients taking fluoxetine 50 to 100 mg daily for at least 3 months developed a number of reactions including central toxicity (agitation, restlessness, aggressive behaviour, worsening of obsessive-compulsive disorders) and peripheral toxicity (abdominal cramps, nausea, diarrhoea) within a few days of starting tryptophan 1 to 4 g daily. These symptoms disappeared when the tryptophan was stopped. Some of the patients had taken tryptophan in the absence of fluoxetine without problems.3

Mechanism, importance and management

Tryptophan is a precursor of serotonin (5-hydroxytryptamine) and the authors point out that the symptoms resemble the serotonin syndrome, which occurs when serotonin levels are increased. They warn against the concurrent use of tryptophan with fluoxetine or other serotonin reuptake inhibitors. This caution is echoed by most of the manufacturers of the SSRIs; the UK manufacturer of paroxetine additionally mentions oxitriptan (L-5-hydroxytryptophan).3

(b) Fluvoxamine

A warning by the CSM in the UK about the risks of giving fluvoxamine with tryptophan appears to be an extrapolation from the serious reaction (the serotonin syndrome) which has been seen with fluoxetine4 (see above).

Clinical evidence, mechanism, importance and management

SSRIs; Citalopram + Irinotecan

An isolated report describes rhabdomyolysis in a patient receiving citalopram and irinotecan. However, an interaction is by no means established.

Clinical evidence, mechanism, importance and management

A 74-year-old man who had been taking citalopram for 2 months developed rhabdomyolysis after undergoing initial treatment for gastrointestinal cancer with irinotecan. All medications were discontinued, but the rhabdomyolysis was exacerbated upon restarting the citalopram for depression. The citalopram was discontinued and he improved over the next 5 days. It was thought that levels of citalopram might have increased because citalopram and irinotecan share at least one metabolic pathway (CYP3A4), and the cytochrome system may also have been compromised in the cancer patient. However, the patient was also taking simvastatin, which is known to be associated with rhabdomyolysis and which is also metabolised by CYP3A4; however, the authors make no mention of this. An interaction between citalopram and irinotecan is therefore by no means established, and speculatively, this could perhaps be an interaction between irinotecan and simvastatin, which was exacerbated by citalopram.

SSRIs; Fluoxetine + Alosetron

Alosetron had no clinically significant effect on fluoxetine pharmacokinetics in healthy subjects.

Clinical evidence, mechanism, importance and management

An open study in 12 healthy subjects found that alosetron 1 mg twice daily for 15 days had no clinically significant effect on the pharmacokinetics of a single 20-mg dose of fluoxetine. There was a median 3-hour delay in time to reach peak levels of both S- and R-fluoxetine, but this was thought unlikely to be clinically relevant for a drug that requires several weeks to achieve its full therapeutic effect.1

SSRIs; Fluoxetine + Aminoglutethimide

Limited evidence suggests that the effects of fluoxetine are increased by aminoglutethimide.

Clinical evidence, mechanism, importance and management

A patient with severe obsessive-compulsive disorder, resistant to clomipramine combined with SSRIs, improved when given fluoxetine 40 mg daily and aminoglutethimide 250 mg four times daily. Over a four-and-a-half year period, whenever attempts were made to reduce the dosage of either drug, the patient started to relapse. Thus at least one patient has taken both drugs together without problems, and the evidence suggests that the aminoglutethimide has a potentiating effect on the fluoxetine. However, more study is needed to confirm the efficacy and safety of this drug combination in other patients.

SSRIs; Fluoxetine + Cannabis

An isolated report describes mania when a patient taking fluoxetine smoked cannabis.

Clinical evidence, mechanism, importance and management

A 21-year-old woman with a 9-year history of bulimia and depression was taking fluoxetine 20 mg daily. A month later, about 2 days after smoking two ‘joints’ of cannabis (marijuana), she experienced a persistent sense of well-being, increased energy, hypersexuality and pressured speech. These symptoms progressed into grandiose delusions, for which she was hospitalised. Her mania and excitement were controlled with lorazepam and perphenazine, and she largely recovered after about 8 days. The reasons for this reaction are not understood but the authors of the report point out that one of the active components of cannabis, dronabinol (Δ9-tetrahydrocannabinol) is, like fluoxetine, a potent inhibitor of serotonin uptake. Thus a synergistic effect on central serotonergic neurones might have occurred. This seems to be the first and only report of an apparent adverse interaction between cannabis and fluoxetine, but it emphasises the risks of concurrent use.

SSRIs; Fluoxetine + Chlorothiazide

Fluoxetine is reported not to affect the pharmacokinetics of chlorothiazide.1 No special precautions would seem necessary on concurrent use.

SSRIs; Fluoxetine + CYP2D6 substrates

There is in vitro evidence that the effects of flecainide and mexiletine may possibly be increased by fluoxetine. The plasma levels of other drugs predominantly metabolised by CYP2D6 (such as encaidine and thioridazine) may also be increased by fluoxetine. The
US manufacturer of fluoxetine contraindicates its use with thioridazine due to the risk of ventricular arrhythmias.

**Clinical evidence, mechanism, importance and management**

Studies in patients and in vitro investigations using human liver microsomes have shown that fluoxetine and its metabolite, norfluoxetine, have a strong inhibitory effect on the activity of the cytochrome P450 isoenzyme CYP2D6 in the liver.\(^1,2\) This means that in practice, fluoxetine may increase and prolong the effects of drugs metabolised by this isoenzyme.

**Flecainide** and **mexiletine** are predominantly or partly metabolised by CYP2D6 but there appear to be no clinical cases of interactions between these drugs and fluoxetine. However, fluoxetine does interact with ‘propafenone’, (p.275), which is also metabolised by CYP2D6 so it would seem prudent to be alert for increased and prolonged effects of these drugs if fluoxetine is added.

The manufacturers of fluoxetine warn that drugs predominantly metabolised by CYP2D6, and which have a narrow therapeutic index, should be initiated at or adjusted to the low end of their dose range in patients taking fluoxetine. This will also apply if fluoxetine has been taken in the previous 5 weeks because of its long elimination half-life.\(^3,4\) The UK manufacturer specifically mentions **flecainide**, **encainide**, and **tricyclic antidepressants**, (p.1241)). For a list of CYP2D6 substrates, see ‘Table I.3’, (p.6). Of interest, the US manufacturer also lists vinblastine as a CYP2D6 substrate, and therefore cautions its use, but note that vinblastine is more usually considered to be a CYP3A4 substrate.

### **SSRIs; Fluoxetine + Orlistat**

The pharmacokinetics of a single 40-mg oral dose of fluoxetine (a lipophilic drug) were not affected by orlistat 120 mg three times daily in healthy subjects.\(^1\)

### **SSRIs; Fluvoxamine + Enoxacin**

A study in healthy subjects suggested that enoxacin slightly inhibits the metabolism of fluvoxamine.

**Clinical evidence, mechanism, importance and management**

A placebo-controlled study in 10 healthy subjects given enoxacin 200 mg daily for 11 days and a single 50-mg dose of fluvoxamine on the eighth day, found that enoxacin increased the plasma levels of fluvoxamine at 2 and 3 hours and the maximum plasma level was increased from 10.2 to 11.6 nanograms/mL. The scores of the Stanford sleepiness scale were also increased. Enoxacin appears to slightly inhibit the metabolism of fluvoxamine, presumably by interfering with cytochrome P450 isoenzyme CYP1A2-mediated pathways, although the exact pathway was not clear.\(^1\)

### **SSRIs; Paroxetine + Barbiturates**

Paroxetine appears not to interact to a clinically important extent with amobarbital, but phenobarbital may reduce the AUC of paroxetine. Two cases of hepatotoxicity have been reported when paroxetine was given with a barbiturate.

**Clinical evidence, mechanism, importance and management**

**Phenobarbital** 100 mg once daily given to 10 healthy subjects for 14 days caused reductions of 10 to 86% in the AUC of paroxetine in 6 subjects, but the mean AUC values were unaltered. One subject showed a 56% increase in AUC.\(^1\) The sedative effects and impairment of psychomotor performance caused by **amobarbital** 100 mg were not increased by paroxetine 30 mg.\(^2\) Two cases of hepatitis in young women were considered to be caused by the concurrent use of **Atrium** (a barbiturate complex) and paroxetine, which are both hepatotoxic.\(^3\)

For an isolated report of a tonic clonic seizure in a woman taking paroxetine who was anaesthetised with methohexitol, see ‘Anaesthetics, general + SSRIs’, p.105.

### **SSRIs; Paroxetine + Miscellaneous**

**Paroxetine** appears not to interact to a clinically important extent with aluminium hydroxide or food, although absorption may be reduced by large quantities of milk. Concurrent use of paroxetine and aprepitant may slightly reduce the plasma levels of both drugs, but this is probably not clinically significant.

**Clinical evidence, mechanism, importance and management**

(a) **Aluminium hydroxide**

**Aladrox** (aluminium hydroxide) 15 mL twice daily increased the absorption of a single 30-mg dose of paroxetine in healthy subjects by about 12%, and increased the maximum plasma concentration by 14%.\(^4\) This is unlikely to be clinically important. No particular precautions would seem to be necessary on concurrent use.

(b) **Aprepitant**

The US manufacturer of aprepitant notes that the concurrent use of paroxetine 20 mg daily and aprepitant 85 or 170 mg daily reduced the AUC of both drugs by about 25%, and reduced the maximum serum levels by about 20%.\(^5\) These changes are unlikely to be clinically important.

(c) **Food or drink**

A study in healthy subjects found that the absorption of paroxetine was not markedly changed by food. A 40% reduction in absorption was seen when paroxetine was taken with one litre of milk,\(^6\) but few people are likely to drink such a large amount regularly, and so this interaction is unlikely to be clinically significant.

### **Tianeptine + Oxazepam**

A study in healthy subjects given tianeptine 12.5 mg and oxazepam 10 mg both three times daily found no significant changes in the pharmacokinetics of either drug.\(^1\)

### **Trazodone + Antidepressants**

Trazodone and fluoxetine have been used concurrently with advantage, but some patients develop increased adverse effects. There have been isolated reports of the serotonin syndrome in patients receiving trazodone and MAOIs, usually in association with...
other serotonergic drugs. A single case report describes the development of anorexia, psychosis and hypomania in a patient receiving trazodone and tryptophan.

Clinical evidence, mechanism, importance and management

(a) MAOIs

A case report describes a patient treated with trazodone, isocarboxazid and mephendate who developed symptoms of the serotonin syndrome.\(^1\) The US manufacturer says due to the absence of clinical experience, if MAOIs are discontinued shortly before or are to be given concurrently with trazodone, therapy should be initiated cautiously with a gradual increase in dosage until optimum response is achieved.\(^2\) However, the UK manufacturer of trazodone says possible interactions with MAOIs have occasionally been reported; they do not recommend concurrent use, nor should trazodone be given within 2 weeks of stopping an MAOI. MAOIs should not be taken within one week of stopping trazodone.\(^3\)

(b) SSRIs

A patient taking trazodone showed a 31% increase in the antidepressant/dose ratio (suggesting increased trazodone levels) when fluoxetine 40 mg daily was added. She became sedated and developed an unstable gait.\(^4\) A study involving 27 patients also found that fluoxetine increases plasma trazodone levels.\(^5\) However, another study reported citalopram and fluoxetine had no significant impact on trazodone serum levels, even though the mean concentration/dose ratios were nearly 30% higher with the combined therapy than with trazodone monotherapy.\(^6\)

A man with traumatic brain injury showed new-onset dysarthria and speech blocking when fluoxetine was added to trazodone. His speech returned to normal when the fluoxetine was stopped.\(^7\) A 39-year-old HIV-positive man taking multiple antiviral and antibacterial drugs experienced bilateral hand tremor while receiving trazodone 50 mg at bedtime, which worsened when the dose of trazodone was increased to 100 mg and fluoxetine 20 mg daily was added. The trazodone and fluoxetine were discontinued and the tremor completely disappeared after 7 days without specific treatment for myoclonus.\(^8\)

Five out of 16 patients receiving fluoxetine stopped taking trazodone 25 to 75 mg, which was given for insomnia, because of excessive sedation the next day.\(^9\) Three out of 8 patients had improvement in sleep and depression when given both drugs but the other 5 were either unaffected or had intolerable adverse effects (headaches, dizziness, daytime sedation, fatigue).\(^10\) However, another report described advantageous concurrent use in 6 patients without an increase in adverse effects.\(^11\)

It appears that the plasma levels of trazodone may be increased by fluoxetine due to inhibition of cytochrome P450 isoforms by fluoxetine and/or norfluoxetine.\(^12\) Trazodone is a substrate for CYP3A4 and, although fluoxetine is a weak inhibitor, its metabolite norfluoxetine is a moderate inhibitor of this enzyme.\(^13\) In vitro data suggest citalopram has little inhibitory effect on CYP3A4.\(^6\)\(^,\)\(^12\)

These cases and studies suggest that the concurrent use of trazodone and fluoxetine can be useful and uneventful but it would seem prudent to monitor the outcome for any evidence of increased adverse effects. Citalopram would not be expected to have a pharmacokinetic interaction. However, the cases with fluoxetine suggest that a pharmacodynamic interaction may be possible, and therefore a degree of caution would be prudent if trazodone is given with any SSRIs.

(c) Tryptophan

A single report describes the effective use of trazodone 100 mg and tryptophan 500 mg, both three times weekly with clonazepam in a patient with schizophrenia and congenital defects. However, the patient stopped eating, lost 4.5 kg in weight over 3 weeks, developed signs of psychosis or hypomania, and soon afterwards she became drowsy and withdrawn. When the drugs were withdrawn the aggressive behaviour restarted, but she responded again to lower doses of trazodone and tryptophan although the signs of psychosis re-emerged.\(^13\)

(d) Venlafaxine

For a report of the serotonin syndrome in a patient taking trazodone and venlafaxine, see ‘SNRIs; Venlafaxine + Antidepressants’, p.1212.

Ketoconazole or itraconazole may inhibit the metabolism of trazodone.

Clinical evidence, mechanism, importance and management

An in vitro study demonstrated that ketoconazole inhibited the metabolism of trazodone to its principal metabolite, meta-chlorophenylpiperazine.\(^1\) Trazodone is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inhibitors of this enzyme such as ketoconazole or itraconazole may inhibit its metabolism, leading to substantial increases in trazodone plasma concentrations with the potential for adverse effects.\(^2\)\(^,\)\(^3\) The FDA in the US and the manufacturers of trazodone recommend that a lower dose of trazodone should be considered if it is given with a potent CYP3A4 inhibitor such as ketoconazole or itraconazole.\(^1\)\(^,\)\(^2\)\(^,\)\(^4\) However, the UK manufacturer also suggests that the combination should be avoided where possible.\(^5\)

Trazodone + Ginkgo biloba

Coma developed in an elderly patient with Alzheimer’s disease after she took trazodone with ginkgo biloba.

Clinical evidence, mechanism, importance and management

An 80-year-old woman with Alzheimer’s disease developed coma a few days after starting low-dose trazodone 20 mg twice daily and ginkgo biloba. The patient woke immediately after being given flumazenil 1 mg intravenously. It was suggested that the flavonoids in the ginkgo had a subclinical direct effect on the benzodiazepine receptor. In addition, increased CYP3A4 metabolism of trazodone to its active metabolite, 1-(m-chlorophenyl)piperazine (mCPP), was thought to have enhanced the release of GABA (gamma-amino butyric acid). Flumazenil may have blocked the direct effect of the flavonoids, thus causing the GABA activity to fall below the level required to have a clinical effect.\(^1\) This appears to be an isolated case, from which no general conclusions can be drawn.\(^1\)

Trazodone + Haloperidol

Low-dose haloperidol is reported not to interact to a clinically relevant extent with trazodone.
**Clinical evidence, mechanism, importance and management**

Nine depressed patients who had been taking trazadone 150 to 300 mg at bedtime for 2 to 19 weeks were given haloperidol 4 mg daily for a week. Plasma trazadone levels were not significantly changed but levels of its metabolite (m-chlorophenylpiperazine) were slightly raised (from 78 to 92 nanograms/mL). This study was carried out to investigate the way trazadone is metabolised, but it also demonstrated that no clinically relevant pharmacokinetic interaction occurs between these two drugs at these ages.

---

**Trazadone + Lysergide (LSD)**

A retrospective study found that 28 of 32 subjects (88%) who took LSD and who had taken an SSRI or trazadone for more than 3 weeks had a subjective decrease or virtual elimination of their responses to LSD.1

---

**Trazodone + Macrolides**

Clarithromycin impaired the clearance of trazadone and enhanced its sedative effects in healthy subjects. Erythromycin is also likely to increase trazodone plasma levels.

**Clinical evidence, mechanism, importance and management**

In a placebo-controlled study in healthy subjects, clarithromycin impaired the clearance and enhanced the sedative effects of a 50-mg dose of trazodone.1 The manufacturers comment that trazodone is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inhibitors of this enzyme may inhibit its metabolism leading to substantial increases in trazodone plasma levels, with the potential for adverse effects.2,3 The UK manufacturer also suggests that the combination should be avoided where possible.5

---

**Trazodone + Pseudoephedrine**

A single report describes toxicity in a woman treated with trazodone when she took pseudoephedrine.

**Clinical evidence, mechanism, importance and management**

An isolated report describes a woman who had been taking trazodone 250 mg daily for 2 years who took two doses of a non-prescription medicine containing pseudoephedrine. Within 6 hours she experienced dread, anxiety, panic, confusion, depersonalisation and the sensation that parts of her body were separating. None of these symptoms had been experienced in the past when she was taking either preparation alone.1 The reasons for this reaction are not understood. This appears to be an isolated case, and therefore no general conclusions can be drawn.

---

**Trazodone + Protease inhibitors**

Ritonavir impairs the clearance of trazadone with an increased potential for adverse effects. Other protease inhibitors may interact similarly.

**Clinical evidence**

A randomised, placebo-controlled, crossover study in 10 healthy subjects found that short-term exposure to low-dose ritonavir (200 mg twice daily for 2 days) impaired the clearance of a single 50-mg dose of trazodone by 52%. Mean peak plasma levels of trazodone were increased by 34%, and the AUC increased more than twofold. In addition, ritonavir enhanced the adverse effects of trazodone with increased sedation, fatigue and performance impairment.1 Symptoms of the serotonin syndrome occurred in an HIV-positive patient taking antiretrovirals and other drugs, including fluoxetine and trazodone, when ritonavir was added. The symptoms resolved on discontinue the trazodone and halving the ritonavir dose.2 The serotonin syndrome has also been seen in a patient taking trazodone, indinavir and excessive amounts of 'grapefruit'.3

---

**Tricyclic antidepressants + ACE inhibitors**

Preliminary evidence from two patients suggests that enalapril may increase the effects of clomipramine, resulting in toxicity.

**Clinical evidence**

Two patients taking enalapril (one taking 20 mg daily and the other taking 20 mg five times weekly) were given clomipramine for depression. The clomipramine dosage of one of them was increased from 25 to 50 mg, and 10 days later he became euphoric and excited. The problem resolved when the clomipramine dosage was reduced to 25 mg again. The other patient had been stable taking clomipramine 100 mg, and 10 days later he became dysphoric and disturbed. The problem resolved when the clomipramine dosage was reduced to 50 mg daily.1

---

**SSRIs, Tricyclics and related antidepressants**

An in vitro study demonstrated that the metabolism of trazodone to its principal metabolite, meta-chlorophenylpiperazine (mCPP), was inhibited by ritonavir, which is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4. Indinavir was also a strong inhibitor of mCPP formation, whereas saquinavir and nelfinavir were considerably less potent inhibitors.3

**Mechanism**

Trazodone is a substrate for CYP3A4 and inhibitors of this enzyme such as ritonavir and indinavir may inhibit its metabolism, leading to substantial increases in trazodone plasma concentrations with the potential for adverse effects.4,5

**Importance and management**

The FDA in the US and the manufacturers of trazodone recommend that a lower dose of trazodone should be considered if it is given with potent CYP3A4 inhibitors such as the protease inhibitors ritonavir and indinavir.4,6 However, the UK manufacturer also suggests that the combination should be avoided where possible.5"
Methylphenidate can increase the levels and rate of response to tricyclic antidepressants. This has led to both increased beneficial and adverse effects. No significant pharmacokinetic interaction has been reported between desipramine and dexamfetamine or methylphenidate. An isolated report describes a blood dyscrasia in a child given methylphenidate and imipramine.

**Clinical evidence**

A study in ‘several patients’ demonstrated a dramatic increase in the plasma levels of imipramine and its active metabolite desipramine when they took methylphenidate. In one patient taking imipramine 150 mg daily, methylphenidate 20 mg daily increased the plasma levels of imipramine from 100 to 700 micrograms/L and of the metabolite desipramine from 200 to 850 micrograms/L over a period of 16 days. Clinical improvement occurred in several of the patients. Similar effects have been described in other reports. It seems that elevation of drug levels takes several days to occur, and several days to wear off. A study of the combined use of tricyclic antidepressants (desipramine, imipramine, nortriptyline, doxepin) with methylphenidate 5 to 15 mg twice daily was undertaken in 20 of 41 patients with depression who responded to a test dose of methylphenidate. Combined use accelerated the antidepressant response to tricyclics with 6 of 20 patients responding after 1 week and 10 of 16 patients responding after 2 weeks. Adverse effects included insomnia, dizziness, hypotension and dry mouth. Methylphenidate was discontinued after less than 2 weeks concurrent use in 3 patients because of increased anxiety, irritability and hypomania. There is also a report of a 9-year-old boy and a 15-year-old boy who exhibited severe behavior problems until the imipramine and methylphenidate they were taking were stopped. Another report describes more frequent adverse effects in 10 paediatric patients taking methylphenidate with desipramine than with methylphenidate alone. Three patients taking tricyclic antidepressants and with labile blood pressure experienced hypertensive episodes when methylphenidate was also given. They responded to withdrawal of methylphenidate and two patients had further hypertensive episodes when rechallenged with methylphenidate. An isolated report describes leucopenia, anaemia, eosinophilia and thrombocytosis in a child of 10 when given imipramine and methylphenidate. In one patient taking desipramine 250 mg daily, concurrent methylphenidate 40 mg daily resulted in a small decrease in serum desipramine levels, but a marked improvement in mood. In contrast, a retrospective review in 142 children and adolescents taking either desipramine alone, or desipramine with dexamfetamine or methylphenidate, indicated the absence of a clinically significant interaction between desipramine and either stimulant. Pharmacokinetic parameters were similar in each group.

**Mechanism**

*In vitro* experiments with human liver slices indicate that methylphenidate inhibits the metabolism of imipramine, resulting in raised blood levels. The accelerated response to tricyclic antidepressants may also be partly due to increased serum levels in the presence of methylphenidate, although the adverse effects observed were not entirely consistent with elevated levels of tricyclics. There are also reports suggesting that methylphenidate does not significantly affect desipramine levels. The blood dyscrasia may have been due to the rare additive effects of both drugs.

**Tricyclic antidepressants + Amfetamines and related drugs**

Markedly increased serum amitriptyline levels developed in five patients and increased serum nortriptyline levels in another patient when they took fluconazole. Mental changes, syncope, and prolonged QTc interval occurred in some of these patients and there is also a report of prolonged QT interval and tordes de pointes associated with the concurrent use of amitriptyline and fluconazole in a further patient.

**Clinical evidence**

(a) Amitriptyline

A man with AIDS given fluconazole 200 mg daily and amitriptyline 25 mg then 50 mg three times a day developed mental changes and visual hallucinations within 3 days. His serum amitriptyline levels were found to be 724 nanograms/mL (therapeutic levels 150 to 250 nanograms/mL). The confusion resolved within 4 days of stopping the amitriptyline when the levels had fallen to 270 nanograms/mL. Two similar cases were described in this report, in one case in a patient with renal impairment. A woman taking amitriptyline 25 mg twice daily, isosorbide mononitrate and metoprolol became lethargic, drowsy and confused 4 days after starting fluconazole 100 mg daily. She was found to have elevated serum levels of amitriptyline plus nortriptyline of 956 nanograms/mL (patient’s usual range 150 to 250 nanograms/mL) and a prolonged QTc interval. At first, amitriptyline overdose was suspected. The patient was intubated but became delirious, agitated and disoriented. She recovered over the next 24 hours and the amitriptyline level had fallen to 190 nanograms/mL after 4 days. It was concluded that the amitriptyline toxicity was due to an interaction with fluconazole.

Other reports similarly describe increased amitriptyline levels when fluconazole was given; in a child who developed syncope as a result and in...
a 57-year-old woman who developed QT-interval prolongation (although hypokalaemia and the use of sertraline, which can increase serum tricyclic levels, may have contributed to this effect).4

(b) Nortriptyline

An elderly woman taking nortriptyline 75 mg daily and other drugs (cisapridin, morphine, metoclopramide, bumetanide as well as an unnamed antibacterial) was given fluconazole (loading dose of 200 mg, followed by 100 mg daily). After concurrent use for 13 days her trough serum nortriptyline levels had risen by 70% (from 149 to 252 nanograms/mL).5

Mechanism

Not understood, but it has been suggested that the fluconazole inhibits the cytochrome P450 isoenzymes CYP2C9, CYP2C19, CYP3A4 and possibly CYP2D6, which are concerned with the metabolism of these tricyclics, and as a result their serum levels rise.1,3

Importance and management

Information about an interaction between tricyclics and fluconazole seems to be limited to these reports, which, bearing in mind the widespread use of these drugs, would suggest that these interactions are uncommon. The evidence suggests that other factors (such as renal impairment and other potentially interacting medications) may be necessary before this interaction occurs. Bear this possible interaction in mind if tricyclic adverse effects become troublesome.

Clinical evidence, mechanism, importance and management

Two groups of 6 healthy subjects were given a single 100-mg dose of either imipramine or desipramine alone, and then again on day 10 of a 14-day course of ketoconazole 200 mg once daily. It was found that the ketoconazole caused the oral clearance of the imipramine to fall by 17%, its half-life to rise by 15% and the AUC of desipramine, derived from the imipramine, to fall by 9%. No significant changes in the pharmacokinetics of the desipramine were seen.1

These findings show that ketoconazole inhibits the demethylation of imipramine without affecting the 2-hydroxylation of imipramine and desipramine, and confirms that cytochrome P450 isoenzyme CYP3A4 has a role in the metabolism of these tricyclic antidepressants.1 However, in practical terms it would seem that any changes are small and unlikely to be of any clinical significance. No special precautions would appear necessary if ketoconazole is used with either of these two drugs. Information about other tricyclics seems to be lacking.

Clinical evidence, mechanism, importance and management

A man with multiple sclerosis, who was taking baclofen 10 mg four times a day to relieve spasticity, complained of leg weakness and was unable to stand within 6 days of starting to take nortriptyline 50 mg at bedtime. His muscle tone returned 48 hours after stopping the nortriptyline. Two weeks later he was given imipramine 75 mg daily and once again his muscle tone was lost.1 The reason is not understood. There seems to be nothing documented about any other tricyclic antidepressant and baclofen. Prescribers should be aware of this report if considering the use of both drugs, but its general importance is not known. It is probably small.

Tricyclic antidepressants + Baclofen

An isolated report describes a patient with multiple sclerosis taking baclofen who was unable to stand within a few days of starting to take nortriptyline, and later imipramine.

Tricyclic antidepressants + Azoles; Ketoconazole

Ketoconazole appears not to interact with desipramine, and only interacts to a small and clinically irrelevant extent with imipramine.

Tricyclic antidepressants + Benzodiazepines and related drugs

Concurrent use is not uncommon and normally appears to be uneventful. However, three patients became drowsy, forgetful and appeared uncoordinated and drunk while taking amitriptyline and chlordiazepoxide. A combined preparation of amitriptyline and chlordiazepoxide is available but its advantages have been questioned: adverse effects have been seen in four patients. Diazepam may increase the risks of carrying out complex tasks (e.g. driving) if added to amitriptyline, as may other combinations of benzodiazepines and tricyclics.
Clinical evidence

(a) Amitriptyline

1. Chlordiazepoxide. Clinical studies in large numbers of patients have shown that the incidence of adverse reactions while taking amitriptyline and clorzepoxide was no greater than might have been expected with either of the drugs used alone, but a few adverse reports have been documented. As depressed patient taking amitriptyline 150 mg and clorazepoxide 40 mg daily became confused, forgetful and uncoordinated. He acted as though he was drunk. Two other patients taking amitriptyline and clorzepoxide experienced drowsiness, memory impairment, slurring of the speech and an inability to concentrate. Both were unable to work and one described himself as feeling drunk.

2. Diazepam. A study demonstrated an increase in amitriptyline levels when diazepam was given, and two others found that the addition of diazepam to amitriptyline 50 to 75 mg further reduced attention and the performance of a number of psychomotor tests. In contrast, two studies suggested that diazepam did not affect amitriptyline levels. Some of these effects seem to arise from increased CNS depression (possibly additive) and/or an increase in the antimuscarinic adverse effects of the tricyclic.

(b) Clomipramine

One study suggested that alprazolam does not affect clomipramine levels.

(c) Desipramine

1. Alprazolam. An in vitro study in human liver microsomes found that alprazolam does not affect the metabolism (hydroxylation) of desipramine. An isolated report describes a patient taking desipramine 300 mg daily whose serum desipramine levels were halved when he was given clonazepam 3 mg daily and rose again when it was withdrawn. Zopiclone-induced reduction in serum desipramine concentration. J Clin Psychopharmacol (1988) 8, 71–3.

2. Clonazepam. An isolated report describes a patient taking desipramine 300 mg daily whose serum desipramine levels were halved when he was given clonazepam 3 mg daily and rose again when it was withdrawn. Zopiclone-induced reduction in serum desipramine concentration. J Clin Psychopharmacol (1988) 8, 71–3.

3. Zolpidem. Visual hallucinations have been seen in one patient given zopiclone and desipramine.

(d) Imipramine

1. Alprazolam. Alprazolam seems to raise imipramine levels by about 20 to 30%. Triazolam. Triazolam is effective in treating insomnia in depressed patients taking imipramine, and does not reduce the effects of the antidepressant.

2. Zaleplon. A single 75-mg dose of imipramine had no effect on the pharmacokinetics of zaleplon 20 mg, and psychomotor tests showed only short term additive effects lasting 1 to 2 hours.

4. Zolpidem. A single-dose study using zolpidem 20 mg and imipramine 75 mg found no effect on the pharmacokinetics of either drug. However, imipramine increased the sedative effects of zolpidem, and antegrade amnesia was seen.

(e) Nortriptyline

Lorazepam may be useful for anxiety or insomnia in elderly depressed patients without impairing the response to treatment with nortriptyline.

Studies on the effects of alprazolam, clordiazepoxide, diazepam, nortriptyline and oxazepam on the steady-state plasma levels of nortriptyline found no interactions.

(f) Trimipramine

In a study in 10 healthy subjects, when zopiclone and trimipramine were given concurrently for a week, the bioavailability of zopiclone was reduced by almost 14% and the bioavailability of the trimipramine by almost 27%, but neither of these changes were statistically significant.

Mechanism

Uncertain. Additive CNS depression and increased antimuscarinic effects are a possibility with some combinations.

Importance and management

There seems to be no reason for avoiding the concurrent use of benzodiazepines and tricyclic antidepressants and benzodiazepines would not be expected to behave differently from those described here. Some patients will possibly experience increased drowsiness and inattention with the more sedative antidepressants such as amitriptyline, particularly during the first few days, and this may be exaggerated by benzodiazepines such as diazepam. Driving risks may therefore be increased.

Bupropion may increase the levels of tricyclic antidepressants that are metabolised by CYP2D6, including desipramine, imipramine, and nortriptyline. Adverse effects including confusion, lethargy and unsteadiness have been reported with nortriptyline and bupropion. A seizure occurred in a patient given trimipramine and bupropion.

Clinical evidence

A pharmacokinetic study in healthy subjects known to be extensive metabolisers of CYP2D6 found that bupropion doubled the maximum plasma levels of desipramine and increased its AUC fivefold. Another study in a 64-year-old woman taking imipramine 150 to 200 mg daily found that when bupropion 225 mg daily was added, there was a fourfold rise in the plasma levels of imipramine and its metabolite desipramine, but no problems were reported. A comparison of the estimated clearances were: without bupropion, imipramine 1.7 mL/minute and desipramine 1.7 mL/minute; with bupropion, imipramine 0.73 mL/minute and desipramine 0.31 mL/minute.

Nortriptyline toxicity occurred in an 83-year-old woman when sustained-release bupropion was also given. Nortriptyline 75 mg at night produced a plasma level of 96 nanograms/mL, but when bupropion...
150 mg twice daily was added she became unsteady, confused and lethargic and her plasma nor-
triptyline level increased by about 200% (to 274 nanograms/mL). The increased plasma nor-
triptyline level and toxicity occurred again when she was rechallenged with bupropion. An isolat-
ed report describes a seizure when trimipramine 100 mg daily was taken with bupropion 150 mg twice daily. The addition of bupropion resulted in a substantial increase in her plasma levels of trimipramine into the ‘toxic’ range. She was later successfully treated with lower doses of both drugs (trimipramine 50 mg at night and bupropion 150 mg daily).

**Mechanism**

In vitro studies have shown that both bupropion and its active metab-
olite, hydroxybupropion, are inhibitors of CYP2D6, the isoenzyme in-
volved in the metabolism of these tricyclics, which would explain why their levels rose.

**Importance and management**

Although clinical evidence is limited it is supported by in vitro data, and so an interaction would seem to be unlikely. It would seem prudent to be alert for increased tricyclic adverse effects if any of these drugs listed here is given with bupropion, and reduce the tricyclic dose as necessary. Note that bupropion is predicted to increase the risk of seizures with tricyclics, and this effect is dose-related. See ‘Bupropion + Miscellaneous’, p.1206.

**Tricyclic antidepressants + Butyrophenones**

Serum desipramine levels can be considerably increased in a few patients by haloperidol. This may have caused a grand mal sei-
zure in one case but toxic reactions appear to be uncommon. Desipramine and bromperidol appear not to interact.

**Clinical evidence**

(a) Bromperidol

When 13 schizophrenics taking bromperidol 12 to 24 mg daily for 1 to 20 weeks were additionally given desipramine 50 mg daily for a week, bromperidol plasma levels remained unchanged and no adverse clinical events were seen.

(b) Haloperidol

1. Desipramine. A comparative study in patients taking similar doses of desipramine (2.5 to 2.55 mg/kg) showed that the two patients also taking haloperidol had steady-state plasma desipramine levels that were more than double those of 15 others not taking haloperidol (225 nanograms/mL compared with 110 nanograms/mL). A case report describes a patient who had a grand mal seizure when taking desipramine with haloperidol. Her serum desipramine levels were unus-
ually high at 610 nanograms/mL.

2. Imipramine. The urinary excretion of a test dose of 14C-imipramine given to two schizophrenic patients was reduced by about 35 to 40% when they took haloperidol 12 to 20 mg daily. The plasma metabolite levels of 14C-nortriptyline of another schizophrenic fell while taking haloperidol 16 mg daily, whereas plasma levels of unchanged nortriptyline rose.

**Mechanism**

Haloperidol reduces the metabolism of the tricyclic antidepressants, there-
by reducing their clearance, which results in a rise in their plasma levels.

**Importance and management**

The interaction between the tricyclic antidepressants and haloperidol is es-
established though its documentation is sparse. Concurrent use is common whereas adverse reactions are not, but be aware that serum desipramine levels may be elevated. This may have been the cause of the grand mal sei-
zure in the case cited. Imipramine appears to interact similarly. Monitor the outcome if haloperidol is added to established treatment with tricyclic antidepressants.

Note that bromperidol and haloperidol prolong the QT-interval, and this effect has been seen with tricyclics, usually in overdose, see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

**Tricyclic antidepressants + Calcium-channel blockers**

Diltiazem and verapamil can increase plasma imipramine levels, possibly accompanied by undesirable ECG changes. Two isolated reports describe increased nortriptyline and trimipramine levels in two patients given diltiazem.

**Clinical evidence**

(a) Imipramine

Twelve healthy subjects were given a 7-day course of verapamil 120 mg every 8 hours and 13 healthy subjects were given a 7-day course of diltiazem 90 mg every 8 hours. The AUCs of a single 100-mg dose of im-

imipramine given on day 4 were increased by 15% by verapamil, and 30% by diltiazem. One hour after taking imipramine (2 hours after taking the calcium-channel blockers), the average PR interval was greater than 200 milliseconds, which represented first-degree heart block. Two sub-
jects developed second-degree heart block after taking imipramine with verapamil.

(b) Nortriptyline

A diabetic patient taking glipizide and aspirin started taking nortriptyline, and, at the same time, his treatment with nifedipine was replaced by diltiazem 180 mg daily initially, raised to 240 mg daily after a week. Sev-
eral changes in the nortriptyline dosage were made over a 4-week period because its plasma levels became unexpectedly high (the ratio of plasma nortriptyline to its dosage were approximately doubled).

(c) Trimipramine

A depressed woman taking trimipramine 125 mg daily developed high plasma levels of 546 micrograms/L while taking diltiazem 60 mg three times daily. Two weeks later they reached 708 micrograms/L, de-
spite a reduction in the trimipramine dosage to 75 mg daily. She showed no toxicity and her ECG was normal.

**Mechanism**

It has been suggested that diltiazem and verapamil increase the bioavaila-
ility of imipramine by decreasing its clearance. The ECG changes appear to result from the increased imipramine levels and the additive effects of both drugs on the atrioventricular conduction time. Diltiazem may simi-
larly affect nortriptyline and trimipramine.

**Importance and management**

Information appears to be limited to these reports so that the general clinical importance of each of these interactions is uncertain. However it would now seem prudent to be alert for evidence of increases in the levels of tricyclic antidepressants if diltiazem or verapamil is added. The evidence of heart block with imipramine and diltiazem is of particular con-

parison of verapamil, diltiazem, and labetalol on the bioavailability and metabolism of imi-
Tricyclic antidepressants + Cannabis

Tachycardia has been described when patients taking tricyclic antidepressants smoked cannabis.

Clinical evidence, mechanism, importance and management

A 21-year-old woman taking nortriptyline 30 mg daily experienced marked tachycardia (an increase from 90 to 160 bpm) after smoking a cannabinoid cigarette. It was controlled with propranolol.1 A 26-year-old complained of restlessness, dizziness and tachycardia (120 bpm) after smoking cannabis while taking imipramine 50 mg daily.2 Four adolescents aged 15 to 18 taking tricyclic antidepressants for attention-deficit hyperactivity disorder had transient cognitive changes, delirium and tachycardia after smoking cannabis.3

Increased heart rates are well-documented adverse effects of both the tricyclic antidepressants and cannabis, and what occurred was probably due to the additive beta-adrenergic and antimuscarinic effects of the tricyclics, with the beta-adrenergic effect of the cannabis. Direct information is limited but it has been suggested that concurrent use should be avoided.1

Tricyclic antidepressants + Carbamazepine

The serum levels of amitriptyline, desipramine, doxepin, imipramine and nortriptyline can be reduced (halved or more) by carbamazepine but there is evidence that this is not necessarily clinically important. In contrast raised clomipramine levels have been seen in patients taking carbamazepine. An isolated report describes carbamazepine toxicity in a patient shortly after she started to take desipramine.

Clinical evidence

(a) Carbamazepine levels increased

A woman receiving long-term treatment with carbamazepine developed toxicity (nausea, vomiting, blurred vision with visual hallucinations, slurred speech, ataxia) within 6 days of starting to take desipramine daily (3 days at 150 mg daily). Her carbamazepine levels were found to have doubled from 7.7 to 15 micrograms/mL.1

(b) Tricyclic levels increased

A study confirming the value of carbamazepine and clomipramine in the treatment of post-herpetic neuralgia found that carbamazepine appeared to double both clomipramine plasma levels and those of its major metabolite (desmethylocloimipramine).2

(c) Tricyclic levels reduced

A study found that carbamazepine reduced the serum levels of nortriptyline by 58% and of amitriptyline plus its metabolite, nortriptyline, by 60% in 8 psychiatric patients. In 17 other patients carbamazepine reduced serum doxepin levels by 54% and doxepin plus its metabolite, nordoxepin, by 55%. A retrospective study of very large numbers of patients confirmed that carbamazepine approximately halves the serum levels of amitriptyline and nortriptyline.3 An elderly woman needed her nortriptyline dosage to be increased from 75 to 150 mg daily to achieve effective antidepressant serum levels when carbamazepine 500 to 600 mg daily was added.4

In a study in 36 children (aged 5 to 16 years) with attention-deficit disorder taking imipramine, or imipramine and carbamazepine for 1 to 6 months, found that even though the imipramine dosage was significantly higher in the combined treatment group, the plasma levels were significantly lower; and the total plasma antidepressant levels were approximately half of those found in the children not taking carbamazepine.5 A study in 6 healthy subjects found that carbamazepine 200 mg twice daily for a month increased the apparent oral clearance of a single 100-mg dose of desipramine (given on day 24) by 31% and shortened its half-life from 22.1 to 17.8 hours. A patient given desipramine and carbamazepine is reported to have had exceptionally low serum desipramine levels and cardiac complaints, which may have been due to the presence of increased levels of the hydroxy metabolite of desipramine.6

A study in 13 patients with endogenous depression (DSM-III-R) taking imipramine, which confirmed that carbamazepine reduced the total serum levels of imipramine and desipramine, found that levels of the pharmacologically active free drugs remained unchanged.9,10 Moreover 10 of the patients demonstrated a positive therapeutic response (greater than a 50% decrease in the Hamilton Depression Rating Scale) and a reduction in adverse drug reactions.9

Mechanism

It seems likely that the carbamazepine (a recognised enzyme-inducing drug) increases the metabolism and loss of these tricyclics from the body, thereby reducing their serum levels. The reason for the increased serum carbamazepine and clomipramine levels is not understood.

Importance and management

The reduction in the serum levels of amitriptyline, desipramine, doxepin, imipramine and nortriptyline caused by the interaction with carbamazepine appears to be established but the clinical importance is very much less certain. Evidence from one study,9 that achieved a beneficial response in patients taking tricyclics and carbamazepine suggests that it is possibly not necessary to increase the tricyclic dosage to accommodate this interaction. The fact that a retrospective study found that increased imipramine doses were being given to those taking carbamazepine suggests that this interaction will be naturally accounted for. If carbamazepine is added to treatment with any of these tricyclics, be aware that the dose of the tricyclic may need to be titrated up to achieve the desired therapeutic response. Remember too that the tricyclics can lower the convulsive threshold and should therefore be used with caution in patients with epilepsy.

Tricyclic antidepressants + Colestyramine

Colestyramine causes a moderate fall in the plasma levels of imipramine. In vitro evidence suggests that amitriptyline, desipramine and nortriptyline are likely to be similarly affected. One patient who had an unusual gut pathology and depression controlled by doxepin became depressed again when colestyramine was added.

Clinical evidence

Six depressed patients taking imipramine 75 to 150 mg, usually twice daily, were given colestyramine 4 g three times daily for 5 days. The plasma levels of imipramine fell by an average of 23% (range 11 to 30%) and the plasma levels of desipramine (the major metabolite) fell, although this was less consistent and said not to be statistically significant.
The effect of these reduced levels on the control of the depression was not assessed.1

A man whose depression was controlled with doxepin relapsed within a week of starting to take colestyramine 6 g twice daily. Within 3 weeks of increasing the dosage separation of the two drugs from 4 to 6 hours his combined serum antidepressant levels (i.e. doxepin plus n-desmethyldoxepin) had risen from 39 to 81 nanograms/mL and his depression had improved. Reducing the colestyramine dosage to a single 6-g dose daily, separated from the doxepin by 15 hours, resulted in a further rise in his serum antidepressant levels to 117 nanograms/mL accompanied by relief of his depression.2

**Mechanism**

It seems almost certain that these tricyclics become bound to the colestyramine (an ion-exchange resin) within the gut, thereby reducing their absorption. An in vitro study3 with simulated gastric fluid found that, at pH 1, amitriptyline, desipramine, doxepin, imipramine and nortriptyline were approximately 79 to 90% bound by colestyramine: at pH 4 they were 36 to 48% bound and at pH 6.5 they were 62 to 76% bound. In an earlier study,4 binding of these tricyclics at pH 1 had ranged from 76 to 100%.

**Importance and management**

The interaction between imipramine and colestyramine is established but of uncertain clinical importance because the fall in the plasma imipramine levels quoted above was only moderate (23%) and the effects were not measured. The single case involving doxepin was unusual because the patient had an abnormal gastrointestinal tract (hemigastrectomy with pyloroplasty and chronic diarrhoea). Nevertheless it would now be prudent to be alert for any evidence of a reduced antidepressant response if colestyramine is given concurrently. A simple way of minimising the admixture of the drugs in the gut is to separate their administration. It is usually suggested that these drugs should be given 1 hour before or 4 to 6 hours after colestyramine. There seems to be no direct clinical information about other tricyclics but in vitro studies suggest that amitriptyline, desipramine and nortriptyline probably interact like imipramine.

**Tricyclic antidepressants + Disulfiram**

Disulfiram reduces the clearance of imipramine and desipramine. The concurrent use of amitriptyline and disulfiram has been reported to cause a therapeutically useful increase in the effects of disulfiram but ‘organic brain syndrome’ has been seen in two patients.

**Clinical evidence, mechanism, importance and management**

It has been noted that amitriptyline increases the effects of both disulfiram and citrated calcium carbimide without any increase in adverse effects.1 However, there is also some evidence that an adverse interaction can occur. A study in two men found that disulfiram 500 mg daily increased the AUC of imipramine (12.5 mg given intravenously after an overnight fast) by about 30%, and of desipramine 12.5 mg given intravenously in one subject by a similar amount.2 Peak plasma levels were also increased. The suggested reason is that the disulfiram inhibits the metabolism of the antidepressants by the liver. There is also a report of a man taking disulfiram who, when given amitriptyline, complained of dizziness, visual and auditory hallucinations, and who became disoriented to person, place and time. A similar reaction was seen in another patient.3 Concurrent use should therefore be well monitored for any evidence of toxicity.

**Tricyclic antidepressants + Fenfluramine**

It has been said that the concurrent use of tricyclics and fenfluramine is safe and effective; however, others have suggested that as fenfluramine can cause depression, concurrent use should be avoided if the tricyclic is given for depression.

**Clinical evidence, mechanism, importance and management**

Excacerbation of depression has been seen in some patients given fenfluramine4 and several cases of withdrawal depression have been observed in patients taking amitriptyline and fenfluramine, following episodes of severe depression.5 The manufacturers have advised that fenfluramine should not be used in patients with a history of depression or in those being treated with antidepressants.6 On the other hand it has also been claimed that fenfluramine can be used safely and effectively with tricyclic antidepressants.4,5 One report describes a rise in the plasma levels of amitriptyline when fenfluramine 60 mg daily was given to patients taking amitriptyline 150 mg daily.6

Note that fenfluramine was widely withdrawn in 1997 because its use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

Tricyclic antidepressants + Flupentixol

Flupentixol did not inhibit the metabolism of imipramine in two patients but high levels of imipramine and its metabolite, desipramine, were found in another patient.

Clinical evidence, mechanism, importance and management

A study using \(^{13}C\)-imipramine showed that, unlike the situation with the ‘phenothiazines’, (p.760), flupentixol 3 to 6 mg daily did not inhibit the metabolism of imipramine in 2 patients. However, there is an isolated report of very high plasma levels of imipramine and its metabolite desipramine in a patient with schizophrenia who was given flupentixol decanoate 40 mg intramuscularly once every 2 weeks and imipramine 150 mg daily. It was suggested that this may have resulted from competitive inhibition of liver enzymes. This is an isolated case and its general significance is unknown.

Tricyclic antidepressants + Food

Limited evidence suggests that very high fibre diets can reduce the serum levels of doxepin and desipramine, and therefore decrease their effects. The bioavailability of amitriptyline may be affected by food.

Clinical evidence, mechanism, importance and management

Three patients showed no response to doxepin or desipramine and had reduced serum tricyclic antidepressant levels while taking very high fibre diets (wheat bran, wheat germ, oat bran, rolled oats, sunflower seeds, coconut shreds, raisins, bran muffins). When the diet was changed or stopped, the serum tricyclic antidepressant levels rose and the depression was relieved. The reasons for this effect are not known. This interaction may possibly provide an explanation for otherwise unaccountable relapses or inadequate responses to tricyclic antidepressant treatment. Another study in 12 healthy subjects found that breakfast had no effect on the bioavailability of a 50-mg dose of imipramine, or on its peak levels or the time to peak levels. A study in 9 healthy subjects given a single 25-mg dose of amitriptyline in the fasting state and with a standardised breakfast found that there were no consistent significant changes in the bioavailability of amitriptyline or its main metabolite nortriptyline. Similar results were found in a parallel study in which the same subjects were given a single 25-mg dose of nortriptyline. However, there were large individual changes in the AUC of amitriptyline after food, ranging from an increase of 94% to a decrease of about 40%. The largest food-related amitriptyline AUC increases occurred among the subjects with the lowest fasting AUC values and the only major food-related decrease occurred in the subject with the largest fasting AUC. It was concluded that for an individual patient, the timing of amitriptyline administration in relation to food intake should be standardised to avoid large variations in drug levels.

Tricyclic antidepressants + Grapefruit juice

Grapefruit juice does not appear to have a clinically significant effect on amitriptyline or clomipramine levels or imipramine absorption.

Clinical evidence, mechanism, importance and management

A study in 6 patients given clomipramine 112.5 to 225 mg daily found that grapefruit juice 250 mL increased the mean plasma levels of clomipramine and desmethyloclopramine by 4.5% and 10.5%, respectively. In another 7 patients taking amitriptyline 100 to 150 mg daily grapefruit juice did not affect tricyclic plasma levels.

Tricyclic antidepressants + \(H_2\)-receptor antagonists

Cimetidine can raise the plasma levels of amitriptyline, desipramine, doxepin, imipramine and nortriptyline. Other tricyclic antidepressants are expected to interact similarly. Ranitidine does not appear to interact with the tricyclics.

Clinical evidence

(a) Amitriptyline

A study in 10 healthy subjects given a single 100-mg oral dose of doxepin 12 hours after starting to take cimetidine 300 mg every 6 hours for two days, the peak plasma levels and the AUC of a single 25-mg dose of amitriptyline were raised by 37% and 80%, respectively.

Another study by the same authors found that ranitidine does not interact with amitriptyline.

(b) Desipramine

In a study in 8 patients cimetidine 1 g daily for 4 days raised the plasma levels of desipramine 100 to 250 mg daily by 51%, and its hydroxylated metabolite (2-hydroxydesipramine) was raised by 46%. Another study showed that this interaction only occurs in those individuals who are [CYP2D6 extensive metabolisers].

(c) Doxepin

A study in 10 healthy subjects given a single 100-mg oral dose of doxepin 12 hours after starting to take cimetidine 300 mg every 6 hours found that the peak plasma level and AUC of doxepin were raised by 28% and 31%, respectively.

In another study cimetidine 600 mg twice daily was found to double the steady-state plasma levels of doxepin 50 mg daily, whereas ranitidine 300 mg daily had no effect. A patient taking doxepin complained that the normally mild adverse effects (urinary hesitancy, dry mouth and decreased visual acuity) became incapacitating when he also took cimetidine. His serum doxepin levels were found to be elevated.

(d) Imipramine

In 12 healthy subjects cimetidine 300 mg every 6 hours for 3 days raised the peak plasma levels and the AUC of a single 100-mg dose of imipramine by 65% and 172%, respectively. After taking ranitidine 150 mg twice daily for 3 days the pharmacokinetics of imipramine were unaltered. These findings with cimetidine confirm those of previous studies.

There are case reports of patients taking imipramine who developed severe antimuscarinic adverse effects (dry mouth, urine retention, blurred vision) associated with very marked rises in serum imipramine levels when they also took cimetidine.

(e) Nortriptyline

After taking cimetidine 300 mg four times daily for 2 days, the peak plasma nortriptyline levels of 6 healthy subjects were not significantly raised, but the AUC was increased by 20%. A case report describes a patient whose serum nortriptyline levels were raised about one-third while taking cimetidine. Another patient complained of abdominal pain and distention (but no other antimuscarinic adverse effects) when treated with nortriptyline and cimetidine.

Mechanism

Cimetidine is a potent liver enzyme inhibitor, which reduces the metabolism of the tricyclic antidepressants, and may also reduce the hepatic clearance of these drugs. This results in a rise in their serum levels. Ranitidine does not interact because it is not an enzyme inhibitor.
Importance and management

The interactions with cimetidine are well established, well documented and of clinical importance. The incidence is uncertain but most patients could be affected. Those taking amitriptyline, desipramine, doxepin, imipramine or nortriptyline who are given cimetidine should be warned that adverse effects such as mouth dryness, urine retention, blurred vision, constipation, tachycardia, postural hypotension may be more likely to occur. Other tricyclic antidepressants would be expected to be similarly affected. If symptoms are troublesome reduce the dosage of the antidepressant (33 to 50% has been suggested) or replace the cimetidine with ranitidine, which does not appear to interact. Other H₂-receptor antagonists that do not cause enzyme inhibition (e.g. famotidine and nizatidine) would also not be expected to interact.

Tricyclic antidepressants + Inotropes and Vasopressors

Patients taking tricyclic antidepressants show a grossly exaggerated response (hypertension, cardiac arrhythmias, etc.) to parenteral noradrenaline (norepinephrine), adrenaline (epinephrine) and to a lesser extent to phenylephrine. Case reports suggest that this interaction only occurs rarely with local anaesthetics containing these vasoconstrictors.

Clinical evidence

The effects of intravenous infusions of noradrenaline (norepinephrine) were increased approximately ninefold, and of adrenaline (epinephrine) approximately threefold, in 6 healthy subjects who had been taking propranolol 60 mg daily for 4 days.¹ ²

The pressor effects of intravenous infusions of noradrenaline were increased four to eightfold, of adrenaline two to fourfold, and of phenylephrine two to threefold in 4 healthy subjects who had been taking imipramine 75 mg daily for 5 days. There were no noticeable or consistent changes in their response to isoprenaline (isoproterenol).³ However, in a study of possible adverse interactions between imipramine and isoprenaline, although no abnormalities of heart rhythm were seen, one out of the 4 healthy subjects studied showed potentiation of isoprenaline-induced tachycardia.⁴

Five patients taking nortriptyline, desipramine or other unamed tricyclic antidepressants experienced adverse reactions, some of them severe (throbhbing headache, chest pain) following the injection of Xylocestin (lidocaine with 1:25 000 noradrenaline) during dental treatment.⁵ Several episodes of marked increases in blood pressure, dilated pupils, intense malaise, violent but transitory tremor, and palpitations have been reported in patients taking unamed tricyclic antidepressants when they were given local anaesthetics containing adrenaline or noradrenaline for dental treatment.⁶

There are other reports describing this interaction of:

• noradrenaline with imipramine,⁷ clomipramine,⁸ desipramine,⁹ nortriptyline,¹⁰ propiprolamine¹⁰ and amitriptyline,⁴¹⁰
• adrenaline with amitriptyline,¹²
corbadrine with desipramine (in dogs).¹³

Mechanism

The tricyclics and some related antidepressants block or inhibit the uptake of noradrenaline (norepinephrine) into adrenergic neurones. Thus the most important means by which noradrenaline is removed from the adrenergic area is inactivated and the concentration of noradrenaline outside the neurone can rise. If more noradrenaline (or one of the other directly acting alpha or alpha/beta agonists) is then given, the adrenoceptors of the cardiovascular system concerned with raising blood pressure become grossly stimulated by this surabundance of amines, and the normal response becomes exaggerated.

Importance and management

A well documented, well established and potentially serious interaction. The parental use of noradrenaline (norepinephrine), adrenaline (epinephrine), phenylephrine or any other sympathomimetic amine with pre- dominantly direct sympathetic actions in patients taking tricyclic antidepressants. If these inotropes must be used, the rate and amount injected must be very much reduced to accommodate the exaggerated responses that will occur. However, the situation where adrenaline or noradrenaline are used with a local anaesthetic for surface or infiltration anaesthesia, or nerve block is much less clear. The cases cited are all from the 1960s or 1970s, and the preparations concerned contained concentrations of adrenaline or noradrenaline several times greater than those used currently. However, it should be noted that preparations such as Xylocaine with adrenaline still carry a caution about their use with tricyclic antidepressants.¹⁴ Anecdotal evidence suggests that local anaesthetics containing sympathomimetics are, in practice, commonly used in patients receiving tricyclic antidepressants,¹⁵ so the sparsity of reports, especially recent ones, would add weight to the argument that the interaction is only rarely significant. However, it would still seem advisable to be aware of the potential for interaction. Aspiration has been recommended to avoid inadvertent intravenous administration. Felypressin has been shown to be a safe alternative.¹⁶ ¹⁷ If an adverse interaction occurs it can be controlled by the use of an alpha-receptor blocker, such as phentolamine.

Doxepin in doses of less than 150 to 200 mg daily blocks neuronal uptake much less than other tricyclic antidepressants and so is unlikely to show this interaction to the same degree, but in larger doses it will interact like other tricyclics.¹⁹ ²⁰ It does not seem to have been established whether the response to oral doses or nasal drops containing phenylephrine is enhanced by the presence of a tricyclic, but there seem to be no reports of problems.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 18 patients were given a single 50-mg dose of clomipramine on day 1 and modafinil 200 mg daily on days 1 to 3. No pharmacokinetic changes were found to have occurred with either of the two drugs. However, a single case report describes a patient taking clomipramine 75 mg daily who had a rise in serum clomipramine and desmethylclomipramine levels when modafinil 200 mg was added. It was suggested that she had low levels of the cytochrome P450 isoenzyme CYP2D6 (a ‘poor metaboliser’) so that the additional inhibition of CYP2C19 by modafinil resulted in elevated serum levels.

Information about other tricyclic antidepressants is lacking, but the manufacturers of modafinil point out that other poor metabolisers (about 7 to 10% of the Caucasian population) may possibly also show increased serum tricyclic antidepressant levels in the presence of modafinil. Therefore monitoring concurrent use would seem to be a prudent precaution.

Tricyclic antidepressants + Nasal decongestants

The effects of phenylpropanolamine, pseudoephedrine and other related drugs would be expected to be reduced by the tricyclic antidepressants, but so far only one case, involving ephedrine and amitriptyline, seems to have been reported.

Clinical evidence, mechanism, importance and management

Drugs such as phenylpropanolamine and pseudoephedrine exert their effects by causing the release of noradrenaline (norepinephrine) from adrenergic neurones. In the presence of a tricyclic antidepressant, the uptake of these amines into adrenergic neurones is partially or totally prevented and the noradrenaline-releasing effects are therefore blocked. Consequently the effects of drugs such as phenylpropanolamine would be expected to be reduced by tricyclic antidepressants. This predicted interaction has been listed by the manufacturers in some data sheets. However, the almost total lack of evidence in the literature suggests that this is no more than a theoretical interaction. The only report found describes an elderly woman taking amitriptyline 75 mg daily, who developed hypotension (70 mmHg systolic) during subarachnoid anaesthesia. Her blood pressure rose only minimally when she was given intravenous boluses of ephedrine totalling 90 mg.1

Bearing in mind how long and how widely both groups of drugs have been in use, the absence of any other reports would suggest that any interaction between them is rarely of practical importance.

Tricyclic antidepressants + Oestrogens

There is evidence that oestrogens can sometimes reduce the effects of imipramine, yet at the same time paradoxically cause imipramine toxicity. The general clinical importance of this interaction has yet to be evaluated.

Clinical evidence

A study in women taking imipramine 150 mg daily for primary depression found that those given ethinylestradiol 25 or 50 micrograms [daily] for one week showed greater improvement than those given imipramine alone. However, after 2 weeks, those given ethinylestradiol 50 micrograms daily showed less improvement than other women given only 25 micrograms of ethinylestradiol [daily] or a placebo. In an earlier associated study 5 patients taking imipramine 150 mg and ethinylestradiol 50 micrograms daily developed signs of imipramine toxicity (severe lethargy 4 patients), hypotension (4), coarse tremor (2), mild depersonalisation (2) that was dealt with by halving the imipramine dose.1 Another study found that oral contraceptives increased the absolute bioavailability

of imipramine by 60%. Long-standing imipramine toxicity was relieved in a woman taking imipramine 100 mg daily when her dosage of conjugated oestrogen was reduced to 25%. However, although several studies have shown that serum clomipramine levels were raised or remained unaffected by the concurrent use of oestrogen-containing contraceptives, they failed to confirm that tricyclic antidepressant toxicity occurs more often in those taking oral contraceptives than those who are not. Akathisia in 3 patients has been attributed to an interaction between conjugated oestrogens and amitriptyline or clomipramine.

Mechanism

Among the possible reasons for these effects are that the oestrogens increase the bioavailability of imipramine, or inhibit its metabolism.

Importance and management

These interactions are inadequately established. There is no obvious reason for avoiding concurrent use, but it would seem reasonable to be alert for any evidence of toxicity and/or lack of response to tricyclic antidepressant treatment in those taking oestrogens in any form. One study suggested that the imipramine dosage should be reduced by about one-third.

Tricyclic antidepressants + Orlistat

Orlistat appears not to affect the plasma levels of clomipramine or desipramine in patients, or the pharmacokinetics of amitriptyline in healthy subjects.

Clinical evidence, mechanism, importance and management

A preliminary study in patients who had been taking psychotropics drugs long-term found no clinically relevant changes in plasma levels of clomipramine (3 patients) or desipramine (1 patient) when they were given orlistat over an 8-week period. A study in 20 healthy subjects found that orlistat 120 mg three times daily for 6 days did not affect the pharmacokinetics of amitriptyline 25 mg three times daily. Although evidence is limited no particular precautions seem likely to be necessary on concurrent use.

Tricyclic antidepressants + Protease inhibitors

Ritonavir raises desipramine levels and is predicted to also raise the levels of other tricyclic antidepressants.

Clinical evidence, mechanism, importance and management

A single 100-mg dose of desipramine was given to 14 healthy subjects before and after they took ritonavir 500 mg twice daily for 10 days. The AUC and half-life of desipramine increased nearly 2.5-fold and 2-fold, respectively. The maximum plasma levels were also increased by about 22%. These changes are considered to be clinically significant, so the authors suggest that a lower initial dose of desipramine should be used if it is to be started in patients taking ritonavir, and careful monitoring should be carried out in the first few weeks of treatment. These effects are likely to be due to the inhibitory effects of ritonavir on the cytochrome P450 isozyme CYP2D6. Because of this, the manufacturers of ritonavir also predict that the levels of other tricyclic antidepressants (e.g. amitriptyline, imipramine, nortriptyline) will also be raised, and they suggest careful monitoring of adverse effects if any tricyclic is used with ritonavir. A dose reduction of the tricyclic may be required.

Tricyclic antidepressants + Quinidine or Quinine

Quinidine can reduce the clearance of desipramine, imipramine, nortriptyline and trimipramine, and quinine can reduce the clearance of desipramine, thereby increasing their serum levels.

Clinical evidence

(a) Quinidine

In a study in 5 healthy subjects quinidine 50 mg given 1 hour before a single 50-mg dose of nortriptyline increased the nortriptyline AUC fourfold, and the half-life threefold (from 14.2 to 44.7 hours). The clearance fell from 5.4 to 1.9 mL/minute. A single-dose study in healthy subjects found that quinidine 200 mg daily reduced the clearance of imipramine 100 mg by 30% and desipramine 100 mg by 85%. A further study in 2 healthy subjects similarly found that quinidine 50 mg almost doubled the half-life of a single 75-mg dose of trimipramine, which was reflected in some waking EEG changes.

In healthy subjects given quinidine 800 mg daily for 2 days, the urinary excretion of 2-hydroxydesipramine from a single 25-mg dose of desipramine was reduced by 97% and 68% in rapid and slow hydroxylators, respectively.

(b) Quinine

Quinine 750 mg daily for 2 days reduced the urinary excretion of 2-hydroxydesipramine from a single 25-mg dose of desipramine in rapid hydroxylators by 56% but had no significant effect on the clearance in slow hydroxylators.

Mechanism

Quinidine reduces the metabolism (hydroxylation) of these tricyclic antidepressants, by inhibiting the cytochrome P450 isozyme CYP2D6, and thereby reduces their loss from the body. Quinine inhibits the metabolism of desipramine to a lesser extent than quinidine.

Importance and management

The clinical importance of these interactions awaits assessment, but be alerted for evidence of increased tricyclic antidepressant effects and possibly toxicity if quinine is added. One report suggested steady-state increases of 30% with imipramine and more than 500% with desipramine in extensive metabolisers. More study is needed. There seems to be no information about the effect of quinidine on other tricyclics. Information about the effect of quinidine on tricyclics is very limited, but the effects are smaller than those of quinidine and therefore less likely to result in clinically significant adverse effects. Note that quinidine, possibly quinine, and the tricyclics (notably in overdose) may prolong the QT interval, see also "Drugs that prolong the QT interval + Other drugs that prolong the QT interval", p. 157.

Tricyclic antidepressants + Rifampicin (Rifampin)

In three patients a marked reduction in nortriptyline or amitriptyline levels occurred when rifampicin was given.

Clinical evidence
A man with tuberculosis needed to take 175-mg doses of nortriptyline to achieve therapeutic serum levels while taking isoniazid 300 mg, rifampicin 600 mg, pyrazinamide 1.5 g and pyridoxine 25 mg daily. Three weeks after stopping the antidepressural drugs, the patient suddenly became drowsy and his nortriptyline serum levels were found to have risen from 193 nanomol/L to 562 nanomol/L, and later to 671 nanomol/L. It was then found possible to maintain his nortriptyline serum levels in the range of 150 to 500 nanomol/L with only 75 mg of nortriptyline daily.1 A woman taking amitriptyline and fluoxetine had a marked fall in her plasma amitriptyline levels when she took rifampicin 600 mg, isoniazid 200 mg and ethambutol 1.2 g daily. When these antidepressural drugs were stopped, her amitriptyline plasma levels rose once again.2 In a further case in a 43-year-old woman taking nortriptyline 50 mg daily, serum levels were not detectable when rifampicin 600 mg daily was given. Increasing the dose of nortriptyline to 75 mg daily failed to produce detectable serum levels. Two weeks after discontinuation of rifampicin, nortriptyline levels increased significantly.3

Mechanism
It seems highly probable that rifampicin (a well recognised and potent enzyme inducer) increased the metabolism of nortriptyline and amitriptyline by the liver thereby reducing their levels.

Importance and management
Information about the interaction between tricyclic antidepressants and rifampicin seems to be limited to just these three reports, which is a little surprising since both have been widely used for a considerable time. This suggests that generally this interaction may have limited clinical importance. However, bear this interaction in mind if patients taking rifampicin seem unresponsive to treatment with tricyclics. Increase the tricyclic dosage if necessary, and remember to readjust the dose if rifampicin is stopped.

Tricyclic antidepressants + SNRIs; Venlafaxine

Venlafaxine can cause a marked increase in the antimuscarinic adverse effects of clomipramine, desipramine and nortriptyline. There are isolated reports of seizures in a patient taking venlafaxine and trimipramine and the serotonin syndrome has been seen in patients taking venlafaxine with, or shortly before, the use of tricyclics.

Clinical evidence
A 74-year-old man taking venlafaxine 150 mg daily and thoridiazine had his treatment changed to daily doses of venlafaxine 75 mg, desipramine 50 mg, haloperidol 500 micrograms and alprazolam 250 micrograms. Within 5 days he exhibited severe antimuscarinic adverse effects (acute confusion, delirium, stupor, urinary retention and paralytic ileus). This was attributed to an interaction between the venlafaxine and amitriptyline.1 Similarly, a 75-year-old man taking haloperidol, alprazolam and venlafaxine developed urinary retention and became delirious when he also took desipramine.2 A woman taking nortriptyline 20 mg and fluoxetine 20 mg daily with only mild antimuscarinic adverse effects developed much more severe effects (dry mouth, worsened constipation, blurred vision) over 4 weeks following the replacement of the fluoxetine by venlafaxine 75 mg daily.3 Similar effects were seen in a 73-year-old man taking venlafaxine with and nortriptyline 20 mg daily and a 61-year-old man taking venlafaxine with clomipramine 150 mg daily.2 A 69-year-old man with bipolar disorder, who had been taking venlafaxine up to 337.5 mg daily, thoridiazine 25 mg at night, and sodium valproate 1.2 g daily for several months with no adverse motor symptoms, experienced extrapyramidal effects 3 to 4 days after the venlafaxine had been gradually replaced by nortriptyline 50 mg daily. Symptoms persisted despite withdrawal of thoridiazine, but improved on reduction of the nortriptyline dosage to 20 mg daily.4 The cause of the reaction was not known, but it was suggested that there may have been an interaction between venlafaxine and nortriptyline possibly modulated by thoridiazine or sodium valproate.

Duloxetine markedly increased the AUC of desipramine; other tricyclics metabolised by CYP2D6 are expected to interact similarly. Note that the use of duloxetine with other serotonergic drugs such as the tricyclics should be undertaken with caution or avoided because of the theoretical increased risk of serotonin syndrome.

Clinical evidence
Duloxetine 60 mg twice daily increased the AUC of a single 50-mg dose of desipramine by 2.9-fold in subjects who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6.1
Mechanism
Not fully established but it is suggested that venlafaxine can inhibit the metabolism of these tricyclics by the cytochrome P450 isozyme CYP2D6, leading to an increase in their serum levels and a marked increase in their antimuscarinic adverse effects.2 Both venlafaxine and trimipramine can cause seizures, although usually after overdose. Either a pharmacokinetic interaction involving inhibition of drug metabolism by the isozyme CYP2D6, or a pharmacodynamic interaction may have resulted in seizures.5

The serotonin syndrome', (p.9), has been reported in patients taking venlafaxine and amitriptyline alone or with other serotonergic drugs. Both can increase serotonergic activity by inhibition of serotonin re-uptake at presynaptic neurons. In addition, one of the cases described above6 is complicated by the fact that pethidine also has serotonergic activity and the metabolism of amitriptyline can be inhibited by ‘fluconazole’, (p.1230).

Importance and management
Information appears to be limited to these reports, three of which are by the same author. The incidence is not known but if venlafaxine and any tricyclic antidepressant are given concurrently, be alert for any evidence of increased antimuscarinic adverse effects. Although there appears to be only one report, the possibility of an increased risk of seizures with concurrent use should be borne in mind. It may be necessary to withdraw one or other of the two drugs. The reports of the serotonin syndrome highlight the need for caution when one or more serotonergic drugs are given either concurrently or within a short period of each other.

Tricyclic and related antidepressants + SSRIs

The levels of the tricyclic antidepressants can be raised by the SSRIs, but the extent varies greatly, from 20% to tenfold: fluvoxamine, fluoxetine and paroxetine appear to have the greatest effects. Tricyclic toxicity has been seen in a number of cases. Tricyclics may increase the levels of citalopram and possibly fluvoxamine, but the significance of this is unclear. There are several case reports of the serotonin syndrome following concurrent and even sequential use of the SSRIs and tricyclics.

Clinical evidence

(a) Citalopram

In one study1 citalopram caused an increase of about 50% in the AUC of desipramine (the primary metabolite of imipramine), and a reduction in the levels of the subsequently formed metabolite of desipramine (2-hydroxydesipramine) after a single 100-mg oral dose of imipramine. In contrast, 5 patients taking amitriptyline, clomipramine or maprotiline had no changes in their plasma tricyclic antidepressant levels when citalopram 20 to 60 mg daily was also given.2 In another general study, in which 18 patients were given citalopram and tricyclic antidepressants, serum levels of citalopram were doubled in those receiving the tricyclic clomipramine; pooled results for all the tricyclics showed a 44% rise in serum citalopram levels.3 An increase of this size is of doubtful clinical importance with citalopram. In 2 patients the plasma levels of clomipramine 100 mg daily remained stable when the dose was reduced to 75 mg daily and citalopram 40 mg daily was started.5 One had elevated levels of desmethylclomipramine and the other had elevated levels of the active metabolite, 8-hydroxydesmethylclomipramine.3

A case report describes elevated desipramine levels in a patient taking paroxetine that resolved when the patient was switched to citalopram.6

(b) Escitalopram

Escitalopram 20 mg daily for 21 days increased the maximum serum levels and AUC of a single 50-mg dose of desipramine by 40% and 100%, respectively.7 The UK manufacturers predict that clomipramine and nortriptyline will be similarly affected.8

(c) Fluoxetine

Four patients given daily doses of desipramine 300 mg, imipramine 150 mg or nortriptyline 100 mg had two to fourfold increases in plasma tricyclic antidepressant levels within 1 to 2 weeks of starting fluoxetine 10 to 60 mg daily. Two of them developed antimuscarinic adverse effects (constipation, urinary hesitancy).9

A number of other reports and studies clearly confirm that marked increases occur in the levels of amitriptyline,10–14 clomipramine,11,14 desipramine,15–24 imipramine15,19,21,25,26 and nortriptyline,17,18,27–29 accompanied by toxicity, if fluoxetine is added without reducing the dosage of the tricyclic antidepressant. Delirium and seizures have also been described,20,30 and a death has been attributed to chronic amitriptyline toxicity caused by fluoxetine.13 The pharmacokinetics of fluoxetine appear not to be affected by amitriptyline.13

A migraine-like stroke developed in a woman 48 hours after her long-standing treatment with fluoxetine 100 mg daily was abruptly changed to clomipramine 200 mg daily.32

(d) Fluvoxamine

The amitriptyline plasma levels of 8 patients rose (range 15 to 233%) when they were also given fluvoxamine 100 to 300 mg daily. Even larger rises in plasma clomipramine levels occurred (up to eightfold) in four other patients given fluvoxamine 100 to 300 mg daily. The tricyclic dosages remained the same or were slightly lower. No toxicity was seen.33–35

A number of other reports and studies confirm that increases occur in the levels of amitriptyline,36–39 clomipramine,40–41 imipramine,36,37,42–46 maprotiline36 and trimipramine47 in the presence of fluvoxamine. This interaction seems severe with clomipramine (a 10-fold rise in one case)31 and mild with desipramine.48,49 One study also suggested that fluvoxamine levels may be raised.49 An isolated report describes worsening depression in a patient taking desipramine 75 mg daily and mianserin within 24 hours of replacing the dosulepin with fluvoxamine 75 mg daily. The symptoms continued during the next day but were reversed within a day of fluvoxamine being replaced with dosulepin.48

(e) Paroxetine

A study in 17 healthy subjects who were extensive metabolisers and taking amaprotiline 50 mg daily found that when they were also given paroxetine 20 mg daily for 10 days the maximum plasma levels of desipramine rose by 358%, the trough plasma levels rose by 511% and the AUC rose by 421%. An approximately tenfold increase in the maximum plasma levels and the AUC of the paroxetine also occurred.50 Another study found a fivefold decrease in desipramine clearance in extensive metabolisers given paroxetine 20 mg daily.51 Paroxetine has also been shown to increase the levels of clomipramine,51 desipramine,52,53 and trimipramine.54 This resulted in a variety of adverse effects including dizziness,55 confusion,56 sedation57 and memory impairment.58

A 21-year-old man developed the serotonin syndrome when he took one tablet of paroxetine only one day after stopping desipramine, which he had taken for 5 days. He recovered after treatment with cyproheptadine.55 A woman taking paroxetine 30 mg daily developed the serotonin syndrome (tachycardia, delirium, bizarre movements, myoclonus) within 2 hours of taking a single 50-mg dose of imipramine. She recovered when treated with intravenous fluids, sedation and cyproheptadine.56

(f) Sertraline

In 9 healthy subjects, sertraline 50 mg daily increased the maximum plasma levels of desipramine 50 mg daily by 31% at steady-state, and increased the AUC by 23%.24 A later related study in 17 healthy subjects by the same group of workers found that, using the same drug dosages, sertraline increased the desipramine maximum plasma levels by 44%, the minimum levels by 19% and the AUC by 37%. The maximum plasma levels and AUC of the sertraline were increased about twofold.59 Other studies have found that sertraline increases desipramine,57,60 imipramine,57 and nortriptyline51 levels, but it has also been suggested that sertraline has no effect on imipramine levels.62,63

SSRIs, Tricyclics and related antidepressants 1241...
Importance and management

The interactions of the SSRIs and tricyclic antidepressants are established and of clinical significance. The SSRIs increase tricyclic levels, with fluoxetine, fluoxetine and paroxetine apparently having the greatest effects. The increased tricyclic levels can be beneficial. However, it has been suggested that patients given fluoxetine should have their tricyclic dose reduced to one-quarter. Similar recommendations have been made with fluvoxamine (reduction in tricyclic dose to one-third) and sertraline. It would seem prudent to consider a dosage reduction of the tricyclic if paroxetine is added. Some suggest that a small initial dose of the SSRI should also be used.

Patients taking any combination of tricyclic and SSRI should be monitored for adverse effects (e.g. dry mouth, sedation, confusion) with tricyclic levels monitored where possible. Remember that the active metabolite of the tricyclic antidepressants. Hence these SSRIs cause tricyclic levels monitored where possible. Remember that the active metabolite

Mechanism

Fluoxetine, paroxetine, and to a lesser extent sertraline and citalopram, inhibit the cytochrome P450 isoenzyme CYP2D6, which is involved in the metabolism of the tricyclic antidepressants. Hence these SSRIs cause tricyclic levels monitored where possible. Remember that the active metabolite}

A woman who had been taking sertraline 50 mg daily (as well as morphine sulfate and pericazine) developed the serotonin syndrome within 3 days of starting to take amitriptyline 75 mg daily. She recovered when all of the psychotropic drugs were withdrawn.

more than double the baseline levels 4 weeks after stopping desipramine. In this study, healthy subjects were extensive CYP2D6 metabolisers, which is the usual phenotype. A case report describes a 3.5-fold increase in desipramine levels, with associated toxicity (dizziness, ataxia, incoordination, and difficulty swallowing), in a 52-year-old man taking desipramine 350 mg daily, which occurred within 2 to 3 weeks of him starting terbinafine. The desipramine was stopped for a few days and restarted at a dose of just 50 mg daily, which gave similar serum levels to those seen before terbinafine was started. When the terbinafine was stopped, the dose of desipramine needed to be gradually titrated up to the initial amount.3

(c) Imipramine

A 51-year-old man who had been taking lithium carbonate and varying doses of imipramine 150 to 200 mg daily for 10 years was also given oral terbinafine 250 mg daily for onychomycosis. About a week later he complained of dizziness, muscle twitching and excessive mouth dryness. His serum imipramine levels, measured 5 days later, had risen from his usual range of 100 to 200 nanograms/mL up to 530 nanograms/mL. Within 10 days of reducing his daily imipramine dose from 200 to 75 mg daily, his serum levels had fallen to 229 nanograms/mL. His liver function was normal.4

(d) Nortriptyline

A report describes a marked increase in the serum levels of nortriptyline (about doubled) accompanied by evidence of toxicity (fatigue, vertigo, loss of energy and appetite, and falls) in a 74-year-old man taking nortriptyline 125 mg daily, roughly 14 days after he started to take terbinafine 250 mg daily. His symptoms responded to a dose reduction to 75 mg daily. His serum levels were similarly elevated when he was later re-challenged with terbinafine. His liver function was normal.5 The same authors reported a similar case in a woman who had been taking nortriptyline and terbinafine for one month before she showed signs of an interaction. A later re-challenge with terbinafine confirmed the interaction.6

Mechanism

Terbinafine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, which is the principal enzyme involved in the metabolism of many tricyclics. Terbinafine can have a very prolonged half-life, so an interaction may occur/continue for a number of weeks after stopping the drug.

Importance and management

Although there are only a few case reports, the increase in levels of tricyclic antidepressant in the presence of terbinafine appears to be clinically important. Caution is recommended if terbinafine is given to patients taking drugs metabolised by CYP2D6 such as tricyclic antidepressants.7 It would seem prudent to monitor for tricyclic adverse effects (such as dry mouth, blurred vision and urinary retention). Tricyclic levels may return to normal only slowly after discontinuation of terbinafine.1,2,6 It is also suggested that there may be a risk of clinically significant interactions if these drugs are given within 3 months of stopping terbinafine.1

Clinical evidence, mechanism, importance and management

The addition of liothyrone 25 micrograms daily was found to increase the speed and efficacy of imipramine in relieving depression.1 Similar results have been described in other studies with desipramine2 or amitriptyline3 but the reasons are not understood. One possible explanation is that the patients had overt or subclinical hypothyroidism, which after correction with liothyrone allowed them to overcome an impaired response to tricyclic antidepressants.4 However, adverse reactions have also been seen. A patient being treated for both hypothyroidism and depression with thyroid 60 mg and imipramine 150 mg daily complained of dizziness and nausea. She was found to have developed paroxysmal atrial tachycardia.5 A 10-year-old girl with congenital hypothyroidism, well controlled on desiccated thyroid 150 mg daily, developed severe thyrotoxicosis after taking imipramine 25 mg daily for 5 months for enuresis. The problem disappeared when the imipramine was withdrawn.6 In another patient the effect of levothyroxine was lost and hypothyroidism developed when dosulepin was started.7

This is normally an advantageous interaction,8 in which liothyrone appears to have a significantly greater antidepressant-potentiating effect than levothyroxine.9 These apparent interactions remain unexplained. There would seem to be no good reason, generally speaking, for avoiding concurrent use unless problems arise.

3. Wheately D. Potentiation of amitriptyline by thyroid hormone. Arch Gen Psychiatry (1972) 26, 229–33.

Tricyclic antidepressants + Tobacco

Smoking tobacco reduces the plasma levels of amitriptyline, clomipramine, desipramine, imipramine and nortriptyline, but this does not appear to result in a clinically significant interaction.

Clinical evidence

Two studies found no difference between the steady-state nortriptyline plasma levels of tobacco smokers and non-smokers,1,2 but others have found that smoking tobacco lowers the plasma levels of amitriptyline, clomipramine, desipramine, imipramine and nortriptyline.3 For example a 25% reduction in plasma nortriptyline levels was found in one study,4 and a 45% reduction in total levels of imipramine and its metabolite, desipramine, was found in another.5

Mechanism

The probable reason for the reduced tricyclic levels is that some of the components of tobacco smoke are enzyme inducers, which increase the metabolism of these antidepressants by the liver.

Importance and management

These interactions are established but it might wrongly be concluded from the figures quoted that smokers need larger doses to control their depression. Some evidence suggests that the plasma levels of free (and pharmacologically active) nortriptyline are greater in smokers than non-smokers (10.2% compared with 7.4%), which probably offsets the fall in total plasma levels.6 Thus the lower plasma levels in smokers may be as therapeutically effective as the higher levels in non-smokers, so that there is probably no need to raise the dosage to accommodate this interaction. These interactions are established but it might wrongly be concluded from the figures quoted that smokers need larger doses to control their depression. Some evidence suggests that the plasma levels of free (and pharmacologically active) nortriptyline are greater in smokers than non-smokers (10.2% compared with 7.4%), which probably offsets the fall in total plasma levels.6 Thus the lower plasma levels in smokers may be as therapeutically effective as the higher levels in non-smokers, so that there is probably no need to raise the dosage to accommodate this interaction.

replaced by clorazepate. The authors of the report attributed this reaction to the valproic acid withdrawal.8

(c) Valpromide

In 10 patients valpromide 600 mg daily for 10 days caused a 65% rise in the plasma levels of nortriptyline (from 61 to 100.5 nanograms/mL) and a 50% rise in the levels of amitriptyline (from 70.5 to 105.5 nanograms/mL).7,8

Mechanism

Uncertain. Inhibition of the metabolism of these tricyclics by valproate has been suggested.3,5

Importance and management

Information seems to be limited to these reports. It would seem prudent to monitor for tricyclic adverse effects (such as dry mouth, blurred vision and urinary retention) in patients given valproate and amitriptyline, clomipramine, or nortriptyline and to reduce the dosage of the tricyclic if necessary. Where possible consider monitoring tricyclic levels. Information about other tricyclic antidepressants seems to be lacking. The occurrence of status epilepticus in another patient reinforces the fact that the tricyclics can lower the convulsive threshold and should therefore be used with caution in patients with epilepsy.

Tricyclic antidepressants; Amitriptyline + Ethchlorvynol

Transient delirium has been attributed to the concurrent use of amitriptyline and ethchlorvynol,1 but no details were given and there appear to be no other reports confirming this alleged interaction.

Tricyclic antidepressants; Amitriptyline + Furazolidone

A report describes the development of toxic psychosis, hyperactivity, sweating and hot and cold flushes in a woman taking amitriptyline with furazolidone, and diphenoxylate with atropine.

Clinical evidence, mechanism, importance and management

A depressed woman taking daily doses of conjugated oestrogens 1.25 mg and amitriptyline 75 mg, was also given furazolidone 300 mg daily and diphenoxylate with atropine sulfate. Two days later she began to experience blurred vision, profuse perspiration followed by alternate chills and hot flushes, restlessness, motor activity, persecutory delusions, auditory hallucinations and visual illusions. The symptoms cleared within a day of stopping the furazolidone.1 The reasons are not understood but the authors point out that furazolidone has MAO-inhibitory properties and that the symptoms were similar to those seen when the tricyclic antidepressants and MAOIs interact. However the MAO-inhibitory activity of furazolidone normally develops over several days. Whether the concurrent use of atropine and amitriptyline (both of which have antimuscarinic activity) had some part to play in the reaction is uncertain. No firm conclusions can be drawn from this slim evidence, but clinicians should be aware of this case when considering the concurrent use of tricyclic antidepressants and furazolidone.

Tricyclic antidepressants; Amitriptyline + Sucralfate

Sucralfate causes a marked reduction in the absorption of amitriptyline.

Clinical evidence, mechanism, importance and management

When 6 healthy subjects took a single 75-mg dose of amitriptyline with a single 1-g dose of sucralfate, the AUC of the amitriptyline was reduced by 50%.1 Concurrent use should be monitored to confirm that the therapeutic effects of the antidepressant are not lost. An increase in the dosage may be needed. There seems to be nothing documented about other tricyclics.

Tricyclic antidepressants; Clomipramine + Ademetionine

A severe reaction, diagnosed as the serotonin syndrome, developed in a woman taking ademetionine shortly after her clomipramine dosage was raised.

Clinical evidence, mechanism, importance and management

An elderly woman with a major affective disorder was treated with intramuscular ademetionine 100 mg daily and clomipramine 25 mg daily for 10 days. About 2 to 3 days after the clomipramine dosage was raised to 75 mg daily, she became progressively agitated, anxious and confused. On admission to hospital she was stuporous, with a pulse rate of 130 bpm, a respiratory rate of 30 breaths per minute, and she had diarrhoea, myoclonus, generalised tremors, rigidity, hyperreflexia, shivering, profound diaphoresis and dehydration. Her temperature rose from 40.5 to 43°C. She had no infection, and the diagnosis was of ‘the serotonin syndrome’, (p.9). The drugs were withdrawn and she was given dantrolene 50 mg intravenously every 6 hours for 48 hours. She made a complete recovery.1 The reason for this severe adverse reaction is not understood.

Tricyclic antidepressants; Clomipramine + Oxybutynin

Oxybutynin reduced the blood levels of clomipramine in one patient.

Clinical evidence, mechanism, importance and management

An elderly woman had clomipramine and desmethyloclopramide blood levels of 405 and 50 nanograms/mL, respectively, after taking clomipramine 25 mg daily and fluvoxamine 100 mg daily for 18 days. Within one week of starting oxybutynin 5 mg daily, the levels of clomipramine and desmethyloclopramide had fallen to 133 and less than 25 nanograms/mL, respectively, and remained low during a further week of concurrent treatment.1 Clomipramine levels may be reduced because oxybutynin is an inducer of cytochrome P450 isoenzymes, which could increase the metabolism of clomipramine, and therefore reduce it levels.1 This appears to be the only report of an interaction, the mechanism of which is not fully clear. It is therefore of unknown general significance. However, note that both tricyclic antidepressants and oxybutynin have antimuscarinic effects, which
may be additive on concurrent use. Consider ‘Antimuscarinics + Antimuscarinics’, p.674, for more on this potential interaction.

### Tricyclic antidepressants; Desipramine + Propafenone

An isolated report describes markedly raised serum desipramine levels in a patient who also took propafenone.

**Clinical evidence, mechanism, importance and management**

A man with major depression responded well to desipramine 175 mg daily with serum desipramine levels in the range of 500 to 1000 nanomol/L. When he was treated for paroxysmal atrial fibrillation with digoxin 250 micrograms daily and propafenone 150 mg twice daily and 300 mg at night he developed markedly elevated serum desipramine levels (2092 nanomol/L) and toxicity (dry mouth, sedation, shakiness) while taking desipramine 150 mg daily. The adverse effects resolved when the desipramine was stopped for 5 days, but when it was restarted at 75 mg daily his serum desipramine levels were still raised (1130 nanomol/L).

The raised desipramine levels are thought to result from decreased metabolism and clearance, caused by propafenone. The general importance of this case is uncertain, but be alert for signs of desipramine toxicity in any patient given propafenone concurrently. Adjust the desipramine dosage appropriately.

### Tricyclic antidepressants; Doxepin + Tamoxifen

An isolated report describes a reduction in doxepin serum levels attributed to the use of tamoxifen.

**Clinical evidence, mechanism, importance and management**

A 79-year-old woman with a long history of bipolar disorder, stabilised on lithium carbonate and doxepin 200 mg at bedtime and also taking propranolol, was given tamoxifen 20 mg daily after a mastectomy for breast cancer. It was noted that her total blood levels of doxepin and its major metabolite were reduced by about 25% over the next 11 months. The control of her depression remained unchanged. The reasons for this apparent interaction are not known. The manufacturer of tamoxifen has another undetailed and isolated report of a possible interaction. This appears to be the first and only clear report of an interaction between a tricyclic antidepressant and tamoxifen so that its general importance is not known. It seems likely to be small.

### Tricyclic antidepressants; Imipramine + Beta blockers

Propranolol increased the imipramine levels in two children. Labetalol has been found to increase imipramine levels in adults. The clinical importance of these interactions is uncertain.

**Clinical evidence**

*(a) Labetalol*

In 13 healthy subjects labetalol 200 mg every 12 hours for 4 days, increased the AUC of a single 100-mg dose of imipramine by 53%, when compared with a placebo. The maximum plasma level increased by 28%.

*(b) Propranolol*

A 9-year-old boy was given propranolol for the control of anger and aggression, and imipramine for stress and depression. When his imipramine dosage was raised from 60 to 80 mg daily and his propranolol dose was also raised, from 360 to 400 mg daily, his levels of imipramine plus metabolite (desipramine) rose sharply from a total of 139 nanograms/mL to 469 nanograms/mL. Reducing the imipramine to 60 mg and raising the propranolol to 440 mg daily only reduced the total imipramine/desipramine levels to 426 nanograms/mL. Another imipramine reduction to 40 mg and an increase in the propranolol dose to 480 mg daily resulted in a final total imipramine/desipramine level of 207 nanograms/mL. No significant adverse effects or heart block occurred.

A 9-year-old girl taking imipramine 75 mg daily with a total imipramine/desipramine level of 260 nanograms/mL, had a marked rise to 408 nanograms/mL within 3 days of starting to take propranolol 10 mg three times daily. Two days after stopping the imipramine, her desipramine level (imipramine not measured) had fallen from 382 to 222 nanograms/mL.

**Mechanism**

Uncertain. The suggestion is that these drugs compete for metabolism (hydroxylation) by the same cytochrome P450 isoenzymes (CYP2D6 and CYP2C8) in the liver, with imipramine being the ‘loser’, resulting in its accumulation in the body.

**Importance and management**

Information seems to be limited to these two studies. The clinical importance of this interaction is uncertain, but it would now be prudent to monitor the outcome if propranolol or labetalol is added to treatment with imipramine. Tricyclic adverse effects include dry mouth, blurred vision and urinary retention. Where possible consider monitoring the plasma imipramine levels. There seems to be no information as yet about other beta blockers or tricyclic antidepressants.

### Tricyclic antidepressants; Imipramine + Vinpocetine

Vinpocetine does not appear to affect plasma imipramine levels.

**Clinical evidence, mechanism, importance and management**

In 18 healthy subjects the steady-state plasma levels of imipramine 25 mg three times daily were unaffected by vinpocetine 10 mg three times daily, taken concurrently for 10 days. No special precautions would seem to be necessary. There seems to be nothing documented about any of the other tricyclic antidepressants.

Acamprosate + Miscellaneous

Naltrexone modestly increases the rate and extent of acamprosate absorption. There is no pharmacokinetic interaction between acamprosate and alcohol or diazepam. Disulfiram does not alter the pharmacokinetics of acamprosate, and acamprosate does not alter the pharmacokinetics of imipramine. The combination of acamprosate and barbiturates, meprobamate, or oxazepam does not appear to increase the risk of adverse effects.

Clinical evidence, mechanism, importance and management

(a) Alcohol

In studies in healthy subjects, the pharmacokinetics of both alcohol and acamprosate were unchanged by concurrent use.1

(b) Antidepressants, anxiolytics and hypnotics

A 15-day study in 591 patients, to assess the effects of the concurrent use of acamprosate with other drugs commonly used in the management of alcohol withdrawal, found no evidence of additional adverse effects with meprobamate, oxazepam, or the barbiturate complex tetrabamate (that includes phenobarbital).2 Other studies found that acamprosate caused no clinically relevant changes in imipramine pharmacokinetics, and the pharmacokinetics of both diazepam and acamprosate were unchanged by concurrent use.1

No special precautions would therefore appear to be needed with any of these drugs.

(c) Disulfiram

In a study in 12 healthy subjects, disulfiram 500 mg once daily for 7 days did not alter the plasma levels of acamprosate 666 mg three times daily.3

(d) Naltrexone

In a study in 24 healthy subjects, the concurrent use of naltrexone 50 mg daily and acamprosate 2 g daily for 7 days modestly increased the rate and extent of absorption of acamprosate, as indicated by a 33% increase in maximum level, a 33% reduction in time to maximum level, and a 25% increase in AUC. There was no change in naltrexone pharmacokinetics.4 Similarly, an increase in acamprosate levels was seen in a study of the use of acamprosate and naltrexone in alcohol-dependent subjects.5 No particular adverse events were identified on concurrent use,34 suggesting that the drugs may be used together.

Agalsidase + Miscellaneous

Agalsidase alfa and agalsidase beta should not be given with amiodarone, chloroquine, gentamicin, monobenzone due to a theoretical risk of inhibition of intra-cellular alpha-galactosidase activity.1,2 These enzymes are unlikely to interact via cytochrome p450-mediated mechanisms.1

Allopurinol + Aluminium hydroxide

Three haemodialysis patients had a marked reduction in the effects of allopurinol while taking aluminium hydroxide. Separating the doses by 3 hours reduced the effects of this interaction.

Clinical evidence

Three patients receiving haemodialysis, taking 5.7 g of aluminium hydroxide daily and allopurinol 300 mg daily for high phosphate and uric acid levels, had no reduction in their hyperuricaemia until the aluminium hydroxide was given 3 hours before the allopurinol, whereupon their uric acid levels fell by 40 to 65%. When one patient returned to taking both preparations together, her uric acid levels began to rise.1

Mechanism

Not understood, but it seems likely that aluminium and allopurinol may bind in the gut, resulting in impaired allopurinol absorption.

Importance and management

Information seems to be limited to this report. Renal patients taking large doses of aluminium should be advised to separate the administration of these two drugs by 3 hours or more to avoid admixture in the gut. The effects of lower doses of aluminium and the effects in patients with normal renal function do not appear to have been studied.

Allopurinol + Iron compounds

No adverse interaction occurs if iron and allopurinol are given concurrently.

Clinical evidence, mechanism, importance and management

Some early animal studies, where allopurinol was given in very large doses, suggested that allopurinol might have an inhibitory effect on the release of iron from hepatic stores. It was feared that this might result in hepatic iron overload. This led the manufacturers of allopurinol in some countries to issue a warning about their concurrent use. However, subsequent research suggests that no special precautions are needed.1,3

Allopurinol + Tamoxifen

A single case report describes allopurinol hepatotoxicity in a man given tamoxifen.

Clinical evidence, mechanism, importance and management

An elderly man who had been taking allopurinol 300 mg daily for 12 years developed fever and marked increases in his serum levels of lactic dehydrogenase and alkaline phosphatase within a day of starting to take tamoxifen 10 mg twice daily. He rapidly recovered when the allopurinol was stopped. The reasons for the reaction are not understood, but the authors suggested that the increased hepatotoxic effect may have resulted from tamoxifen inhibiting allopurinol metabolism, thereby increasing the serum levels of allopurinol and its metabolite. The general importance of this isolated report is not known.

Allopurinol + Thiazide diuretics

Severe allergic reactions to allopurinol have been seen in a few patients with renal impairment who were also taking thiazide diuretics.

Clinical evidence, mechanism, importance and management

Most patients tolerate allopurinol very well, but life-threatening hypersensitivity reactions (e.g. rash, vasculitis, hepatitis, eosinophilia, progressive renal impairment) develop very occasionally with doses of 200 to 400 mg of allopurinol daily. A report of six such hypersensitivity reactions found that all of the reported cases were associated with pre-existing renal impairment, and in half of these, the patients were also taking thiazide diuretics. Another report describes two patients who developed a hypersensitivity vasculitis while taking allopurinol and hydrochlorothiazide. The excretion of oxipurinol (the major metabolite of allopurinol) is reduced in renal impairment, but studies indicate that in healthy subjects with normal renal function thiazide diuretics, such as hydrochlorothiazide, do not appear to affect either the plasma levels of oxipurinol or its excretion. However, other studies have shown that the effects of allopurinol on pyrimidine metabolism are enhanced by the use of thiazides (i.e. they potentially increase hyperuricaemia, which may lead to renal damage). Some caution is therefore appropriate if both drugs are used, particularly if renal function is impaired, but more study is needed to confirm this possible interaction.

Allopurinol + Uricosuric drugs

Probencid and benz bromarone increase the renal excretion of oxipurinol, the active metabolite of allopurinol, but this probably does not alter clinical efficacy. Theoretically, the use of uricosuric drugs with allopurinol could lead to uric acid precipitation in the kidneys and therefore maintenance of a high urine output is recommended when allopurinol is given by injection. Probencid markedly increases the serum levels of allopurinol riboside, which may be advantageous in some circumstances.

Clinical evidence, mechanism, importance and management

(a) Allopurinol

Probencid appears to increase the renal excretion of the active metabolite of allopurinol, oxipurinol, while allopurinol is thought to inhibit the metabolism of probencid. Allopurinol can increase the half-life and raise the serum levels of probencid by about 50% and 20%, respectively. In another study, benzbromarone lowered the AUC of oxipurinol by about 40%, but did not affect allopurinol levels. It has been suggested that the use of allopurinol and probencid might lead to an increase in the excretion of uric acid, which could result in the precipitation of uric acid in the kidneys. Conversely, increased renal excretion of oxipurinol might decrease the efficacy of allopurinol. However, the clinical importance of these mutual interactions seems to be minimal. No problems were reported in two studies in patients given 100 to 600 mg of allopurinol and 500 mg to 2.5 g of probencid daily for between 8 and 16 weeks. Similarly, combined use of allopurinol and benzbromarone was more effective in lowering serum uric acid than allopurinol alone. Nevertheless, the UK manufacturer recommends that the significance of any reduction in efficacy, which may occur when uricosuric drugs are given with allopurinol, should be assessed in each case. For allopurinol injection, the US manufacturer recommends that to help prevent renal precipitation of urates in patients receiving concurrent uricosuric drugs, a fluid intake sufficient to give a urinary output of at least 2 litres daily, and the maintenance of neutral or slightly alkaline urine, are desirable.

(b) Allopurinol riboside

A study in 3 healthy subjects found that probencid halved the clearance, increased the peak plasma levels and AUC, and extended the half life of allopurinol riboside. In some circumstances such an interaction may be advantageous as there is some evidence that the cure rate of American trypanosomiasis (Chagas’ disease) and cutaneous leishmaniasis is better when the two drugs are used together.

Alprostadil + Miscellaneous

Some manufacturers advise that intracavernosal alprostadil and other drugs used for erectile dysfunction should not be used concurrently.

Clinical evidence, mechanism, importance and management

There appear to be no published reports of adverse interactions between intracavernosal alprostadil (prostaglandin E1) and other drugs used for erectile dysfunction, but some manufacturers say that smooth muscle relaxants such as papaverine and other drugs used to induce erections such as alpha-blocking drugs (e.g. intracavernosal phentolamine) should not be used concurrently because of the risks of priapism (painful prolonged abnormal erection).

Aluminium hydroxide + Ascorbic acid (Vitamin C) or Citrates

Patients with renal failure, given aluminium and oral citrate, can develop a potentially fatal encephalopathy due to a very marked rise in blood aluminium levels. There is evidence that aluminium and vitamin C may interact similarly. Some also suggest that...
those with normal renal function should not take aluminium antacids within 2 to 3 hours of foods and drinks that contain citrates. It is worth noting that formulations of a wide range of drugs (including many non-prescription preparations) contain citrates as the effervescent or dispersing agent.

**Clinical evidence**

(a) Ascorbic acid

A study in 13 healthy subjects given aluminium hydroxide 900 mg three times daily found that ascorbic acid (vitamin C) 2 g daily increased the urinary excretion of aluminium threefold. Ascorbic acid significantly increases the concentration of aluminium in the liver, brain, and bones of rats given aluminium hydroxide.2

(b) Citrates

Four patients with advanced chronic renal impairment taking aluminium hydroxide and citrate (Shohl’s) solution died due to hyperaluminaemia.3 Comparison of these 4 patients with another 34 renal patients revealed that they had taken more aluminium hydroxide, more citrate, and were older. In the group as a whole, increased serum aluminium levels were correlated with increased citrate intake.4 Five healthy subjects were then given aluminium hydroxide with or without citrate solution: aluminium levels were 11 micrograms/L at baseline, rising to 44 micrograms/L when aluminium hydroxide was given, and rising to 98 micrograms/L when citrate was added. Aluminium clearance also dramatically increased in the presence of citrate.4 Another report describes this interaction in 2 patients with renal impairment, and in a possible further 6 patients, all of whom died.5 In a further single-dose study in 6 patients with end-stage renal disease, sodium citrate/citric acid 30 mL markedly increased the AUC of aluminium, from a 30-mL dose of aluminium hydroxide gel, by 4.6-fold.6 A number of other studies in healthy subjects have confirmed that citrate markedly increases aluminium absorption, see mechanism, below.

A tenfold rise in serum aluminium levels that occurred in a haemodialysis patient given effervescent co-codamol, was attributed to the presence of sodium citrate in the formulation, which is used to produce the effervesence.7

**Mechanism**

Studies in healthy subjects clearly demonstrate that citrate markedly increases the absorption of aluminium from the gut.4,8,9 The absorption is increased threefold if taken with lemon juice,10 eight to tenfold if taken with orange juice,11,12 and five to 50-fold if taken with citrate.4,8,9,11 but the reason is not understood. It could be that a highly soluble aluminium citrate complex is formed.5,8

**Importance and management**

(a) Patients with renal impairment

The interaction between aluminium and citrates in patients with renal impairment is established and clinically important: it is potentially fatal. Concurrent use should be strictly avoided. The authors of one report emphasise the risks associated with any of the commonly used citrates (sodium, calcium or potassium citrates, citric acid, Shohl’s solution (citric acid/sodium citrate), etc).8 Remember too that some effervescent and dispersible tablets (including many proprietary non-prescription analgesics, indigestion and hangover remedies such as Alka-Seltzer) contain citric acid or citrates,7,12 and they may also occur in soft drinks.11 Haemodialysis patients should be strongly warned about these. The interaction between aluminium and ascorbic acid is not yet well established, but the information available so far suggests that this combination should also be avoided. It is not clear whether orange juice is also unsafe but the available evidence suggests that concurrent administration is probably best avoided.

(b) Patients with normal renal function

The importance of the interaction between aluminium and citrates in subjects with normal renal function is by no means clear, because it is still not known whether increased aluminium absorption results in aluminium accumulation over the long term, in those with normal renal function.12

However, some authors have recommended that food or drinks containing citric acid (citrus fruits and fruit juices) should not be taken at the same time as aluminium-containing medicines, but that their ingestion should be separated by 2 to 3 hours.12

**Aprepitant + CYP2C9 substrates**

Aprepitant slightly reduces the plasma levels of ‘warfarin’, (p.385) and ‘tolbutamide’ (p.515), because it is an inducer of the cytochrome P450 isoenzyme CYP2C9. The manufacturers therefore recommend caution when aprepitant is given with other drugs that are known to be metabolised by CYP2C9, because of the possibility that their plasma levels may be reduced.1,2 They specifically mention phenytoin. They also note that, because phenytoin is a ‘CYP3A4 inducer’, (below), it is predicted to decrease levels of aprepitant and might reduce its efficacy.1,2 Consequently, the UK manufacturer advises avoiding the concurrent use of phenytoin. Other CYP2C9 substrates are listed in ‘Table 1.3’, (p.6).

**Aprepitant + CYP3A4 inducers**

Rifampicin markedly reduced the AUC of aprepitant, and reduced efficacy would be expected. In the UK, the manufacturer recommends that concurrent use of aprepitant and other strong inducers of CYP3A4 should be avoided.

**Clinical evidence, mechanism, importance and management**

The manufacturers note that when a single 375-mg dose of aprepitant was given on day 9 of a 14-day regimen of rifampicin 600 mg daily, the AUC of aprepitant was decreased about 11-fold (91%), and the half-life about threefold (68%).1,2 Rifampicin is an inducer of the cytochrome P450 isoenzyme CYP3A4, by which aprepitant is metabolised. Concurrent use therefore decreases aprepitant levels

Although not assessed, this marked reduction in aprepitant levels could result in reduced efficacy. In the UK, the manufacturer recommends that concurrent use of aprepitant and strong inducers of CYP3A4, such as rifampicin, be avoided. They also name phenytoin (see also ‘Aprepitant + CYP2C9 substrates’, above), carbamazepine, and phenobarbital, and
also recommend that concurrent use of St John’s wort is avoided.1 Other inducers of CYP3A4 are listed in ‘Table 1.4’, (p.6).

**Aprepitant + CYP3A4 inhibitors**

Ketoconazole markedly increases aprepitant levels. The manufacturer recommends caution when aprepitant is used with ketoconazole or other strong inhibitors of CYP3A4.

Clinical evidence, mechanism, importance and management

The manufacturers note that when a single 125-mg dose of aprepitant was given on day 5 of a 10-day course of ketoconazole 400 mg daily, the AUC of aprepitant was increased by about fivefold, and the half-life by about threefold.1,2

Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which aprepitant is metabolised. Concurrent use therefore raises aprepitant levels.

Although the effect of these increases has not been assessed, such marked increases in levels could increase adverse effects. The manufacturers recommend caution when aprepitant is given with ketoconazole and other drugs that are strong inhibitors of CYP3A4. They specifically name ritonavir, clarithromycin,1,2 telithromycin,1itraconazole, nefazodone, troleandomycin, and neflinavir.2 For the effect of diltiazem (a moderate CYP3A4 inhibitor), see ‘Calcium-channel blockers + Aprepitant’, p.861. Other inhibitors of CYP3A4 are listed in ‘Table 1.4’, (p.6).

**Aprepitant + CYP3A4 substrates**

Aprepitant can increase the levels of CYP3A4 substrates in the short-term, then reduce them within 2 weeks. Caution is advised. Note that the manufacturers of aprepitant specifically contraindicate its concurrent use with pimozone, terfenadine, astemizole or cisapride.

Clinical evidence, mechanism, importance and management

In the first few days of use, aprepitant 125/80 mg markedly increased levels of midazolam, a probe drug substrate for the cytochrome P450 isoenzyme CYP3A4. Then, within 2 weeks, a reduction in levels was seen, see ‘Benzodiazepines + Aprepitant’, p.721. This effect was not seen with the 40/25 mg dose regimen. Aprepitant is therefore both a dose-dependent inhibitor and an inducer of CYP3A4.

Because of this, aprepitant is expected to increase drug levels of other CYP3A4 substrates during treatment by up to about threefold, and the manufacturer recommends caution.1,2 They specifically recommend caution with ergot derivatives. Moreover, because of the risk of life-threatening torsade de points arrhythmias with increased levels of pimozone, terfenadine, astemizole or cisapride, they specifically contraindicate the concurrent use of aprepitant with these CYP3A4 substrates. For a list of CYP3A4 substrates, see ‘Table 1.4’, (p.6). Within 2 weeks of aprepitant therapy, a reduced level of CYP3A4 substrates might occur, and caution is also advised during this time.

**Ascorbic acid (Vitamin C) + Salicylates**

Aspirin reduces the absorption of ascorbic acid by about one-third. Serum salicylate levels do not appear to be affected by ascorbic acid.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that the absorption of a single 500-mg dose of aspirin was about one-third lower in those given aspirin 900 mg concurrently, and the urinary excretion was about 50% lower.1 The clinical importance of this is uncertain. It has been suggested that the normal physiological requirement of 30 to 60 mg of aspiric acid daily may need to be increased to 100 to 200 mg daily in the presence of aspirin.2 Another study in 9 healthy subjects found that ascorbic acid 1 g three times daily did not significantly affect serum salicylate levels of choline salicylate.2

**Baclofen + Ibuprofen**

A man developed baclofen toxicity when given ibuprofen.

Clinical evidence, mechanism, importance and management

An isolated report describes a man taking baclofen 20 mg three times a day, who developed baclofen toxicity (confusion, disorientation, bradycardia, blurred vision, hypotension and hypothermia) after taking 8 doses of ibuprofen 600 mg three times daily. It appeared that the toxicity was caused by ibuprofen-induced acute renal impairment leading to baclofen accumulation.1 Renal impairment is a relatively rare adverse effect of ibuprofen. The general importance of this interaction is likely to be very small. There appears to be no information about baclofen and other NSAIDs, and little reason for avoiding concurrent use.

**Baclofen + Tizanidine**

No clinically significant pharmacokinetic interaction appears to occur between baclofen and tizanidine.

Clinical evidence, mechanism, importance and management

In a randomised, three-period study, 15 healthy subjects were given baclofen 10 mg three times daily and tizanidine 4 mg three times daily, together and alone, for 7 consecutive doses. None of the pharmacokinetic parameters of either drug were changed by more than 30%, a figure calculated to indicate the presence of an interaction.1 No changes in the dosages of either drug are therefore likely to be needed if they are taken concurrently.

**Benzbromarone + Aspirin**

Aspirin antagonises the uricosuric effects of benzbromarone.

Clinical evidence, mechanism, importance and management

A single 160-mg dose of benzbromarone increased the percent ratio of urate to creatinine clearance by 371% at its peak in 6 subjects with gout (i.e. benzbromarone increases urate clearance). However, when the same dose of benzbromarone was given with a single 600-mg dose of aspirin, the peak ratio of urate to creatinine clearance with benzbromarone 160 mg was reduced by about 75%1 (i.e. aspirin reduces the effect of benzbromarone on urate clearance). In another study aspirin, in divided doses of 650 mg, up to a total of 5.2 g daily, was given to 29 healthy subjects taking benzbromarone 40 to 80 mg daily. The urate lowering effects of benzbromarone were most affected by aspirin 2.7 g; benzbromarone reduced the urate levels by 60%, but in the presence of aspirin 2.7 g the levels were only reduced by 48%.2 Aspirin and other salicylates antagonise the effects of uricosuric drugs such as benzbromarone, and should generally be
avoided in those with hyperuricaemia or gout (see also ‘Aspirin or other Salicylates + Probencid’, p.138).

Benzbromarone + Chlorothiazide

Benzbromarone lowers uric acid levels in patients taking chlorothiazide, without affecting diuretic activity.1,2

Betaistine + Terfenadine

A single report describes the re-emergence of labyrinthine symptoms when a patient taking betahistine was given terfenadine.

Clinical evidence, mechanism, importance and management

An isolated and very brief report describes a patient whose labyrinthine symptoms (vertigo, dizziness, nausea and vomiting), controlled by betahistine, returned during the concurrent use of terfenadine and other unspecified drugs.1 This interaction had been predicted on theoretical grounds because betahistine, is an analogue of histamine, and would therefore be expected to interact like this with any antihistamine.2 The use of antihistamines should be carefully considered in patients taking betahistine.

Bisphosphonates + Aminoglycosides

Severe hypocalcaemia occurred in two patients taking sodium clodronate when they were given netilmicin or amikacin. Theoretically, additive calcium lowering effects could occur with any bisphosphonate aminoglycoside combination.

Clinical evidence

A 62-year-old woman with multiple myeloma was given sodium clodronate 2.4 g daily for osteolysis and bone pain. After 7 days she developed grand mal seizures, and her serum calcium was found to be 1.72 mmol/L (normal range 2.25 to 2.60 mmol/L). Despite daily calcium infusions her calcium remained low. The authors state that symptomatic hypocalcaemia (normal range 2.25 to 2.60 mmol/L). Despite daily calcium infusions her calcium remained low. The authors state that symptomatic hypocalcaemia is said to be rare.2 It seems therefore that the addition of the aminoglycoside in these two cases precipitated severe clinical hypocalcaemia. The authors of both reports therefore advise care if bisphosphonates are given with aminoglycosides, and recommend close monitoring of calcium and magnesium levels. They also point out that the renal loss of calcium and magnesium can continue for weeks after aminoglycosides are stopped, and that bisphosphonates can also persist in bone for weeks.1,2 This means that the interaction is potentially possible whether the drugs are given concurrently or sequentially.

Bisphosphonates + Aspirin or NSAIDs

The concurrent use of alendronate and naproxen increased the incidence of gastric mucosal damage in a small pharmacological study, and increased the risk of upper gastrointestinal disorders in a case-control study. However, two analyses of placebo-controlled studies found no increased risk of gastrointestinal damage with the combination. There was no increased risk of gastrointestinal adverse effects in NSAID users given risedronate. Indometacin raises tiludronate bioavailability, whereas aspirin and diclofenac do not appear to affect the pharmacokinetics of tiludronate. NSAIDs may exacerbate the renal dysfunction sometimes seen with clodronate.

Clinical evidence, mechanism, importance and management

(a) Alendronate

In a short-term endoscopy study in 26 healthy subjects, gastric mucosal damage developed in 8% of those given alendronate alone, in 12% of those given naproxen alone, and 38% of those given both drugs.1 In a case-control study,2 the risk of having an acid-related upper gastrointestinal disorder with alendronate was increased by the concurrent use of NSAIDs (relative risk 1.7). However, retrospective analysis of data from a very large long-term placebo-controlled study found no evidence that the risk of upper gastrointestinal adverse effects with concurrent use of NSAIDs and alendronate was any greater than with NSAIDs and placebo.3 Note that this finding has been questioned,4 and some of the issues responded to.5 Similarly, in a retrospective analysis of a 12-week placebo-controlled study, in those taking regular NSAIDs (about half of the patients) there was no difference in incidence of upper gastrointestinal adverse events between those given alendronate and those given placebo.

The most commonly used NSAIDs in this study were aspirin, celecoxib, rofecoxib, ibuprofen and naproxen.6 Alendronate is commonly known to be associated with oesophageal adverse effects, and there are strict dosing instructions to minimise this risk.7 It may also cause local irritation of the stomach, although its potential to cause gastric ulcers is not considered established.7,8 The status of this interaction is currently controversial. Some consider that alendronate should not be given to patients receiving NSAIDs,4 while others urge caution in their use together.1,2 However, some consider that there is no evidence that alendronate adds to the known gastrointestinal toxicity of NSAIDs,5 and the manufacturer issues no caution about the concurrent use of NSAIDs.7 Until further evidence is available, it would seem sensible to monitor the concurrent use of alendronate and NSAIDs carefully.

(b) Clodronate

The manufacturer notes that patients receiving NSAIDs in addition to clodronate have developed renal impairment, although a synergistic action has not been established.8 Clodronate alone may cause renal impairment,
and the manufacturers suggest that renal function should be assessed before giving clodronate.\(^8\) This would seem particularly important in those taking NSAIDs.

(c) Risedronate

The manufacturer notes that in phase III osteoporosis studies of risedronate, no clinically relevant interactions were noted, even though aspirin and NSAIDs being used by 33% and 45% of patients, respectively.\(^3\) Similarly, in a retrospective analysis of a 2-year placebo-controlled study, in those using regular NSAIDs (about two-thirds of patients) there was no difference in incidence of upper gastrointestinal adverse events between those given risedronate and those given placebo.\(^9\)

(d) Tiludronate

Single-dose studies in 12 healthy subjects found that diclofenac 25 mg and aspirin 600 mg had no significant effect on the pharmacokinetics of tiludronate. On the other hand, indomethacin 50 mg increased the maximum serum concentration and the AUC of tiludronate about twofold when taken together, but not when they were given 2 hours apart.\(^10\) For this reason the manufacturers advise that indomethacin and tiludronate should be given 2 hours apart.\(^12\)

### Bisphosphonates + Polyvalent cations

The oral absorption of bisphosphonates is reduced by 	extit{Maalox} and by other antacids, calcium-rich foods, calcium supplements, iron preparations, magnesium-containing laxatives or milk.

#### Clinical evidence

(a) Clodronate

In a randomised study in 31 healthy subjects the AUC of clodronate was reduced to 10% of the optimum level when it was taken with breakfast. Delaying administration until 2 hours after breakfast only slightly improved the AUC (34% of optimum). The best AUC was achieved when clodronate was given 2 hours before breakfast, although the AUC one hour before was similar (91% of optimum).\(^1\)

(b) Tiludronate

The maximum serum levels and AUC of tiludronate in 12 healthy subjects were halved when \textit{Maalox} (aluminium/magnesium hydroxide) was taken one hour before tiludronate, but the bioavailability was only slightly affected when \textit{Maalox} was taken 2 hours after the tiludronate.\(^2\)

#### Mechanism

The bisphosphonates can form complexes with a number of polyvalent metallic ions (e.g. Al\(^{3+}\), Ca\(^{2+}\), Fe, Mg\(^{2+}\)), which can impair their absorption.

#### Importance and management

Established and important interactions, although the documentation is limited. Bisphosphonates should be prevented from coming into contact with a range of preparations such as antacids (containing aluminium, bismuth, calcium, magnesium), laxatives (containing magnesium), iron preparations and calcium or other mineral supplements. Food, milk and dairy products in particular, contain calcium, and may also impair absorption.

Recommendations on the timing of administration of bisphosphonates in relation to food and other drugs varies.

- The manufacturers of \textit{alendronate}\(^6\) suggest that, in order to avoid absorption interactions, patients should wait at least 30 minutes after taking alendronate before taking any other drug or food, and that alendronate should be taken with plain water only.
- The manufacturers of \textit{tiludronate}\(^7\) recommend that it is taken with water on an empty stomach (at least two hours before or after meals). In addition, they recommend administration of tiludronate and antacids or calcium compounds should be separated by 2 hours.
- The manufacturers of \textit{clodronate}\(^8\) suggest leaving 1 hour between the administration of food and clodronate.
- The manufacturers of \textit{risedronate}\(^9\) recommend it is taken with water at least 30 minutes before the first food or drink of the day. Alternatively, they say it should be given at least 2 hours from any food or drink at any other time of the day, at least 30 minutes before going to bed.
- Similarly, the manufacturers of \textit{etidronate}\(^10\) recommend it is given on an empty stomach at least 2 hours from any food or medicines containing polyvalent cations (as listed above).

Bitter orange + Cytochrome P450 isoenzyme substrates

Bitter orange does not alter the metabolism of caffeine, chlorozoxazone, debrisoquine, or midazolam, and is therefore unlikely to interact with drugs that are metabolised by CYP1A2, CYP2E1, CYP2D6 or CYP3A4.

#### Clinical evidence, mechanism, importance and management

Bitter orange (\textit{Citrus aurantium}) 350 mg, standardised to 4% synephrine, was given to 12 healthy subjects twice daily for 28 days. Single doses of caffeine 100 mg, chlorozoxazone 250 mg, debrisoquine 5 mg, and midazolam 8 mg were given before and at the end of the treatment with bitter orange. The metabolism of these drugs was not affected by the concurrent use of bitter orange, which suggests that bitter orange is unlikely to affect the metabolism of other drugs that are substrates of the cytochrome P450 isoenzymes CYP1A2, CYP2E1, CYP2D6 or CYP3A4.\(^1\) For a list of drugs that are substrates of these enzymes, see ‘Table 1.2’, (p.4), ‘Table 1.3’, (p.6), and ‘Table 1.4’, (p.6).

Black cohosh + Cytochrome P450 isoenzyme substrates

Black cohosh does not affect the metabolism of caffeine, chlorozoxazone and debrisoquine, and is therefore unlikely to affect the metabolism of drugs that are substrates for CYP1A2, CYP2E1 and CYP2D6.
Clinical evidence, mechanism, importance and management

In a study in 12 non-smoking healthy subjects given black cohosh root extract 1090 mg twice daily for 28 days before receiving single doses of caffeine, chlorzoxazone and debrisoquine, no clinically significant changes in the metabolism of these drugs were noted. It is therefore unlikely that other drugs metabolised by CYP1A2, CYP2E1, or CYP2D6 (see ‘Table 1.2’, (p.4), and ‘Table 1.3’, (p.6)) will be affected by the use of black cohosh (cimicifuga). For the lack of effect of black cohosh on midazolam, see ‘benzodiazepines’, (p.724).

Charcoal, activated + Miscellaneous

Small doses of activated charcoal appear to have little effect on the absorption of ciprofloxacin and oral contraceptives (administration separated), and only modestly reduces nizatidine absorption. Case reports describe the lack of efficacy of mitobronitol and reduced serum phenobarbital levels in the presence of small doses of activated charcoal.

Clinical evidence, mechanism, importance and management

The use of activated charcoal, in a usual dose of 50 g, to reduce the absorption of drugs and poisons after acute overdose is well established, as is repeated doses of activated charcoal to enhance the elimination of some drugs taken in overdose after they have been absorbed (e.g. carbamazepine, theophylline). Studies and references supporting these therapeutic uses of activated charcoal are not reviewed here.

Activated charcoal is also included in various remedies used for gastrointestinal disorders such as flatulence or diarrhoea. Doses in these instances are very much lower (1 to 2 g daily) than those used in the treatment of poisoning, and there seems to be little reported about the effects of these doses on the absorption of other drugs. In one single-dose study in healthy subjects, nizatidine absorption was reduced by about 30% when it was taken one hour before activated charcoal 2 g.1 In another single-dose study in 6 subjects, taking activated charcoal 1 g soon after ciprofloxacin 500 mg, had little effect on the pharmacokinetics of ciprofloxacin 500 mg (AUC reduced by 10%).2

In one case report, an antiemetic complementary remedy containing activated charcoal was thought to be the cause of a lack of effect of mitobronitol 125 mg used to treat primary thrombocythaemia in one patient.3 In another case report,4 activated charcoal 2 g three times daily was given with phenobarbital and enteral nutrition via a gastric fistula tube. The charcoal appeared to reduce the absorption of phenobarbital (serum level 4.3 mg/L compared with a previous level of 24.8 mg/L). Giving the activated charcoal at least one hour apart from the phenobarbital resulted in an increase in serum levels to about 16 to 18 mg/L.

Activated charcoal 5 g four times daily was taken for 3 days, mid-cycle, with the first daily dose taken 3 hours after the morning dose of a combined oral contraceptive (ethinylestradiol/norethisterone or ethinylestradiol/gestodene), had no effect on the pharmacokinetics of the combined oral contraceptive.5,6

Chlorzoxazone + Disulfiram

Disulfiram markedly increases the plasma levels of chlorzoxazone.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects to identify the activity of cytochrome P450 isoenzyme CYP2E1 found that a single 500-mg dose of disulfiram markedly increased the metabolism of a single 750-mg dose of chlorzoxazone (clearance reduced by 85%, half-life increased from 0.92 to 5.1 hours, and a two-fold increase in peak plasma levels).1

No increased adverse effects were seen while using these single doses, but an increase in toxicity would be expected (sedation, headache, nausea) with multiple doses. Be alert for the need to reduce the chlorzoxazone dosage if disulfiram is given concurrently.1

Chlorzoxazone + Isoniazid

The adverse effects of chlorzoxazone may be increased in some patients (particularly slow-acetylators of isoniazid) if they also take isoniazid.

Clinical evidence

Five out of 10 healthy slow acetylators of isoniazid experienced an increase in the adverse effects of a 750-mg dose of chlorzoxazone (sedation, headache, nausea) after taking isoniazid 300 mg daily for 7 days. These symptoms disappeared within 2 days of withdrawing the isoniazid.1 Pharmacokinetic analysis showed that the clearance of chlorzoxazone was reduced by 56% when given on the last day of isoniazid administration, then increased by 56% when given 2 days after stopping isoniazid.1 Similar findings were reported in another study in slow acetylators of isoniazid: chlorzoxazone clearance was reduced by 78% when subjects had taken isoniazid 300 mg daily for 14 days, at which point the isoniazid was stopped. Two days later chlorzoxazone clearance was increased by 58%, and it had returned to normal 2 weeks later.2 Rapid acetylators of isoniazid also had a 60% reduction in chlorzoxazone clearance on the last day of isoniazid administration, but did not have any increase 2 days later.2

Mechanism

Isoniazid appears to cause a dual interaction. During administration, it inhibits the activity of cytochrome P450 isoenzyme CYP2E1, the enzyme involved in the metabolism of chlorzoxazone. Shortly after stopping isoniazid, the metabolism of chlorzoxazone is increased, possibly because of induction of CYP2E1, although this effect was only evident in the slow acetylators.1,2

Importance and management

The increase in chlorzoxazone levels is established, and occurs in both slow and fast acetylators of isoniazid, although the increase in levels is slightly greater in slow acetylators. In practical terms this means that it may be necessary to reduce the chlorzoxazone dosage in some patients if they take isoniazid. Monitor concurrent use carefully. The rebound increase in chlorzoxazone clearance in slow acetylators on stopping isoniazid was short-lived and is probably of little clinical importance.1

CNS depressants + CNS depressants

The concurrent use of two or more drugs that depress the CNS may be expected to result in increased CNS depression. This may have undesirable and even life-threatening consequences.
Clinical evidence, mechanism, importance and management

Many drugs have the propensity to cause depression of the central nervous system, resulting in drowsiness, sedation, respiratory depression and at the extreme, death. If more than one CNS depressant is taken, their effects may be additive. It is not uncommon for patients, particularly the elderly, to be taking numerous drugs (and possibly alcohol as well). Such patients are therefore at risk of cumulative CNS depression ranging from mild drowsiness through to a befuddled stupor, which can make the performance of the simplest everyday task more difficult or even impossible. The importance of this will depend on the context: it may considerably increase the risk of accident in the kitchen, at work, in a busy street, driving a car, or handling other potentially dangerous machinery where alertness is at a premium. It has been estimated that as many as 600 traffic accident fatalities each year in the UK can be attributed to the sedative effects of psychoactive drugs.1 In a Spanish study of fatal road traffic accidents, blood samples were analysed from 9.7% of drivers killed in road accidents over a 10-year period. Of these drivers, medicines were detected in 4.7% (269 cases), and of these benzodiazepines were the most common (73%). Other drugs present in 6% to 12% of cases included antidepressants, analgesics, antiepileptics, barbiturates and antihistamines. Of the benzodiazepine cases, almost three quarters had another substance detected, mainly illicit drugs (cocaïne, opiates, or cannabis) or alcohol. Only 7.7% had taken benzodiazepines or another medicinal drug alone.2 Alcohol almost certainly makes things worse.

An example of the lethal effects of combining an antihistamine, a benzodiazepine and alcohol is briefly mentioned in the monograph ‘Alcohol + Antihistamines’, p.47. A less spectacular but socially distressing example is that of a woman accused of shoplifting while in a confused state and later alopecia) 16 days after starting to take Actired, a Beechams Powder and Dolobid (containing tripolidrine, salicylamide and diflunisal, respectively).3

Few if any well-controlled studies have investigated the cumulative or additive detrimental effects of CNS depressants (except with alcohol), but the following is a list of some of the groups of drugs that to a greater or lesser extent possess CNS depressant activity and which might be expected to interact in this way: alcohol, opioid analgesics, anticonvulsants, antidepressants, antihistamines, antiepileptics, anxiolytics and hypnotics. Some of the interactions of alcohol with these drugs are dealt with in individual monographs.

Colchicine + Macrolides

Several case reports describe acute life-threatening colchicine toxicity caused by the addition of erythromycin or clarithromycin, and one retrospective study found that 9 of 88 patients who had received the combination of colchicine and clarithromycin died.

Clinical evidence

A 29-year-old woman with familial Mediterranean fever and amyloidosis, who was taking long-term colchicine 1 mg daily, developed acute and life-threatening colchicine toxicity (fever, diarrhoea, myalgia, pancytopenia and later alopecia) 16 days after starting to take erythromycin 2 g daily. This patient had both cholestasis and renal impairment, factors that would be expected to reduce colchicine clearance and therefore predispose her to colchicine toxicity.1 Colchicine levels rose from below 12.6 nanograms/mL to 22 nanograms/mL after the addition of erythromycin.1 In another patient, who had been taking colchicine 1.5 mg daily for 6 years, similar signs of acute colchicine toxicity developed 4 days after starting a 7-day course of clarithromycin 1 g daily, amoxicillin and omeprazole for H. pylori associated gastritis. The colchicine dose was reduced to 500 micrograms daily and then, after recovery, gradually increased slowly back to 1.5 mg daily.2

In another case, a 67-year-old man on CAPD taking colchicine 500 micrograms twice daily was admitted with symptoms of colchicine toxicity (including pancytopenia) 4 days after starting a course of clarithromycin 500 mg twice daily for an upper respiratory tract infection. All drugs were stopped and supportive treatment given, but he later died from multi-organ failure.3

These case reports led to a retrospective study of patients who had received the combination of colchicine and clarithromycin as inpatients. Of 116 patients given the drugs, 88 had received them concurrently and 28 received them sequentially. Nine of the concurrent group died (compared with only 1 of the sequential group), and of the nine, five had pancytopenia, and six had renal impairment. In the 88 patients receiving the drugs concurrently, longer overlapping therapy increased the relative risk of death 2.16-fold, the presence of renal impairment increased the risk 9.1-fold, and the development of pancytopenia increased the risk 23.4-fold.4

Two further cases of fatal agranulocytosis, presumed to result from use of colchicine with clarithromycin, have been reported,5 and 2 other cases describe colchicine toxicity during clarithromycin use in patients with renal impairment.6

Mechanism

Erythromycin and clarithromycin may inhibit the hepatic metabolism of colchicine via the cytochrome P450 isoenzyme CYP3A4, and/or might increase its bioavailability via effects on P-glycoprotein.2,4 These effects would be more marked in patients with renal impairment.

Importance and management

Information on this interaction is limited, but it appears that macrolide antibiotics can provoke acute colchicine toxicity, at the very least in predisposed individuals. If any patient is given colchicine and a macrolide (except probably azithromycin, which is not a notable CYP3A4 inhibitor), be aware of the potential for toxicity, especially in patients with pre-existing renal impairment.

Contrast media + Phenothiazines

Two isolated case reports describe epileptiform reactions in two patients when metrizamide was used for lumbar myelography in the presence of chlorpromazine or dixyrazine. No such cases appear to have been reported for intrathecal iohexol: nevertheless, the manufacturer of iohexol advises the avoidance of phenothiazines and other drugs that lower seizure threshold when iohexol is used intrathecally.

Clinical evidence

A patient receiving long-term treatment with chlorpromazine 75 mg daily had a grand mal seizure three-and-a-half hours after being given metrizamide (16 mL of 170 mg iodine per mL by the lumbar route). He had another seizure 5 hours later.1 One out of 34 other patients demonstrated epileptogenic activity on an EEG when given metrizamide for lumbar myelography. The patient was taking dixyrazine 10 mg three times daily.2 However, a clinical study in 26 patients given levomepromazine for the relief of lumbo-sciatic pain found no evidence of an increased risk of seizures after receiving metrizamide for myelography.3

Mechanism

Intrathecal metrizamide or iohexol alone are rarely associated with seizures. Theoretically, this risk might be increased in patients taking other drugs that lower the seizure threshold, such as the phenothiazines.
Importance and management

The case report with intrathecal metrizamide led to the advice to stop phenothiazines prior to giving this contrast agent. Intrathecal iohexol has also rarely been associated with seizures, and consequently, the US manufacturer recommends that drugs that lower seizure threshold, especially phenothiazines are not recommended for use with iohexol by this route. \(^2\) They should be stopped 48 hours before the procedure and not restarted until at least 24 hours after the procedure. This advice specifically includes phenothiazines used for their antiemetic properties. Although this risk is theoretical this would seem to be a prudent precaution. This advice does not apply to other routes of iohexol administration.\(^2\)

Contrast media; iopanoic acid + Colestyramine

A single report describes poor radiographic visualisation of the gall bladder in a man due to an interaction between iopanoic acid and colestyramine within the gut.

Clinical evidence, mechanism, importance and management

The cholecystogram of a man with post-gastrectomy syndrome taking colestyramine who was given oral iopanoic acid as an x-ray contrast medium, suggested that he had an abnormal and apparently collapsed gall bladder. A week after stopping the colestyramine a repeat cholecystogram gave excellent visualisation of a gall bladder of normal appearance.\(^1\) The same effects have been observed experimentally in dogs.\(^3\) The reason seems to be that the colestyramine binds with the iopanoic acid in the gut; so that little is absorbed and little is available for secretion in the bile, hence the poor visualisation of the gall bladder.

On the basis of reports about other drugs that similarly bind to colestyramine, it seems probable that this interaction could be avoided if the administration of the iopanoic acid and the colestyramine were to be separated as much as possible (note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine). Whether other oral acidic x-ray contrast media bind in a similar way to colestyramine is uncertain, but this possibility should be considered.

Cyclobenzaprine + Fluoxetine and Droperidol

A patient taking cyclobenzaprine and fluoxetine developed torsade de pointes arrhythmia and ventricular fibrillation when droperidol was added.

Clinical evidence, mechanism, importance and management

A 59-year-old woman receiving long-term treatment with fluoxetine and cyclobenzaprine, who had a prolonged baseline QTc interval of 497 milliseconds, was given droperidol before surgery on her Achilles tendon. During the surgery she developed torsade de pointes arrhythmia, which progressed to ventricular fibrillation. On the first postoperative day after the cyclobenzaprine had been withdrawn, her QTc interval had decreased towards normal (440 milliseconds).\(^1\)

A likely explanation is that her cyclobenzaprine serum levels were already raised by fluoxetine (a known inhibitor of cytochrome P450 isoenzyme CYP2D6, an enzyme involved in the metabolism of cyclobenzaprine) and as a result her QTc interval was prolonged. Cyclobenzaprine is structurally like the tricyclic antidepressants and shares their ability to cause arrhythmias, particularly in high doses. Therefore the addition of the droperidol, also known to prolong the QT interval, simply further extended the QTc interval and precipitated the torsade de pointes. This case not only illustrates the existence of an interaction between cy-clobenzaprine and fluoxetine, but also the life-threatening risks of taking multiple ‘drugs that can further prolong the QT interval’, (p.257).

Dantrolene + Metoclopramide

Metoclopramide increases the bioavailability of dantrolene.

Clinical evidence, mechanism, importance and management

A study in 7 paraplegics and 6 quadriplegics with spinal cord injuries found that a single 10-mg intravenous dose of metoclopramide increased the bioavailability of a single 100-mg oral dose of dantrolene by 57%. The reasons are not known, although it was suggested that absorption may have been affected. The clinical relevance of this interaction is uncertain but the authors of the study suggest that patients should be well monitored if metoclopramide is added or withdrawn from patients who are taking dantrolene.\(^1\)

Dextromethorphan + Amiodarone

Amiodarone can reduce the clearance of dextromethorphan.

Clinical evidence

A study in 8 patients with cardiac arrhythmias found that amiodarone (1 g daily for 10 days followed by 200 to 400 mg daily for a mean duration of 76 days) changed their excretion of dextromethorphan 40 mg and its metabolite. The amount of unchanged dextromethorphan in the urine rose by nearly 150%, whereas the amount of its metabolite (dextrophan) fell by about 25%.\(^6\)

Mechanism

In vitro studies using liver microsomes have shown that amiodarone inhibits the metabolism (O-demethylation) of dextromethorphan by inhibiting the cytochrome P450 isozyme CYP2D6 within the liver.\(^1\) Thus the dextromethorphan is cleared more slowly.

Importance and management

Information seems to be limited to this study. The clinical implications are that amiodarone may interfere with the results of phenotyping if dextromethorphan is used to determine CYP2D6 activity, and that dextromethorphan toxicity (excitation, confusion) may possibly develop in patients taking amiodarone. Be alert for any signs of toxicity if both are used. As yet, too little is known about this interaction to say by how much the dextromethorphan dosage should be reduced. Remember that dextromethorphan occurs in a considerable number of proprietary cough preparations.

Dextromethorphan + Bupropion

Bupropion may reduce the metabolism of dextromethorphan in some patients.

Clinical evidence, mechanism, importance and management

A study in 21 subjects who were quitting smoking and were CYP2D6 extensive metabolisers, found that 6 of 13 subjects who received bupropion 150 mg once daily for 3 days and then twice daily for 14 days had metabolic ratios of dextromethorphan 30 mg similar to those seen in poor metabolisers: the metabolism of dextromethorphan to dextrophan was substantially reduced. No such change was seen in the 8 subjects who received placebo. It has been suggested that care should be taken when ini-
tiating or discontinuing bupropion in patients taking dextromethorphan, due to the possibility of raised dextromethorphan levels. Patients should be warned that they may experience increased adverse effects to dextromethorphan and advised that this is found in non-prescription preparations such as cough suppressants.

**Dextromethorphan + Echinacea**

Echinacea does not appear to have a clinically relevant effect on the pharmacokinetics of dextromethorphan.

**Clinical evidence, mechanism, importance and management**

In a study, 12 healthy subjects were given *Echinacea purpurea* root 400 mg four times daily for 8 days with a single 30-mg dose of dextromethorphan on day 6. In the 11 subjects who were of the cytochrome P450 isoenzyme CYP2D6 extensive metaboliser phenotype (see ‘Genetic factors in drug metabolism’, (p.4)), there were no changes in the pharmacokinetics of dextromethorphan. In contrast, the one subject who was a poor metaboliser had a 42% increase in the AUC of dextromethorphan and a 31% increase in its half-life. In another study, in 12 healthy subjects given *Echinacea purpurea* 800 mg twice daily for 28 days, there was no change in the debrisoquine urinary ratio after a single dose of debrisoquine 5 mg, suggesting that *Echinacea purpurea* does not alter the activity of the cytochrome P450 isoenzyme CYP2D6.

The findings of these studies suggest that echinacea is unlikely to have a clinically relevant effect on CYP2D6 substrates (see Table 1.3, (p.6), for a list).

**Dextromethorphan + Ginkgo biloba**

Ginkgo biloba does not affect the metabolism of dextromethorphan.

**Clinical evidence, mechanism, importance and management**

Ginkgo biloba leaf extract 120 mg twice daily for 16 days was given to 12 healthy subjects with a single 30-mg dose of dextromethorphan on day 14. The *Ginkgo biloba* preparation (Ginkgold) contained ginkgo flavonol glycosides 24% and terpene lactones 6%. There was no change in the metabolism of dextromethorphan when it was taken after the *Ginkgo biloba*. Dextromethorphan is a probe substrate for the cytochrome P450 isoenzyme CYP2D6, and the findings suggest that *Ginkgo biloba* is unlikely to interact with other drugs that are substrates of CYP2D6, see ‘Table 1.3’, (p.6).

**Clinical evidence**

In a study in 6 extensive CYP2D6 metabolisers given dextromethorphan 60 mg twice daily, steady-state plasma dextromethorphan levels averaged only 12 nanograms/mL. However, after being given quinidine 75 mg twice daily for a week, then a single 60-mg dose of dextromethorphan, their plasma dextromethorphan levels were over threefold higher, at 38 nanograms/mL. Some of the patients given the combination had an increase in dextromethorphan adverse effects (nervousness, tremors, restlessness, dizziness, shortness of breath, confusion etc.). Similarly, other pharmacokinetic studies have found increases in dextromethorphan levels in extensive CYP2D6 metabolisers, but not in poor CYP2D6 metabolisers. In a dose-ranging study, quinidine 25 to 30 mg daily produced maximal increases in dextromethorphan levels, with higher doses producing no further increases, and lower doses producing smaller increases. In one experimental study of citric acid-induced cough, quinidine increased the cough-suppressant effect of dextromethorphan.

**Mechanism**

Quinidine inhibits the oxidative metabolism of dextromethorphan by the cytochrome P450 isoenzyme CYP2D6 to dextromethorphan, effectively making extensive metabolisers of CYP2D6 into the poor metaboliser phenotype, see ‘Genetic factors in drug metabolism’, (p.4), for further discussion of metaboliser phenotypes.

**Importance and management**

An established interaction. Extensive metabolisers of CYP2D6 are likely to become more sensitive to dextromethorphan if they are taking quinidine.

Low-dose quinidine has been combined with dextromethorphan to sustain therapeutic levels of dextromethorphan and thereby try and improve its efficacy in various neurological disorders (dextromethorphan is a N-methyl-D-aspartate antagonist, which means it can affect pain transmission). A fixed dose combination is being investigated.

**Dextromethorphan + Saw palmetto**

Saw palmetto does not alter the metabolism of dextromethorphan.

**Clinical evidence, mechanism, importance and management**

Saw palmetto 320 mg daily, given to 12 subjects for 16 days, did not affect the metabolism of a single 30-mg dose of dextromethorphan given on day 14. No change was seen in the dextromethorphan metabolic ratio. This suggests that saw palmetto is unlikely to alter the pharmacokinetics of drugs that are metabolised by the cytochrome P450 isoenzyme CYP2D6, of which dextromethorphan is a probe substrate. This finding was confirmed by a further study in 12 healthy subjects who were given saw palmetto and debrisoquine, another substrate of CYP2D6.

For a list of drugs that are substrates of this enzyme, see ‘Table 1.3’.

Dextromethorphan + St John’s wort (Hypericum perforatum)

St John’s wort does not affect the pharmacokinetics of dextromethorphan.

Clinical evidence, mechanism, importance and management

St John’s wort (LI160, Lichtwer Pharma, 0.12 to 0.3% hypericin) 300 mg three times daily was given to 12 healthy subjects for 16 days with a single 30-mg dose of dextromethorphan on day 14. There was no consistent change in the urinary dextromethorphan to dextrorphan metabolic ratio: 6 subjects had an increase in the production of dextromethorphan while the other 6 subjects had a reduction in dextromethorphan production. This finding was within the normal inter-patient variation in dextromethorphan metabolism, and suggests that St John’s wort does not significantly affect the cytochrome P450 isoenzyme CYP2D6. Similar findings were reported in another study of 16 healthy subjects given a single 25-mg dose of dextromethorphan on the last day of a 14-day course of St John’s wort (Jarstein; 900 micrograms of hypericin) 300 mg three times daily.2

St John’s wort would not therefore be expected to alter the pharmacokinetics of other substrates of CYP2D6, for a list see ‘Table 1.3’, (p.6).

Disulfiram + Cannabis

An isolated case report describes a hypomanic-like reaction when a man taking disulfiram used cannabis.

Clinical evidence, mechanism, importance and management

A man with a 10-year history of drug abuse (alcohol, amphetamines, cocaine, cannabis) taking disulfiram 250 mg daily, experienced a hypomanic-like reaction (euphoria, hyperactivity, insomnia, irritability) on two occasions, associated with the concurrent use of cannabis. The patient said that he felt as though he had been taking amphetamine.1 The reason for this reaction is not understood. In a randomised study in alcohol dependent subjects who had previously used cannabis, no unusual interaction effects were found in a group of 11 subjects receiving disulfiram and smoking cannabis twice weekly for 4 weeks.2 Therefore the interaction described in the case report would not appear to be of general significance.

Dutasteride + Miscellaneous

Preliminary evidence suggests that diltiazem and verapamil, inhibitors of cytochrome P450 3A4 isoenzyme CYP3A4, cause moderate increases in dutasteride levels but this is probably not clinically significant. In the UK, the manufacturer says that dutasteride dosage adjustments may be needed with potent inhibitors of CYP3A4 such as indinavir, ritonavir, ketoconazole, nefazodone and ritonavir. No clinically significant interaction appears to occur between dutasteride and amloidipine, digoxin, or warfarin. There is no interaction when dutasteride is given one hour before colestyramine.

Clinical evidence, mechanism, importance and management

(a) Colestyrnmine

In a study in 12 healthy subjects the absorption of dutasteride 5 mg was not affected when it was given one hour before a single 12-g dose of colestyramine.1,2 No precautions seem necessary if this dosing interval is observed.

(b) CYP3A4 inhibitors and substrates

When dutasteride was given with amloidipine (4 subjects), diltiazem (5 subjects) or verapamil (6 subjects) during dose-ranging studies, amloidipine did not significantly affect the clearance of dutasteride but diltiazem and verapamil were associated with a decrease of 44% and 37%, respectively.3 This was thought to be due to the inhibitory effect of cipamaline and verapamil on P-glycoprotein and the cytochrome P450 isoenzyme CYP3A4. Dutasteride has a wide safety margin, so these changes were not thought to be clinically significant.4 However, in the UK, the manufacturers warn that potent CYP3A4 inhibitors (they name indinavir, ritonavir, ketoconazole, nefazodone and ritonavir) may cause a clinically significant increase in dutasteride levels, and so they suggest reducing the dosing frequency if increased dutasteride adverse effects occur in the presence of these drugs.1

(c) Diginox

A placebo-controlled study in 20 healthy subjects taking digoxin found that its pharmacokinetics were unchanged by dutasteride 500 micrograms daily for 3 weeks.2 No digoxin dose adjustment would be expected to be necessary on concurrent use.

(d) Warfarin

Dutasteride 500 micrograms daily, given to 23 healthy subjects with warfarin for 35 days had no effect on the pharmacokinetics of S- or R-warfarin, and the prothrombin time was unaffected by the presence of dutasteride.2 No warfarin dose adjustment would be expected to be necessary on concurrent use.

Enteric-coated, delayed-release preparations + Drugs that affect gastric pH

Theoretically, enteric-coated, delayed-release preparations may possibly dissolve prematurely if they are taken at the same time as antacids. This has been seen with some preparations, but not others. Release characteristics are likely to depend on the specific coating, and the manufacturers advice should be followed.

Clinical evidence

(a) Antacid

A placebo-controlled, crossover study in 21 healthy subjects, found that when extended-release oxybutynin 10 mg (Ditropan XL) was given at the same time as Maalox 20 mL (aluminium/magnesium hydroxide and simethicone) there was no change in the pharmacokinetics of oxybutynin or its metabolite.1

In an identical study in 23 healthy subjects, Maalox increased the maximum plasma level of a single 4-mg dose of extended-release tolterodine (Detrol LA) by 50%, but did not change any other pharmacokinetic parameter (time to maximum level, elimination half-life, AUC).1

(b) Omeprazoloe

In a placebo-controlled, crossover study in 39 healthy subjects, pre-treatment with omeprazole 20 mg daily for 4 days did not alter the pharmacokinetics of extended-release oxybutynin 10 mg [Ditropan XL]. The metabolites of oxybutynin were similarly unaffected. Pretreatment with omeprazole increased the maximum plasma level a single 4-mg dose of extended release tolterodine [Detrol LA] by 38%, but did not change any other pharmacokinetic parameter (time to maximum level, elimination half-life, AUC).2

The bioavailability of enteric-coated preparations of aspirin, diclofenac, and ketoprofen are unaffected by omeprazole, see ‘NSAIDs or Aspirin + Proton pump inhibitors’, p.155.
Mechanism
A marked rise in pH caused by antacids might cause premature dissolution of the coating of preparations formulated to prevent release of the contents until they reach the more alkaline conditions within the small intestine. Other types of delayed release preparations that have release characteristics independent of pH, such as those based on the osmotic principle, would not be expected to be affected.

Importance and management
Traditionally, it has been considered that drugs formulated with enteric coatings to resist gastric acid, or formulated as delayed release preparations, should not be given with antacids. Accelerated drug release from a delayed release product (dose dumping) might lead to increased adverse effects and lack of efficacy for the duration of the dose interval. The evidence above for extended-release tolterodine suggest that an antacid did cause a faster release of tolterodine from this product, but whether the 50% increase in maximum level is sufficient to cause an increase in adverse effects is not known. Pre-treatment with omeprazole caused a smaller 38% increase in maximum tolterodine levels. The extended-release oxybutynin product was not affected by antacid or omeprazole, which was unexpected because release from this product is osmotically driven and pH independent.

Release characteristics are likely to depend on the specific coating, and therefore no general advice can be given. The manufacturers advice should be followed.

Ethylene dibromide + Disulfiram

The very high incidence of malignant tumours in rats exposed to both ethylene dibromide and disulfiram is the basis of the recommendation that concurrent exposure to these compounds should be avoided.

Clinical evidence, mechanism, importance and management
Research conducted to establish the occupational safety of exposure to ethylene dibromide found that the incidence of malignant tumours in rats exposed to 20 ppm ethylene dibromide (7 hours daily, 5 days weekly), while receiving a diet containing 0.05% disulfiram by weight, is very high indeed.1,2 The reasons are not understood. In addition to the precautions needed to protect workers from the toxic effects of ethylene dibromide, it has been strongly recommended that disulfiram should not be given to those who may be exposed to this compound.3 This information is also summarised in another report.3

Evening primrose oil + Phenothiazines

Although seizures have occurred in a few schizophrenics taking phenothiazines and evening primrose oil, no adverse effects were seen in others, and there appears to be no firm evidence that evening primrose oil should be avoided by epileptic patients.

Clinical evidence
Twenty-three patients were enrolled in a placebo-controlled study of evening primrose oil in schizophrenia. During the treatment phase, patients were given 8 capsules of Efamol in addition to their normal medication. Seizures developed in 3 patients, one during treatment with placebo. The other two patients were taking evening primrose oil, one was receiving fluphenazine decanoate 50 mg every 2 weeks and the other fluphenazine decanoate 25 mg once every 2 weeks with thioridazine, which was later changed to chlorpromazine.1 In another study, 3 long-stay hospitalised schizophrenics were taking evening primrose oil. Their schizophrenia became much worse and all 3 patients showed EEG evidence of temporal lobe epilepsy.2

In contrast, no seizures or epileptiform events were reported in a crossover study of 48 patients (most of them schizophrenics) taking phenothiazines when they were given evening primrose oil for 4 months.3 Concurrent use was also apparently uneventful in another study in schizophrenic patients.4

Mechanism
Not understood. One suggestion is that evening primrose oil possibly increases the well-recognised epileptogenic effects of the phenothiazines, rather than having an epileptogenic action of its own.5 Another idea is that it might unmask temporal lobe epilepsy.1,2

Importance and management
The interaction between phenothiazines and evening primrose oil is not well established, nor is its incidence known, but clearly some caution is appropriate during concurrent use, because seizures may develop in a few individuals. There seems to be no way of identifying the patients at particular risk. The extent to which the underlying disease condition might affect what happens is also unclear.

No interaction between anticonvulsants and evening primrose oil has been established and the reports cited above.1,2 appear to be the sole basis for the suggestion that evening primrose oil should be avoided by epileptics. No seizures appear to have been reported in patients taking evening primrose oil in the absence of phenothiazines. The manufacturers of Epogam, an evening primrose oil preparation, claim that it is known to have improved the control of epilepsy in patients previously uncontrolled with conventional antiepileptic drugs, and other patients are said to have had no problems during concurrent treatment.5 Even so, until the situation is formally examined it would seem prudent to monitor concurrent use.

Folic acid + Adsorbents

In vitro studies show that folic acid is markedly adsorbed by magnesium trisilicate and edible clay.1 This would be expected to reduce its absorption from the gut, but the clinical importance of this awaits assessment.

Folic acid + Sulfasalazine

Sulfasalazine can reduce the absorption of folic acid.

Clinical evidence, mechanism, importance and management
The absorption of folic acid was reduced by about one-third (from 65 to 44.5%) in patients with ulcerative and granulomatous colitis, when compared with healthy subjects, and even further reduced (down to 32%) when sulfasalazine was taken.4 Another study confirmed that serum folate levels are lower in patients with ulcerative colitis taking sulfasalazine, and that the impairment of the absorption of folates by sulfasalazine was a mechanism in this.5 Sulfasalazine is also known to interfere with folate metabolism.

It is well established that sulfasalazine is, rarely, associated with blood dyscrasias due to folate deficiency and also other haematological toxicities, and consequently regular blood counts are recommended to detect
Garlic dose not affect the pharmacokinetics of alprazolam or dextromethorphan, and is therefore not expected to interact with drugs metabolised by CYP3A4 or CYP2D6.

**Clinical evidence, mechanism, importance and management**

A study in 14 healthy subjects found that garlic (*Allium sativum*), 600 mg twice daily for 14 days, did not affect the pharmacokinetics of a single 2-mg dose of *alprazolam* or the metabolism of a single 30-mg dose of *dextromethorphan*. This suggests that garlic is unlikely to affect the metabolism of other drugs that are substrates of the cytochrome P450 iso-enzymes CYP3A4 or CYP2D6. For a list of drugs that are substrates of these enzymes, see ‘Table 1.3’, (p.6), and ‘Table 1.4’, (p.6).

Ginseng does not appear to affect the metabolism of alprazolam or dextromethorphan.

**Clinical evidence, mechanism, importance and management**

A study in 12 healthy subjects found that Siberian ginseng, 485 mg twice daily for 14 days, did not affect the pharmacokinetics of a single 2-mg dose of *alprazolam* or the metabolism of a single 30-mg dose of *dextromethorphan*. This suggests that Siberian ginseng is unlikely to affect the metabolism of other drugs that are substrates of the cytochrome P450 iso-enzymes CYP3A4 or CYP2D6. For a list of drugs that are substrates of these enzymes, see ‘Table 1.3’, (p.6), and ‘Table 1.4’, (p.6).

The blood glucose-elevating effects of glucagon may be reduced by propranolol.

**Clinical evidence, mechanism, importance and management**

The blood glucose-elevating effects of glucagon were reduced in the presence of *propranolol* in 5 healthy subjects. Blood glucose levels increased by about 45% in the presence of glucagon, but when *propranolol* was also given the increase was only about 15%. The reason is uncertain, but one suggestion is that the *propranolol* inhibits the effects of the catecholamines that are released by glucagon. The clinical importance of this interaction is uncertain.

5-HT3-receptor antagonists + Cimetidine

Cimetidine had no important effect on dolasetron or granisetron pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Dolasetron

A study in 18 healthy subjects given dolasetron 200 mg daily found that cimetidine 300 mg four times daily for 7 days increased the AUC and maximum plasma level of the active metabolite of dolasetron, hydrodolasetron, by 24% and 15%, respectively, probably due to the inhibitory effect of cimetidine on the cytochrome P450-mediated metabolism of dolasetron. As 400-mg oral doses of dolasetron have been shown to be well tolerated (the usual oral dose is up to 200 mg) these changes were not considered to be clinically significant. Therefore no special precautions appear necessary if cimetidine and dolasetron are used concurrently.

(b) Granisetron

Pretreatment with cimetidine 200 mg four times daily for 8 days had no effect on the pharmacokinetics of a single 40-microgram/kg intravenous dose of granisetron given on day 8 in a study in 12 healthy subjects. No granisetron dose adjustments are likely to be necessary if cimetidine is given.

5-HT3-receptor antagonists + Drugs that prolong the QT interval

All available 5-HT3-receptor antagonists (dolasetron, granisetron, ondansetron, palonosetron, tropisetron) have caused small increases (generally not exceeding 15 milliseconds) in the QTc interval. Some consider that these changes are not clinically relevant. Nevertheless, many of the manufacturers give various cautions about using 5-HT3-receptor antagonists together with other drugs known to prolong the QT interval.

Clinical evidence, mechanism, importance and management

The 5-HT3-receptor antagonists are now known to cause small increases (generally not exceeding 15 milliseconds) in the QTc interval. It has been concluded that this class effect is too small to be of clinical relevance, and that there is insufficient evidence to differentiate the 5-HT3-receptor antagonists by this effect. Nevertheless, manufacturers issue differing guidance about concurrent use with other QT prolonging drugs as follows:

• Dolasetron: the UK manufacturer contraindicates the concurrent use of dolasetron and class I or class III antiarrhythmics, and recommends caution with other drugs that prolong QT intervals in patients at risk. The US manufacturer advises caution with all drugs that may prolong the QT interval. They include diuretics, for potential inducing electrolyte abnormalities.

• Granisetron: Neither the UK nor the UK manufacturers mention QT prolongation.

• Ondansetron: the UK manufacturer recommends caution in patients treated with antiarrhythmics or beta blockers whereas the US manufacturer does not issue any cautions regarding QT-prolongation.

• Palonosetron: the UK and US manufacturers recommend caution with other drugs that increase the QT interval.

5-HT3-receptor antagonists + Enzyme inducers

Rifampicin causes a minor reduction in dolasetron levels and a modest reduction in ondansetron levels, and may affect granisetron and tropisetron similarly, but does not appear to alter palonosetron levels. However, with the possible exception of ondansetron, none of the changes are thought to be clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Dolasetron

In a study in 17 healthy subjects given dolasetron 200 mg daily, rifampicin (rifampin) 600 mg daily for 7 days decreased the AUC and maximum plasma level of the active metabolite of dolasetron, hydrodolasetron, by 28% and 17%, respectively, probably due to induction of hydrodolasetron metabolism by rifampicin. These changes were not considered to be clinically significant and therefore no special precautions appear necessary if rifampicin and dolasetron are used concurrently.

(b) Granisetron

The US manufacturer notes that, in a pharmacokinetic study, the enzyme inducer phenobarbital increased the clearance of granisetron by 25%. They say that the clinical relevance of this change is unknown, but such a modest change is not likely to be important.

(c) Ondansetron

Pretreatment with rifampicin 600 mg once daily for 5 days markedly decreased the AUC of a single 8-mg dose of oral ondansetron by 65% and intravenous ondansetron by 48% in a study in 10 healthy subjects. This is most likely due to the induction of CYP3A4-mediated metabolism of ondansetron by rifampicin. The authors concluded that ondansetron may not be as effective if given to patients taking rifampicin. Nevertheless, the US manufacturer says that, although the potent inducers CYP3A4, phenytion, carbamazepine, and rifampicin increased ondansetron clearance, on the basis of available data, no ondansetron dose adjustment is recommended for patients taking these drugs.

(d) Palonosetron

The UK manufacturer notes that, in a population pharmacokinetic analysis, enzyme inducers (dexamethasone and rifampicin) had no effect on palonosetron clearance. No palonosetron dose adjustment is likely to be necessary when given with these drugs.
5-HT₃-receptor antagonists; Dolasetron + Miscellaneous

Food does not affect dolasetron absorption. Atenolol modestly reduced the clearance of the active metabolite of dolasetron. One patient taking verapamil and given dolasetron experienced heart block.

Clinical evidence, mechanism, importance and management

(a) Atenolol
The US manufacturer notes that atenolol reduced the clearance of the active metabolite of dolasetron, hydrodolasetron, by 27%. This change is not likely to be clinically significant.

(b) Food
In a single-dose study, 23 healthy subjects were given 200 mg of dolasetron orally either alone, or following a high-fat breakfast (containing fat 55 g, protein 33 g and carbohydrate 58 g). Although there was a slight delay in absorption, dosing with a meal and dosing without a meal were considered to be bioequivalent. Therefore dolasetron may be given without regard to meals.

(c) Verapamil
The US manufacturer notes that, in one case, a 61-year-old woman taking verapamil developed complete heart block following the use of dolasetron, although this was not proven to be as a result of an interaction. In other patients taking verapamil, the clearance of hydrodolasetron (the active metabolite of dolasetron) was unchanged.

5-HT₃-receptor antagonists; Ondansetron + Miscellaneous

Food slightly increases the bioavailability of ondansetron, but an antacid was found to have no effect.

Clinical evidence, mechanism, importance and management

(a) Aluminium-containing antacids

Although concurrent use has not been formally studied, the manufacturer recommends that dolasetron is not taken with aluminium-containing antacids. Deferasirox has a lower affinity for aluminium than for iron, but theoretically aluminium might reduce the efficacy of deferasirox.

(b) CYP2C8 substrates

In vitro studies suggested that the only cytochrome P450 isoenzyme that was inhibited by deferasirox at concentrations similar to those that might be achieved clinically was CYP2C8. For this reason, the EMA has re-
quested that a clinical drug-drug interaction study be conducted to exclude a potential interaction with CYP2C8 substrates. Pending the findings of this, the UK manufacturers warn that an interaction between deferasirox and CYP2C8 substrates, such as paclitaxel and repaglinide cannot be excluded. Therefore, bear the possibility of an interaction in mind. See ‘Table 1.3’, (p.6), for a list of clinically relevant CYP2C8 substrates.

(c) Digoxin
In healthy subjects, deferasirox had no effect on the pharmacokinetics of digoxin.1,2 No digoxin dose adjustment would be expected to be necessary on concurrent use.

(d) Food
Food increased the bioavailability of deferasirox to a variable extent, and the manufacturer recommends that it is taken on an empty stomach at least 30 minutes before food.1,2 The tablets for oral suspension can be dispersed in water, orange juice, or apple juice.2

(e) Hydroxycarbamide
In vitro, hydroxycarbamide did not inhibit the metabolism of deferasirox.2,3 Although an interaction has not been formally studied, the manufacturer considers it unlikely that concurrent use in patients with sickle cell anaemia will result in an interaction.2,3

(f) UGT enzyme inducers
Deferasirox metabolism is predicted to be increased if it is given with UGT enzyme inducers such as rifampicin (rifampin), phenobarbital or phenytoin because deferasirox is metabolised principally by glucuronidation. Pending the results of a drug-interaction study,2 the UK manufacturer recommends that the efficacy of deferasirox (serum ferritin levels) should be monitored if these drugs are used together with deferasirox, and when they are stopped, and the dose of deferasirox adjusted if necessary.1

Deferasirox is metabolised principally by glucuronidation. Pending the results of a drug-interaction study,2 the UK manufacturer recommends that the efficacy of deferasirox (serum ferritin levels) should be monitored if these drugs are used together with deferasirox, and when they are stopped, and the dose of deferasirox adjusted if necessary.1

The absorption of iron and the expected haematological response can be reduced by the concurrent use of antacids.

Clinical evidence
A study in healthy subjects who were mildly iron-deficient (due to blood donation or menstruation) found that about 5 mL of Mylanta II (aluminium/magnesium hydroxide with simetidine) had little effect on the absorption of 10 or 20 mg of ferrous sulfate at 2 hours. However, sodium bicarbonate 1 g almost halved the absorption of ferrous sulfate, and calcium carbonate 500 mg reduced it by two-thirds. Conversely, iron absorption from a multivitamin and mineral preparation was little affected by whether or not the tablet contained 200 mg of calcium (as calcium carbonate).3 Another study found that an antacid containing aluminium/magnesium hydroxides and magnesium carbonate reduced the absorption of ferrous sulfate and ferric fumarate (both containing 100 mg of ferrous iron) in healthy iron-replete subjects by 37% and 31%, respectively.7 Poor absorption of iron during treatment with sodium bicarbonate and aluminium hydroxide has been described elsewhere.3,4

One study did not find that the absorption of ferrous sulfate (iron 10 mg/kg) was affected by doses of magnesium hydroxide (5 mg for every 1 mg of iron) when given 30 minutes apart.5 However, it has been suggested that iron absorption was not measured for a sufficient period to fully rule out a reduction in absorption.6

When oral iron failed to cause an expected rise in haemoglobin levels in patients taking non-absorbable alkalis such as magnesium trisilicate, a study was undertaken in 9 patients. Each patient was given 5 mg of isotopically labelled ferrous sulfate after a 35-g dose of magnesium trisilicate. The magnesium reduced the absorption of iron by an average of 70 to 88%, the reduction being small in some patients, but one individual had a fall from 67% to 5%.7

Mechanism
Uncertain. One suggestion is that magnesium sulfate changes ferrous sulfate into less easily absorbed salts, or increases its polymerisation.1 Carbohydrates possibly cause the formation of poorly soluble iron complexes.3 Aluminium hydroxide is believed to precipitate iron as the hydroxide and ferric ions can become intercalated into the aluminium hydroxide crystal lattice,3 leaving less available for absorption.

Important and management
Information is limited and difficult to assess because of the many variables (e.g. different dosages ranging from very small to those mimicking over-dose, and a mix of subjects and patients). However, a reasonable ‘blanket precaution’ to achieve maximal absorption would be to separate the administration of iron preparations and antacids as much as possible to avoid admixture in the gut. This may not prove to be necessary with some preparations.

Iron compounds + Antacids
The absorption of iron and the expected haematological response can be reduced by the concurrent use of antacids.

However, a reasonable ‘blanket precaution’ to achieve maximal absorption would be to separate the administration of iron preparations and antacids as much as possible to avoid admixture in the gut. This may not prove to be necessary with some preparations.
Mechanism
Chloramphenicol can cause two forms of bone marrow depression. One is serious and irreversible, and can result in fatal aplastic anaemia, whereas the other is probably unrelated, milder and reversible, and appears to occur at chloramphenicol serum levels of 25 micrograms/mL or more. This occurs because chloramphenicol can inhibit protein synthesis, the first sign of which is a fall in the reticulocyte count, which reflects inadequate red cell maturation. This response to chloramphenicol has been seen in animals, healthy individuals, a series of patients with liver disease, and in anaemic patients being treated with iron dextran or vitamin B₁₂.

Importance and management
An established interaction of clinical importance. The authors of one study recommend that chloramphenicol dosages of 25 to 30 mg/kg are usually adequate for treating infections without running the risk of elevating serum levels to 25 micrograms/mL or more, which is when this type of marrow depression can occur. Monitor the effects of using iron or vitamin B₁₂ together with chloramphenicol. A preferable alternative would be to use a different antibacterial. Note that chloramphenicol should not be used in patients with pre-existing bone-marrow depression or blood dyscrasias.

Clinical evidence, mechanism, importance and management
Studies have shown that chloramphenicol binds with iron, and in rats this was found to halve the absorption of a single 100-microgram dose of ferrous sulfate. Nobody seems to have checked on the general clinical importance of this in patients. Until more is known it would seem prudent to separate the dosages of the iron and chloramphenicol to avoid mixing in the gut, thereby minimising the effects of this possible interaction. The standard recommendation is to avoid other drugs one hour before or 4 to 6 hours after chloramphenicol.

Iron compounds + Coffee or Tea
Coffee may possibly contribute towards the development of iron-deficiency anaemia in pregnant women, and reduce the levels of iron in breast milk. As a result their babies may also be iron deficient. Tea may also possibly be associated with microcytic anaemia in children.

Clinical evidence
(a) Coffee
A controlled study among pregnant women in Costa Rica found that coffee consumption was associated with reductions in the haemoglobin levels and haematocrits of the mothers during pregnancy, and of their babies shortly after birth, despite the fact that the women were taking ferric sulfate 200 mg and 500 micrograms of folate daily. The babies also had a slightly lower birth weight (3189 g versus 3310 g). Almost a quarter of the mothers were considered to have iron-deficiency anaemia (haemoglobin levels of less than 11 g/dL), compared with none among the control group of non-coffee drinkers. Levels of iron in breast milk were reduced by about one-third. The coffee drinkers drank more than 450 mL of coffee daily, equivalent to more than 10 g of ground coffee.²

(b) Tea
A much higher incidence of microcytic anaemia has been described in teadrinking infants in Israel. The tea-drinkers consumed a median of 250 mL of tea each day, and the incidence of anaemia was 64%, which was about twice that of the non-tea drinking control group (31%).² A case report describes an impaired response to iron, given to correct an iron-deficiency anaemia, in the presence of 2 litres of black tea taken daily. The patient recovered when the black tea was stopped.³ Another report describes no change in the absorption of iron supplements in daily doses of 2 to 15.8 mg/kg in 10 iron-deficient tea-drinking children, although note that the children were only given 150 mL of tea.⁴

Mechanism
Tannins are thought to form insoluble complexes with iron and thus reduce its absorption.²,⁴

Importance and management
The general importance of these findings is uncertain, but be aware that coffee or tea consumption may contribute to iron-deficiency anaemia.

Iron compounds + Colestyramine
Colestyramine binds with ferrous sulfate in the gut and reduces its absorption, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management
Apart from a brief and unconfirmed report alleging that cimetidine reduced the response to ferrous sulfate in three patients, there appears to be no other evidence that H₂-receptor antagonists reduce the absorption of iron to a clinically relevant extent. Iron causes only a small and clinically irrelevant reduction in the serum levels of cimetidine and famotidine.

Iron compounds + H₂-receptor antagonists
A brief report describes 3 patients taking cimetidine 1 g and ferrous sulfate 600 mg daily whose ulcers healed after 2 months, but their anaemia and altered iron metabolism persisted. When the cimetidine was reduced to 400 mg daily, but with the same dose of iron, the blood picture resolved satisfactorily within a month.¹ The author of the report attributed this response to the cimetidine-induced rise in gastric pH, which reduced the absorption of the iron. However, this suggested mechanism was subsequently disputed, as medicinal iron is already in the most absorbable form, Fe²⁺, and so does not need an acidic environment to aid absorption.² A study in patients with iron deficiency, or iron-deficiency anaemia, found that the concurrent use of famotidine, nizatidine, or ranitidine, did not affect their response to 2.4 g of iron succinyl-protein complex (equivalent to 60 mg of iron twice daily).³ No special precautions would seem necessary on concurrent use.

Mechanism
H₂-receptor antagonists
In a series of 3 studies, healthy subjects were given a 300-mg tablet of cimetidine with either a 300-mg tablet of ferrous sulfate or 300 mg of ferrous sulfate in solution. The reductions in the AUC and maximum serum level reductions were also very small (10% or less). These small reductions are almost certainly due to the formation of a weak complex between the iron and these H₂-receptor antagonists.⁴ An in vitro study with ranitidine found that, while it also binds with iron, it forms a very weak complex, and is less likely to bind than cimetidine or famotidine.⁴ It was concluded that no clinically relevant interaction occurs between ferrous sulfate and any of these H₂-receptor antagonists.⁴

Note that tea and coffee are not generally considered to be suitable drinks for babies and children, because of their effects on iron absorption. More study is needed.

Iron compounds + Neomycin

Neomycin may alter the absorption of iron.

Clinical evidence, mechanism, importance and management

A study in 6 patients found that neomycin markedly reduced the absorption of iron (iron\(^{29}\) as ferrous citrate) in 4 patients, but increased the absorption in the other 2 patients who initially had low serum iron levels. None of the patients were anaemic at any time.\(^1\) The importance of this is uncertain, but consider this possible interaction if the response to iron is poor.

Iron compounds + Phosphate binders

Calcium carbonate and calcium acetate (in phosphate-binding doses) caused a modest reduction in the absorption of iron from ferrous sulfate, whereas sevelamer had only a minor effect.

Clinical evidence, mechanism, importance and management

In a single-dose study in 23 fasting healthy subjects,\(^1\) the bioavailability of iron from ferrous sulfate 200 mg was reduced by 27% by calcium acetate 2.7 g, 19% by calcium carbonate 3 g, and 10% by sevelamer 2.8 g. It was suggested that calcium may form insoluble complexes with iron, so reducing its absorption. This study suggests that these calcium phosphate-binders may have a clinically relevant effect on iron absorption, whereas sevelamer probably does not. However, the findings need replicating in a patient group taking the phosphate binders long-term with meals. See also \(\text{antacids}', (p.1262) for data suggesting that lower doses of \text{calcium carbonate} may or may not reduce iron absorption.

Vitamin E impaired the response to iron in a group of anaemic children.

Clinical evidence, mechanism, importance and management

A group of 26 anaemic children aged 7 to 40 months were given iron dextran 5 mg/kg daily for 3 days. Vitamin E 200 units daily was also given to 9 of the children, starting 24 hours before the iron dextran and continued for a total of 4 days. It was noted that after 6 days, those taking vitamin E had a reticulocyte response of only 4.4% compared with 14.4% in the patients not given vitamin E. The vitamin E group also had reduced haemoglobin levels and a lower haematocrit. The reasons are not understood. Check for any evidence of a reduced haematological response in anaemic patients given iron and vitamin E. The authors of the report point out that this dosage of vitamin E was well above the recommended daily dietary intake.\(^1\)

Kava + Cytochrome P450 isoenzyme substrates

Kava does not appear to affect the metabolism of debrisoquine and mephenytoin. Kava may inhibit the metabolism of chlorzoxazone but not all studies have found this effect.

Clinical evidence, mechanism, importance and management

In a study in 6 subjects (3 of whom smoked tobacco), who usually took 7 to 27 g of kavalactones weekly as an aqueous kava extract, the metabolism of chlorzoxazone, debrisoquine, and mephenytoin (which are substrates of CYP2E1, CYP2D6, and CYP2C19, respectively), was not affected when the subjects stopped taking kava for 30 days.\(^1\) Similar results were found in a study in 12 healthy subjects given kava root extract 1 g twice daily for 28 days before receiving a single dose of debrisoquine, but when the interaction between kava kava root extract and chlorzoxazone was also studied in these subjects a 40% inhibitory effect of kava on CYP2E1 was seen, which is in contrast to the previous study.\(^2\) For a list of drugs which are substrates of CYP2E1, CYP2D6, and CYP2C19, see ‘Table 1.3’, (p.6).

Consider also ‘midazolam’, (p.730), ‘caffeine’, (p.1165), which are substrates for CYP1A2 and CYP1A2, respectively.

Melatonin + Caffeine

Caffeine increases the levels of both endogenous and orally administered melatonin.

Clinical evidence

A crossover study in 12 healthy subjects found that a single 200-mg dose of caffeine (equivalent to one large or two small cups of coffee), taken 1 hour before and 1 and 3 hours after a single 6-mg oral dose of melatonin, increased the average AUC and maximum levels of melatonin by 120% and 137%, respectively, although the half-life of melatonin was not significantly affected. The interaction was less pronounced in smokers (6 subjects) than in non-smokers (6 subjects).\(^1\)

Another crossover study in 12 healthy subjects (by the same authors) found that a single 200-mg dose of caffeine, taken 12 or 24 hours before a single 6-mg dose of melatonin, did not affect the melatonin levels, although 2 subjects had raised melatonin levels when caffeine was taken 12 hours, but not 24 hours, before melatonin.\(^2\)

In 12 healthy subjects given a single 200-mg dose of caffeine, taken in the evening, endogenous, nocturnal melatonin levels were found to be increased, and the AUC of melatonin was increased by 32%.\(^3\)

Mechanism

Caffeine is thought to reduce the metabolism of melatonin by competing for metabolism by the cytochrome P450 isoenzyme CYP1A2.\(^1,3\)

Importance and management

Melatonin is produced by the pineal gland in the body and is also available as a supplement in some parts of the world. However, the effects of long-term use of this supplement are unknown. From the above studies, it appears that caffeine significantly increases the levels of single doses of supplementary melatonin, however the long-term effects of caffeine and concurrent multiple dosing of melatonin do not appear to have been studied. Melatonin can cause drowsiness when taken on its own, so patients who take melatonin should be advised that this effect may be increased if they also take caffeine. This increased drowsiness may oppose the stimulating effect of caffeine.

Methoxsalen + Phenytoin

The serum levels of methoxsalen can be markedly reduced by the concurrent use of phenytoin. This resulted in failure of treatment for psoriasis in one patient.

Clinical evidence, mechanism, importance and management

A patient with epilepsy failed to respond to treatment for psoriasis with PUVA (12 treatments of methoxsalen 30 mg given orally and ultraviolet A irradiation) while taking phenytoin 250 mg daily. Methoxsalen serum levels were normal in the absence of phenytoin, but abnormally low while taking phenytoin, due, it is suggested, to the enzyme inducing effects of the phenytoin. This interaction could lead to serious erythema and blistering if the phenytoin dose is reduced during therapy, as methoxsalen levels rise and therefore photosensitivity caused by the methoxsalen may be increased. Concurrent use should be avoided or very closely monitored.

Metyrapone + Miscellaneous

The results of the metyrapone test for Cushing’s syndrome are unreliable in patients taking cyproheptadine or phenytoin. The manufacturer also states that barbiturates, antidepressants, some hormones, and antipsychotics may influence the results of the test.

Clinical evidence

(a) Cyproheptadine

Pretreatment with cyproheptadine 4 mg every 6 hours, 2 days before and throughout a standard metyrapone test (750 mg every 4 hours for 6 doses), reduced the metyrapone-induced urinary 17-hydroxycorticosteroid response in 9 healthy subjects by 32%, and also reduced the serum 11-deoxycorticisol response.1

(b) Phenytoin

A study in 5 healthy subjects and 3 patients taking phenytoin 300 mg showed that their serum metyrapone levels 4 hours after taking a regular 750-mg dose were very low, when compared with a control group (6.5 versus 48.2 micrograms/100 mL). The response to metyrapone (i.e. the fall in circulating glucocorticoids) is related to serum levels and was therefore proportionately lower.2 Other reports confirm that the urinary steroid response to metyrapone is subnormal in patients taking phenytoin.3,4

Doubling the dose of metyrapone from 750 mg every 4 hours to every 2 hours has been shown to give results similar to those in subjects not taking phenytoin.2

Mechanism

Phenytoin is a potent liver enzyme inducer that increases the metabolism of metyrapone, thereby reducing its effects.2,5

Importance and management

The results of metyrapone tests for Cushing’s syndrome will be unreliable in patients taking cyproheptadine and phenytoin, and therefore these should be withdrawn prior to the test. The manufacturer also states that barbiturates, antidepressants (they name amitriptyline) and antipsychotics (they name chlorpromazine), hormones that affect the hypothalamo-pituitary axis, and antithyroid drugs may influence the results of the test. They recommend that, if any of these drugs cannot be withdrawn prior to the test, the necessity of carrying out the metyrapone test should be reviewed.6

Mifepristone + Aspirin or NSAIDs

The manufacturers of mifepristone say that the antiprostaglandin effects of NSAIDs including aspirin could theoretically decrease the efficacy of mifepristone. They recommend using non-NSAID analgesics.1

Milk thistle + Cytochrome P450 isoenzyme substrates

Milk thistle does not alter the metabolism of caffeine, chloroxazone, or debrisoquine.

Clinical evidence, mechanism, importance and management

Milk thistle 175 mg, standardised to 80% silymarins, was given to 12 healthy subjects twice daily for 28 days. Subjects also received single doses of caffeine 100 mg, chloroxazone 250 mg, and debrisoquine 5 mg, before and at the end of the treatment with milk thistle. The metabolism of these drugs was not affected by the concurrent use of milk thistle, which suggests that milk thistle is unlikely to affect the metabolism of drugs that are substrates of the cytochrome P450 isoenzymes CYP1A2, CYP2E1, or CYP2D6.1 For a list of drugs that are substrates of these isoenzymes, see Table 1.2, (p.4), and Table 1.3, (p.6).

For the lack of effect of milk thistle on CYP3A4, see ‘Benzodiazepines + Milk thistle’, p.732.

Moxisylyte + Miscellaneous

There is a theoretical possibility of increased blood pressure lowering effects if moxisylyte is used with antihypertensives or tricyclic antidepressants.

Clinical evidence, mechanism, importance and management

Moxisylyte is an alpha-1, and to a lesser extent, an alpha-2 blocker, which may be used orally as a peripheral vasodilator in Raynaud’s syndrome. The manufacturers suggest that if moxisylyte is used by patients taking antihypertensives, it may theoretically potentiate the antihypertensive effect, although at the recommended doses this has not been reported.1 They also say that tricyclic antidepressants might increase any hypoten- sive effect of moxisylyte.1

Nicotine + Vasopressin

A case report described marked hypotension and bradycardia in a young woman during surgery, attributed to the combined effects of vasopressin and nicotine from a transdermal patch.
Clinical evidence

A 22-year-old woman in good health was anaesthetised for surgery with nitrous oxide/oxygen and isoflurane. Twenty minutes after induction she was given an injection of 0.2 units of vasopressin into the cervix. Within seconds she developed severe hypotension and bradycardia, and over the next 30 minutes blood pressures as low as 70/35 mmHg and heart rates as low as 38 bpm were recorded. She was treated with atropine and adrenaline (epinephrine), and eventually made a full recovery. This patient was wearing a transdermal nicotine patch.1

Mechanism

The circulatory collapse was attributed by the authors to the combined effects of the injected vasopressin and the nicotine from the transdermal patch. Both of these drugs can increase afterload and cause coronary artery vasoconstriction, which the authors suggest may have decreased the blood supply to the heart and resulted in cardiac depression.1

Importance and management

This is an isolated report and any interaction is therefore not well established. Nevertheless the recommendation of the authors seems sensible, namely that nicotine patches should be removed the night before or 24 hours before surgery, and that patients should be asked to avoid smoking before surgery to make sure that nicotine levels are minimal. More study is needed.

Clinical evidence, mechanism, importance and management

Undesirably prolonged erections (duration of 5 and 6 hours) occurred in 2 patients who had been given 5 or 10 mg of diazepam intravenously for anxiety before a 60-mg intracavernosal injection of papaverine.1 Papaverine acts by relaxing the arterioles that supply the corpora so that the pressure rises. The increased pressure in the corpora compresses the trabecular venules so that the pressure continues to maintain the erection. Diazepam also relaxes smooth muscle and it would seem that this can be additive with the effects of papaverine. The authors of the report say that caution should be exercised in the choice of papaverine dosage in patients taking anxiolytics (i.e. use less) although these two cases involving diazepam seem to be the only ones recorded.1

Penicillamine + Food

Food can reduce the absorption of penicillamine by as much as a half.

Clinical evidence

The presence of food reduced the plasma levels of penicillamine 500 mg by about 50% in healthy subjects. The total amount absorbed was similarly reduced.1,2 These figures are in good agreement with previous findings.3

Mechanism

Uncertain. One suggestion is that food delays gastric emptying so that the penicillamine is exposed to more prolonged degradation in the stomach.2 Another idea is that the protein in food reduces penicillamine absorption.
Penicillamine levels. Be alert for evidence of toxicity if both drugs are used. Note that the US manufacturer states that penicillamine should not be used in patients who are receiving antimalarials (which would include chloroquine and hydroxychloroquine) because these drugs are also associated with serious haematological effects.3 There is some evidence that using gold with penicillamine may increase the risk of adverse effects, and the manufacturer says that they should not be used together.2,3 In addition, patients who have had an adverse reaction to gold may be at a greater risk of serious adverse reactions to penicillamine,2,3 and caution is recommended.3

(b) NSAIDs

Indometacin has been found to increase the AUC of penicillamine by 26% and the peak plasma levels by about 22%.1 The UK manufacturer notes that use of NSAIDs may increase the risk of renal damage with penicillamine. The US manufacturer specifically recommends avoiding oxyphenbutazone or phenylbutazone because these drugs are also associated with serious haematological and renal effects.2 Urinalysis for detection of haematuria or proteinuria should be regularly carried out in patients taking penicillamine.2,3 Be alert for evidence of toxicity if NSAIDs and penicillamine are used together.

(c) Oral contraceptives

A woman with Wilson’s disease began to develop dark facial hair about 4 months after starting to take penicillamine 1.25 to 1.5 g daily. After 20 months her testosterone levels were found to be slightly raised, and so she was given a combined oral contraceptive, but within a month her breasts began to enlarge and become more tender. After a further 6 months the penicillamine was replaced by trientine hydrochloride.4 The reasons are not understood, but the authors of the report suggest that the penicillamine was the prime cause of the macromastia, but it possibly needed the presence of a ‘second trigger’ (i.e. the oral contraceptive) to set things in motion.4

There are 12 other cases of macromastia and gynaecomastia on record associated with the use of penicillamine, in some of which the second trigger may possibly have been a corticosteroid or cimetidine.4 Macromastia appears to be an unusual adverse effect of penicillamine and there would seem to be no general reason for patients taking penicillamine to avoid oral contraceptives.

Phenylpropanolamine + Indinavir

A report describes a hypertensive crisis when a patient taking indinavir was also given phenylpropanolamine.

Clinical evidence, mechanism, importance and management

A 28-year-old woman was prescribed HIV- prophylaxis following a needle stick injury. She was initially given zidovudine, indinavir and lamivudine, but after one week stavudine was substituted for zidovudine as she was experiencing nausea and vomiting. Six hours after taking Tavist-D (clemastine with phenylpropanolamine) for a sinus complaint she had a feeling of chest tightness associated with difficulty in breathing, and shortly afterwards she experienced left-sided upper extremity weakness, followed by a severe right-sided temporal headache. Her blood pressure was 220/120 mmHg, but returned to normal within 4 hours, and the neurological deficit resolved over the next 8 hours. However, 12 hours later, the same neurological deficit recurred, although no increase in blood pressure was noted. The neurological deficit was thought to be due to reversible cerebral vasoconstriction, secondary to phenylpropanolamine toxicity. She was treated with nimodipine 60 mg every 4 hours and aspirin 325 mg daily, and her symptoms did not recur.1

The patient had been taking phenylpropanolamine intermittently for several years without any adverse reaction and it was thought that the recent addition of the anti-HIV regimen potentiated the effect of the phenylpropanolamine.1 It seems likely that the indinavir was responsible for the interaction as it is a potent enzyme inhibitor. This is an isolated report and

Miscellaneous drugs 1267

Phenylpropanolamine + Indinavir

A report describes a hypertensive crisis when a patient taking indinavir was also given phenylpropanolamine.

Clinical evidence, mechanism, importance and management

A 28-year-old woman was prescribed HIV- prophylaxis following a needle stick injury. She was initially given zidovudine, indinavir and lamivudine, but after one week stavudine was substituted for zidovudine as she was experiencing nausea and vomiting. Six hours after taking Tavist-D (clemastine with phenylpropanolamine) for a sinus complaint she had a feeling of chest tightness associated with difficulty in breathing, and shortly afterwards she experienced left-sided upper extremity weakness, followed by a severe right-sided temporal headache. Her blood pressure was 220/120 mmHg, but returned to normal within 4 hours, and the neurological deficit resolved over the next 8 hours. However, 12 hours later, the same neurological deficit recurred, although no increase in blood pressure was noted. The neurological deficit was thought to be due to reversible cerebral vasoconstriction, secondary to phenylpropanolamine toxicity. She was treated with nimodipine 60 mg every 4 hours and aspirin 325 mg daily, and her symptoms did not recur.1

The patient had been taking phenylpropanolamine intermittently for several years without any adverse reaction and it was thought that the recent addition of the anti-HIV regimen potentiated the effect of the phenylpropanolamine.1 It seems likely that the indinavir was responsible for the interaction as it is a potent enzyme inhibitor. This is an isolated report and
its general significance is not known, but it would be prudent to be alert for this interaction in patients given both drugs.

Phenylpropanolamine + Indomethacin

An isolated report describes a patient taking phenylpropanolamine who developed serious hypertension after taking a single dose of indomethacin, but a controlled study in other subjects failed to find any evidence of an adverse interaction.

Clinical evidence

A woman who had been taking phenylpropanolamine 85 mg daily for several months as an appetite suppressant, developed a severe bifrontal headache within 15 minutes of taking indomethacin 25 mg. Thirty minutes later her systolic blood pressure was 210 mmHg and her diastolic blood pressure was unrecordable. A later study in this patient confirmed that neither drug on its own caused this response, but when they were taken together the blood pressure rose to a maximum of 200/150 mmHg within about 30 minutes of taking the indomethacin, and was associated with bradycardia. The blood pressure was rapidly reduced by phenolamine.1

In contrast, a controlled study in 14 healthy young women found no evidence that sustained-release indomethacin 75 mg twice daily given with sustained-release phenylpropanolamine 75 mg daily caused a rise in blood pressure.2

Mechanism

Not understood.

Importance and management

Direct information seems to be limited to these reports. They suggest that an adverse hypertensive response is unlikely in most individuals given these drugs. However, note that phenylpropanolamine alone has been associated with severe hypertension and has been implicated in causing stroke.3 It is therefore no longer available in the US and UK and its use has been restricted in many other countries.

Phosphodiesterase type-5 inhibitors + Alpha blockers

Postural hypotension may occur with higher doses of sildenafil, tadalafil or vardenafil given at the same time as doxazosin or terazosin. The effect may be less marked with tamsulosin.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

Retrospective analysis of pooled data from various clinical studies including patients taking non-nitrate antihypertensives such as the alpha blockers suggests that the adverse effect profile, blood pressure, or heart rate were not significantly different when they also took sildenafil or placebo.1 However, the manufacturer notes that when sildenafil 100 mg was given simultaneously with doxazosin 4 mg after at least 14 consecutive daily doses of doxazosin, severe postural hypotension occurred in one of 4 subjects with benign prostatic hypertrophy, and 2 others had mild dizziness. Two of the subjects had a standing systolic BP of less than 85 mmHg. This did not occur in a further 17 subjects who, as a result of these effects, were given a lower dose of sildenafil 25 mg. In two other studies, 2 of 19 and 3 of 20 patients had a standing systolic BP of less than 85 mmHg after receiving 14 days of doxazosin then a single simultaneous dose of sildenafil 50 mg or 100 mg with doxazosin.2

The manufacturers recommend that patients should be stable on an alpha blocker before sildenafil is started and that consideration should be given to starting sildenafil at the lowest dose (25 mg).2,3 The UK manufacturer notes that a hypotensive effect is most likely within 4 hours of taking an alpha blocker. When starting an alpha blocker in a patient taking sildenafil, the US manufacturer states that the alpha blocker should be started at the lowest dose.2

(b) Tadalafil

A placebo-controlled, randomised, two-period, crossover study in 18 healthy subjects found that a single 20-mg dose of tadalafil increased the blood pressure-reducing effects of doxazosin following 7 days of treatment with doxazosin 8 mg daily. The mean maximum systolic falls for the combination were 3.6 mmHg when lying and 9.8 mmHg when standing. Some of the subjects felt dizzy, but none of them fainted.4 Conversely, a small and clinically irrelevant effect was seen when tadalafil 10 or 20 mg was given with tamsulosin.4,5 A further study in which a single 20-mg oral dose of tadalafil or placebo was given to 17 healthy subjects on the seventh day of taking extended-release alfuzosin 10 mg daily found that none of the subjects had a decrease in standing systolic BP of more than 30 mmHg. No syncope or severe adverse events were reported. However, note that the doses were separated by 4 hours.4

The UK manufacturer of tadalafil says that the concurrent use of alpha blockers and tadalafil is not recommended as it may lead to symptomatic hypotension in some patients.5 Conversely, the US manufacturer recommends that patients should be stable on their alpha blocker before tadalafil is used, and that tadalafil should be initiated at the lowest recommended dose. When starting an alpha blocker in a patient taking the optimum dose of tadalafil, the alpha blocker should be initiated at the lowest possible dose.4

(c) Vardenafil

The manufacturers of vardenafil have conducted several placebo-controlled, randomised, crossover studies, in patients with BPH and in healthy subjects taking alpha blockers, to assess the effects of concurrent vardenafil on blood pressure. Vardenafil 5 mg was given to 21 patients taking terazosin 5 or 10 mg daily. Vardenafil given simultaneously caused significant hypotension in one patient (BP 80/60 mmHg) and 5 patients experienced postural hypotension of greater than 30 mmHg (compared with only 2 patients in the placebo group). When vardenafil was given 6 hours after the alpha blocker no adverse effects were reported.6 Vardenafil 10 or 20 mg was also given to healthy subjects taking terazosin 10 mg daily. Due to significant hypotension in a large number of the subjects the study was halted.6

Vardenafil 5 mg was given to 21 patients taking tamsulosin 400 micrograms daily. Vardenafil given simultaneously caused significant hypotension in 2 patients (systolic BP less than 85 mmHg) and 2 patients experienced postural hypotension of greater than 30 mmHg (compared with only one patient in the placebo group). When vardenafil was given 6 hours after the alpha blocker significant hypotension still occurred in 2 patients and one experienced postural hypotension of greater than 30 mmHg.6 Larger doses of vardenafil (10 or 20 mg) given to 23 patients taking tamsulosin 400 or 800 micrograms resulted in postural hypotension of greater than 30 mmHg in one patient, and 3 patients became dizzy. When vardenafil was given to 20 healthy subjects with tamsulosin 400 micrograms daily 7 subjects became dizzy.6

The manufacturer recommends that patients should be stable on their alpha blocker before using vardenafil, and that vardenafil should be initiated at a dose of 5 mg,6 (or less in the presence of potent inhibitors of CYP3A4 such as the ‘azoles’, (p.1270) or the ‘protease inhibitors’, (p.1273)).5 The UK manufacturer also says that the doses should be separated if vardenafil is to be given with an alpha blocker (with the exception of tamsulosin, where they consider this precaution unnecessary).6 From the data above, 6 hours would seem adequate. When starting an alpha blocker in a patient taking vardenafil, the US manufacturer states that the alpha blocker should be started at the lowest dose.6

Phosphodiesterase type-5 inhibitors + Antacids

No clinically significant interaction appears to occur between sildenafil, tadalafil or vardenafil and aluminium/magnesium hydroxide antacids.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a single dose study in 12 healthy subjects the bioavailability of sildenafil was not affected by single 30-mL doses of an aluminium/magnesium hydroxide antacid.1

(b) Tadalafil

An open-label, randomised, crossover study in 12 healthy subjects found that 20 mL of Maalox (aluminium/magnesium hydroxide) reduced the mean maximum serum level of a single 10-mg dose of tadalafil by 30%. Although peak tadalafil levels were delayed by 2.5 hours, the total amount of tadalafil absorbed was unchanged. None of the changes caused were considered to be clinically relevant, and there would appear to be no reason for avoiding concurrent use.2

(c) Vardenafil

In a two-way crossover study a single 20-mg dose of vardenafil was given to 12 healthy subjects with 10 mL of an aluminium/magnesium hydroxide antacid (Maalox 70). The bioavailability of vardenafil was not significantly altered by the antacid, therefore no additional precautions are needed if these drugs are used together.3

Phosphodiesterase type-5 inhibitors + Antihypertensives

No clinically relevant interactions appear to occur between sildenafil, tadalafil or vardenafil and most antihypertensive drugs. The exceptions may be diltiazem and verapamil. The potentially serious interactions of sildenafil, tadalafil and vardenafil with the alpha blockers and nitrates are discussed elsewhere. See ‘Phosphodiesterase type-5 inhibitors + Alpha blockers’, p.1268 and ‘Phosphodiesterase type-5 inhibitors + Nitrates’, p.1272.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a study in 8 hypertensive men taking one to five antihypertensives (amlodipine (5 patients), a diuretic (4), an ACE inhibitor (3), an angiotensin II receptor antagonist (2), diltiazem (1)), a single 50-mg dose of sildenafil reduced the systolic BP by a mean maximum of 24 mmHg, compared with only 6 mmHg for placebo. One patient had a blood pressure fall of 48/23 mmHg, but none complained of hypotensive symptoms.1 Two retrospective analyses of pooled data from various clinical trials suggests that patients on non-nitrate antihypertensives (ACE inhibitors, alpha blockers, calcium-channel blockers, diuretics) and sildenafil showed no significant difference blood pressure, or heart rate compared with those taking antihypertensives and placebo,2 and that the incidence of dizziness did not differ between sildenafil recipients on antihypertensives and those not.2,3 In a placebo-controlled study in patients with hypertension receiving stable therapy with 2 or more antihypertensives (including diuretics, calcium-channel blockers, ACE inhibitors, beta blockers, alpha blockers, angiotensin II receptor antagonists), the occurrence of adverse events potentially related to hypotensive effects (dizziness, hypotension, labile BP, vertigo) was less than 4% in sildenafil recipients.4 Note that combined use with alpha blockers may be especially likely to induce hypotensive events, see ‘Phosphodiesterase type-5 inhibitors + Alpha blockers’, p.1268.

The manufacturers report that in population pharmacokinetic analysis, there was no effect on sildenafil pharmacokinetics in those taking ACE inhibitors, calcium-channel blockers and thiazide and related diuretics, whereas the AUC of the less potent active metabolite of sildenafil is increased by 62% by ACE inhibitors, potassium-sparing diuretics and by 102% by non-selective beta blockers, although these changes were not considered clinically relevant.5

When sildenafil 100 mg was given to hypertensive patients taking amlo- dipine the mean additional fall in blood pressure (8/7 mmHg) was of the same magnitude as that seen when sildenafil was given alone to healthy subjects.5,6

It should be noted that some calcium-channel blockers (e.g. diltiazem, verapamil) are known to inhibit the cytochrome P450 3A4 enzyme involved in the metabolism of sildenafil, and so may have the potential to raise sildenafil levels. Although the manufacturers do not specifically mention these drugs, they do recommend a lower starting dose of sildenafil in patients taking potent inhibitors of CYP3A4,5,6 and this would seem a sensible precaution in patients taking diltiazem or verapamil (usually considered to be moderate CYP3A4 inhibitors). There is a case of a patient taking diltiazem 30 mg three times daily who underwent coronary angiography 48 hours after taking sildenafil 50 mg, and who developed profound and persistent hypotension (BP 70/40 mmHg) after receiving sublingual nitrate related to angina during the procedure.7 It was suggested that diltiazem may have inhibited the metabolism of sildenafil so that it interacted with the nitrate,8 although the time scale for this interaction has been disputed.9

The manufacturer notes that in population pharmacokinetic analysis of patients with pulmonary hypertension, there appeared to be an increase in sildenafil exposure when it was taken with beta blockers (none named) in combination with CYP3A4 substrates (none named).10,11 The clinical relevance of this is uncertain, and further study is needed.

(b) Tadalafil

Placebo-controlled studies in patients taking enalapril, metoprolol or bendroflumethiazide, found that a 10-mg dose of tadalafil did not affect blood pressure or heart rate.12 Similar results were seen in a study in patients taking amlo- dipine and given tadalafil 20 mg.12 In another study in patients taking unnamed angiotensin II receptor antagonists (alone or in combination with thiazides, calcium-channel blockers or beta blockers13), tadalafil 20 mg lowered the mean BP by 8/4 mmHg more than placebo, and about twice as many patients had a potentially clinically relevant decrease in blood pressure, although no potential hypotensive symptoms (dizziness) were reported.14 In phase III studies, there was no difference in blood pressure changes in patients taking antihypertensives (ACE inhibitors, calcium-channel blockers, thiazide diuretics, beta blockers, angiotensin II receptor antagonists, alpha blockers and loop diuretics) between those given tadalafil and those given placebo, and there was no difference in the number of patients with a potentially clinically relevant reduction in systolic BP (greater than 30 mmHg). Similarly, in patients taking tadalafil, there was a similar incidence of dizziness between those taking antihypertensives and those not.12 The manufacturers say that tadalafil 20 mg may induce a small fall in blood pressure in patients taking antihypertensives, but this is unlikely to be clinically relevant, with the exception of ‘alpha blockers’, (p.1268). Nevertheless, they still advise caution on concurrent use as some patients with underlying cardiovascular disease may possibly be affected.13,14

There would therefore appear to be no reason for avoiding the concurrent use of any of these drugs nor (the implication is) with other drugs that fall into these drug classes. However, it should be noted that some calcium-channel blockers (e.g. diltiazem, verapamil) are known to have a moderate inhibitory effect on the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of tadalafil, and so may have the potential to raise tadalafil levels.13 Although the manufacturers do not specifically mention these calcium-channel blockers, they do recommend caution13 or a lower dose of tadalafil14 in patients taking potent inhibitors of CYP3A4. Some caution is therefore appropriate.

(c) Vardenafil

In a randomised, double-blind, crossover study, 22 patients with hypertension, stabilised on slow-release nifedipine 30 or 60 mg daily were given a single 20-mg dose of vardenafil, or placebo. Vardenafil slightly decreased the maximum plasma levels and relative bioavailability of nifedipine, as well as causing a further decrease in supine blood pressure.
of about 6/5 mmHg. Heart rate was increased by 4 bpm. Nifedipine did not alter vardenafil levels.

Vardenafil alone may decrease blood pressure, and the US manufacturer cautions that vardenafil may add to the blood pressure lowering effects of antihypertensive drugs. The UK manufacturers say that, although not specifically studied, population pharmacokinetic analysis has suggested that ACE inhibitors, beta blockers, and diuretics have no effect on vardenafil pharmacokinetics.

### Clinical evidence

**Phosphodiesterase type-5 inhibitors + Aspirin**

**Sildenafil, tadalafil and vardenafil do not potentiate the increased bleeding time seen with aspirin.**

#### (a) Sildenafil

In a pharmacological study, sildenafil 50 mg did not potentiate the increase in bleeding time seen with aspirin 150 mg. No additional precautions therefore seem necessary on concurrent use.

#### (b) Tadalafil

A randomised, double-blind, parallel-group study in a total of 28 subjects found that a single 10-mg dose of tadalafil did not increase the bleeding time after aspirin 300 mg daily was taken for 5 days. There would seem to be no reason for taking special precautions if both drugs are used.

#### (c) Vardenafil

The manufacturers say that population pharmacokinetic analysis suggests that aspirin had no effect on vardenafil pharmacokinetics. In addition, vardenafil 10 mg and 20 mg did not potentiate the bleeding time caused by aspirin 162 mg. No additional precautions therefore seem necessary on concurrent use.

### Clinical evidence

- **Sildenafil**
  - ‘Erythromycin’, (p.1272), increases sildenafil levels threefold. The manufacturers therefore predict that other more potent CYP3A4 inhibitors such as itraconazole and ketoconazole will have even greater effects. They say that population data from clinical studies suggests that CYP3A4 inhibitors such as ketoconazole reduced sildenafil clearance without increasing the incidence of adverse effects. In a study in dogs, the concurrent use of itraconazole enhanced and prolonged the adverse effects of sildenafil. However, a case report describes the apparently uneventful concurrent use of sildenafil 100 mg with itraconazole 400 mg daily for 7 days each month in a 56-year-old man.

- **Tadalafil**
  - In an open label, randomised study in 12 healthy subjects, ketoconazole 200 mg daily increased the AUC of a single 10-mg dose of tadalafil by twofold and itraconazole 400 mg daily increased the AUC fourfold. The manufacturers predict that itraconazole will interact similarly. This prediction has been borne out by a case report of a 56-year-old man who was taking itraconazole 400 mg daily for 7 days each month. Within a few hours of his first 10-mg dose of tadalafil he developed priapism, which lasted for more than 4 hours. The same reaction occurred when he took tadalafil during the following month. He had seemingly previously taken sildenafil with itraconazole without adverse effect.

- **Vardenafil**
  - Ketoconazole 200 mg daily increased the AUC of a 5-mg dose of vardenafil tenfold, and increased the maximum plasma levels fourfold. Although not specifically studied, itraconazole is expected to cause similar rises in vardenafil levels.

### Mechanism

Sildenafil, tadalafil and vardenafil are all metabolised by the cytochrome P450 isoenzyme CYP3A4. Ketoconazole and itraconazole are potent inhibitors of CYP3A4, and therefore inhibit sildenafil, tadalafil and vardenafil metabolism, which leads to an increase in their levels.

### Importance and management

Information about the interaction between phosphodiesterase type-5 inhibitors and azoles is sparse, but what is known is in line with the predicted effects.

For **sildenafil**, when used for erectile dysfunction, the manufacturers recommend that a low starting dose of sildenafil (25 mg) should be considered if itraconazole or ketoconazole are used concurrently. When used for pulmonary hypertension, the manufacturers say that concurrent use of sildenafil with ketoconazole and itraconazole is contraindicated in the UK, and not recommended in the US.

For **tadalafil**, the UK manufacturer advises caution and the US manufacturer advises that the dose of tadalafil should not exceed 10 mg in a 72-hour period for patients taking potent CYP3A4 inhibitors such as ketoconazole. However, note that this dose has caused priapism in one patient taking itraconazole.

The **vardenafil** levels are greatly increased by ketoconazole and probably itraconazole so the UK manufacturer advises avoiding concurrent use in all patients. The use of ketoconazole or itraconazole in patients over 75 years is specifically contraindicated with vardenafil. In contrast, the US prescribing information recommends that the dose of vardenafil should not exceed 5 mg in 24 hours when used with ketoconazole or itraconazole 200 mg daily, or 2.5-mg in 24 hours with ketoconazole or itraconazole 400 mg daily.

Phosphodiesterase type-5 inhibitors + CYP3A4 inducers

Rifampicin markedly reduced tadalafil levels, and is predicted to interact similarly with sildenafil and vardenafil. Other CYP3A4 inducers are likely to have the same effect with these phosphodiesterase type-5 inhibitors.

Clinical evidence

(a) Sildenafil

On the basis of the 63% reduction in AUC seen with the moderate CYP3A4 inducer ‘bosentan’, (p.1274), the US manufacturer of sildenafil says that concurrent use with potent inducers of CYP3A4 such as rifampicin is predicted to cause a greater reduction in sildenafil levels.1,2

(b) Tadalafil

A study2,3 in 12 healthy subjects found that rifampicin 600 mg daily given for 13 days decreased the AUC of a single 10-mg dose of tadalafil by 88%.

Mechanism

Rifampicin induces the activity of the cytochrome P450 isoenzyme CYP3A4, the principal enzyme concerned with the metabolism of sildenafil, tadalafil and vardenafil.

Importance and management

The pharmacokinetic interaction between rifampicin and tadalafil is established, and will almost certainly occur with sildenafil. It is unlikely that standard doses of these phosphodiesterase type-5 inhibitors would be as effective as usual in patients taking rifampicin. Other CYP3A4 inducers such as barbiturates,2 carbamazepine,1,2 flavirenz,2 nevirapine,2 phenobarbital,2,3 phenytoin,2,3 rifabutin,2 and St John’s wort2 are predicted by the manufacturers to do the same (for a list of CYP3A4 inducers see Table 1.4, (p.6)). Despite the marked interaction, the US manufacturer of tadalafil states that no dosage adjustment is warranted.3 Conversely, the manufacturers of sildenafil state that efficacy should be closely monitored in patients taking CYP3A4 inducers,3 or that dose adjustment may be necessary.2 If these phosphodiesterase type-5 inhibitors are not effective in a patients taking a CYP3A4 inducer, it would seem sensible to try a higher dose with close monitoring.

Although the manufacturer of vardenafil does not mention CYP3A4 inducers,2 like tadalafil and sildenafil, vardenafil is principally metabolised by CYP3A4, and its levels are markedly raised by CYP3A4 inhibitors such as ‘ketoconazole’, (p.1270). It is therefore very likely that vardenafil levels will be reduced by rifampicin and similar drugs, and concurrent use should be monitored.

Phosphodiesterase type-5 inhibitors + Grapefruit juice

Grapefruit juice modestly increases the absorption of sildenafil. Tadalafil and vardenafil are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

Grapefruit juice 250 mL was given to 24 healthy subjects both one hour before and with a 50-mg dose of sildenafil. The AUC of sildenafil was increased by 23% by grapefruit juice, but the maximum plasma level was not significantly changed. Inter-individual variation in sildenafil pharmacokinetics was also increased by grapefruit juice. The authors suggest that although the slight rise in AUC is unlikely to be clinically significant, the combination is best avoided due to the increased variability in sildenafil pharmacokinetics.1 However, this seems overcautious, since the manufacturer permits reduced doses of sildenafil with much more potent inhibitors of CYP3A4, such as ‘itraconazole’, (p.1270).

The manufacturers of tadalafil predict that grapefruit juice will increase its levels2,3 and the UK manufacturer advises caution with concurrent use.2

The manufacturers of vardenafil also predict that grapefruit juice will increase its levels1,2 and recommend avoiding this combination.4

Phosphodiesterase type-5 inhibitors + H₂-receptor antagonists

Sildenafil levels are modestly raised by cimetidine. No interaction appears to occur when nizatidine is given with tadalafil and when cimetidine or ranitidine is given with vardenafil.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a study in 10 healthy subjects, cimetidine 800 mg daily for 4 days increased the AUC of a single 50-mg dose of sildenafil given on day 3 by 56%, when compared with 10 healthy subjects given sildenafil and placebo.1 It has been suggested that these changes occur because cimetidine is a non-specific cytochrome P450 inhibitor.2 The manufacturers say that population pharmacokinetic analysis revealed a reduced clearance of sildenafil in patients taking CYP3A4 inhibitors, such as ketoconazole, erythromycin and cimetidine.3,5 The UK manufacturers say that, although no increase in adverse effects was seen, a starting dose of 25 mg of sildenafil should be considered.2 For cimetidine, studies suggest the increase is modest, compared to ‘erythromycin’, (p.1272), and this therefore seems overcautious. Furthermore, no recommendation is made about the sildenafil dose with cimetidine by the US manufacturer.2

(b) Tadalafil

An open-label, randomised, three-period, crossover study in 12 healthy subjects found that nizatidine 300 mg reduced the mean maximum serum levels of tadalafil by 14% following a single 10-mg dose, but other pharmacokinetic parameters, including the extent of absorption, were largely unchanged. None of the changes caused were considered to be clinically relevant and there would appear to be no reason for avoiding concurrent use.4

Any alterations in the absorption of tadalafil are therefore unlikely to be caused by changes in gastric pH.4

(c) Vardenafil

In a three-way crossover study, a single 20-mg dose of vardenafil was given to 10 healthy subjects following a 3-day course of cimetidine 400 mg twice daily, ranitidine 150 mg twice daily or with no pre-treatment. Cimetidine slightly increased the relative bioavailability of vardenafil (by about 12%, not considered clinically relevant), while ranitidine had no effect. It was concluded that any alterations in the absorption of vardenafil are not caused by changes in gastric pH.5 No special precautions appear to be necessary during concurrent use.

Erythromycin raises sildenafil levels almost threefold and raises vardenafil levels fourfold. Clarithromycin raises sildenafil levels about twofold. Erythromycin is predicted to similarly raise tadalafil levels. Azithromycin does not interact with sildenafil.

**Clinical evidence**

(a) **Sildenafil**

In a study in 24 healthy subjects, erythromycin 500 mg twice daily for 5 days was found to increase the AUC of single 100-mg doses of sildenafil almost threefold. In the same study, azithromycin 500 mg once daily for 3 days had no effect on the pharmacokinetics of sildenafil. In another study, in 12 healthy subjects, clarithromycin 500 mg increased the AUC of sildenafil 50 mg 2.3-fold, and the maximum level 2.4-fold.

(b) **Tadalafil**

‘Ketoconazole’, (p.1270), doubles tadalafil levels. The manufacturers therefore predict that other CYP3A4 inhibitors such as erythromycin will interact similarly.

(c) **Vardenafil**

Erythromycin 500 mg three times daily increased the AUC of a 5-mg dose of vardenafil fourfold, and increased the maximum plasma levels threefold in healthy subjects.

**Mechanism**

Sildenafil, tadalafil and vardenafil are all metabolised by the cytochrome P450 isoenzyme CYP3A4. Many macrolides are moderate inhibitors of this isoenzyme and therefore inhibit sildenafil, tadalafil and vardenafil metabolism, which leads to increased levels of the phosphodiesterase inhibitors. Azithromycin does not usually act as a CYP3A4 inhibitor and therefore does not interact.

**Importance and management**

The interaction of the macrolides with the phosphodiesterase type-5 inhibitors is established, although most of the studies concern the use of erythromycin. These interactions are expected to result in both increased efficacy and increased incidence of adverse effects.

For **sildenafil**, the manufacturers recommend that a low starting dose of sildenafil 25 mg should be considered in patients with erectile dysfunction taking inhibitors of CYP3A4 such as erythromycin. For pulmonary hypertension, the UK manufacturer says that a downward reduction of the sildenafil dose to 20 mg twice daily should be considered with erythromycin, and 20 mg once daily with clarithromycin or tadalafil. 

For **tadalafil**, caution is advised by the UK manufacturers as adverse effects may be increased in some patients. They specifically mention erythromycin and azithromycin on the pharmacokinetics of sildenafil citrate in healthy volunteers. BR J Clin Pharmacol (2002) 53, 37S–43S.

For **vardenafil**, the UK manufacturer says that dosage adjustment might be necessary in patients taking erythromycin and recommend that the dose of vardenafil should not exceed 5 mg. The US prescribing information similarly recommends that the dose of vardenafil should not exceed 5 mg in 24 hours for erythromycin, but further restricts the dose in the presence of clarithromycin to 2.5 mg in 24 hours.

Dosing guidance is not given for the other macrolides, but it would seem prudent to follow the advice given for erythromycin in patients taking any macrolide known to inhibit CYP3A4 (e.g. clarithromycin, telithromycin). Azithromycin seems unlikely to interact.

**Phosphodiesterase type-5 inhibitors + Macrolides**

**Phosphodiesterase type-5 inhibitors + Nitrates**

The phosphodiesterase type-5 inhibitors potentiate the hypotensive effects of nitrates in a proportion of patients, which might result in potentially serious hypotension or even precipitate myocardial infarction. Therefore, the concurrent use of sildenafil, tadalafil or vardenafil with organic nitrates (glyceryl trinitrate (nitroglycerin), isosorbide dinitrate, isosorbide mononitrate, etc.) is contraindicated. The concurrent use of nicorandil and all phosphodiesterase type-5 inhibitors is also contraindicated.

**Clinical evidence**

(a) **Sildenafil**

1. Erectile dysfunction. Two double-blind, placebo-controlled studies in groups of 15 or 16 men with angina found that the fall in blood pressure seen when taking nitrates and a single 50-mg dose of sildenafil was about doubled. Those given sildenafil and isosorbide dinitrate 20 mg twice daily had a mean blood pressure fall of 44/26 mmHg compared with 22/13 mmHg with placebo. Those who used 500 micrograms of sublingual glyceryl trinitrate one hour before the sildenafil had a mean blood pressure fall of 36/21 mmHg compared with 26/11 mmHg with glyceryl trinitrate and placebo. Individual blood pressure falls as great as 84/52 mmHg were seen.

A postmarketing report from the FDA in the US for the period late March to July 1998 briefly lists 69 fatalities after taking sildenafil. These were mostly in middle-aged and elderly men (average age 64), 12 of whom had also taken glyceryl trinitrate (nitroglycerin) or a nitrate medication, but it is not clear what part (if any) the nitrates played in the deaths.

In a limited and preliminary study it was reported that no blood pressure alteration was seen when a small dose of glyceryl trinitrate (amount not specified) was given as a dermal patch while subjects were taking 50 mg of sildenafil. In addition, the beneficial effects of the glyceryl trinitrate on the radial artery pressure waveform were approximately doubled, and persisted for up to 8 hours.

2. Pulmonary hypertension. In a study of the combined use of intravenous sildenafil and inhaled nitric oxide in the management of pulmonary hypertension in 15 infants, significant hypotension occurred, which, along with a decrease in oxygenation, was considered sufficiently detrimental for the study to be stopped early. Conversely, beneficial combined use has been described in one adult patient with severe hypoxemia caused by pulmonary hypertension. Note that nitric oxide is not to be confused with the anaesthetic nitrous oxide, which is not a nitric oxide donor and therefore poses no risk, see Mechanism below.

(b) **Tadalafil**

In a double-blind, randomised, placebo-controlled study, 51 patients with chronic stable angina were given tadalafil 5 mg, 10 mg or a placebo, followed 2 hours later by a single 400-microgram dose of sublingual glyceryl trinitrate. Although tadalafil caused little additional decrease in blood pressure to that seen with glyceryl trinitrate, a potentially clinically significant blood pressure reduction (standing systolic BP less than 85 mmHg) was seen in 13 and 11 of the patients when given tadalafil 5 and 10 mg, respectively, compared with one patient in the placebo group.

In a similar study in 45 patients taking long-term oral isosorbide mononitrate, tadalafil 5 or 10 mg had minimal effects on the decrease in blood pressure caused by this nitrate, but again, more patients had a standing systolic BP of less than 85 mmHg when receiving tadalafil 10 mg than placebo (6 versus 0). Another similar study in 48 healthy subjects compared the effects of tadalafil 10 mg, sildenafil 50 mg, and placebo, in combination with sublingual glyceryl trinitrate 400 micrograms. Again, it was found that the presence of the tadalafil had minimal effects on the mean maximum decreases in blood pressure, but it was noted that 23 pa-

---

A single 400-microgram dose of sublingual glyceryl trinitrate (nitroglycerin) given to 18 healthy subjects 1 to 24 hours after a single 10-mg dose of vardenafil was found to be no different to placebo in causing changes in heart rate and blood pressure. However, a single 20-mg dose of vardenafil did potentiate the blood pressure-lowering effects and increases in heart rate (about an 8 mmHg additional drop in systolic BP and about a 2 mmHg additional rise in diastolic BP), the manufacturers of vardenafil 11,13 and tadalafil19,20 say that this effect is not more frequent than the general population of men with erectile dysfunction.8

Mechanism

Sexual stimulation causes the endothelium of the penis to release nitric oxide (NO), which in turn activates guanylate cyclase to increase the production of cyclic guanosine monophosphate (cGMP). This relaxes the blood vessel musculature of the corpus cavernosum thus allowing it to fill with blood and cause an erection. The erection ends when the guanosine monophosphate is removed by an enzyme (type 5 cGMP phosphodiesterase, or PDE5). Sildenafil, tadalafil and vardenafil inhibit this enzyme thereby increasing and prolonging the effects of the guanosine monophosphate. Because this vasodilatation is usually fairly localised (these drugs are highly selective for PDE5) it normally only causes mild to moderate falls in blood pressure (on average about 10 mmHg) with mild headache or flushing. However, if other nitrates (e.g. glyceryl trinitrate) are taken concurrently, high levels of nitric oxide enter the circulation, and this markedly increases systemic vasodilatation and hence the hypotensive effect.

Importance and management

The interaction between phosphodiesterase type-5 inhibitors and nitrates is established, clinically important, potentially serious and even possibly fatal. Sildenafil and organic nitrates of any form are contraindicated both for erectile dysfunction4,14,15 (within 24 hours of each other) and for pulmonary hypertension16,17 because of the risk of precipitating serious hypotension, or even myocardial infarction. The ACC/AHA Expert consensus document provides a useful list of many of the organic nitrates available, which include glyceryl trinitrate (nitroglycerin), isosorbide mononitrate, isosorbide dinitrate and illicit substances such as amyl nitrite.6

Similarly, the manufacturers of vardenafil11,13 and tadalafil19,20 say that their combination with nitrates should not be given for at least 48 hours after the last dose of tadalafil.19,20 It is not yet known whether nicorandil interacts with the phosphodiesterase-inhibitors to a clinically relevant extent or not21 but because part of its vasodilatory actions are mediated by the release of nitric oxide (like conventional nitrates), the manufacturers of nicorandil contraindicate its use with all phosphodiesterase inhibitors.22

Indinavir, saquinavir and ritonavir can cause marked rises in serum sildenafil levels. A fatal heart attack occurred in a man taking ritonavir and saquinavir when he also took sildenafil. Similar marked interactions occur between vardenafil and indinavir or ritonavir, and are predicted to occur between vardenafil and the other protease inhibitors. Ritonavir caused less marked increases in tadalafil levels.

Clinical evidence

A. Sildenafil

(a) Indinavir

A study in 6 HIV-positive patients found that sildenafil 25 mg did not significantly alter the plasma levels of indinavir. However, the sildenafil AUC was about 4.4-fold higher than the AUC in historical control patients taking sildenafil (data normalised to a 25 mg dose) without indinavir.1 A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of nelfinavir.2

(b) Nelfinavir

A study in 5 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of nelfinavir.2

(c) Ritonavir

In a randomised, placebo-controlled, double-blind, crossover study, 28 healthy subjects were given sildenafil 100 mg before and after taking ritonavir for 7 days (300, 400 and 500 mg twice daily on days 1, 2 and 3 to 7, respectively). It was found that the sildenafil AUC was increased 11-fold and the maximum serum levels 3.9-fold by ritonavir, but the incidence and severity of the sildenafil adverse effects and the steady-state levels of ritonavir remained unchanged. However, the clinical significance of this interaction is highlighted by a case report of a 47-year-old man, with no cardiovascular risk factors apart from smoking, who had a fatal heart attack when he took sildenafil 25 mg while he was also taking ritonavir and saquinavir. One hour after the ninth dose, he had an onset of severe chest pain, and died soon after.4

A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of ritonavir (given with saquinavir).3

(d) Saquinavir

In a randomised, placebo-controlled, double-blind crossover study, 28 healthy subjects were given sildenafil 100 mg before and after taking saquinavir 1.2 g three times daily for 7 days. It was found that the sildenafil AUC was increased 3.1-fold and the maximum serum levels 2.4-fold, but the incidence and severity of the sildenafil adverse effects and the steady-state levels of saquinavir remained unchanged.3 Also see (c) above for a case report of a fatal interaction involving sildenafil, ritonavir and saquinavir.

A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of ritonavir-boostered saquinavir.2

Patients given tadalafil and 23 given sildenafil had a standing systolic blood pressure of 85 mmHg or less following the use of the nitrate, compared with 12 in the placebo group.6,9 In a further study, a haemodynamic interaction between tadalafil 20 mg and sublingual glyceryl trinitrate was seen when the glyceryl trinitrate was given 4, 8 and 24 hours after the tadalafil, and was not seen at 48 hours and beyond. Note that no time points between 24 and 48 hours were examined.10 An analysis of the rates of serious cardiovascular adverse events (mortality, myocardial infarction, thrombotic strokes) in clinical studies involving tadalafil indicated that adverse events were no more frequent than in the general population of men with erectile dysfunction.8

Phosphodiesterase type-5 inhibitors + Protease inhibitors

Indinavir, saquinavir and ritonavir can cause marked rises in serum sildenafil levels. A fatal heart attack occurred in a man taking ritonavir and saquinavir when he also took sildenafil. Similar marked interactions occur between vardenafil and indinavir or ritonavir, and are predicted to occur between vardenafil and the other protease inhibitors. Ritonavir caused less marked increases in tadalafil levels.

Phosphodiesterase type-5 inhibitors + Protease inhibitors
Phosphodiesterase type-5 inhibitors; Sildenafil + Antidepressants

Retrospective analysis of clinical study data suggested that SSRIs and tricyclic antidepressants did not alter sildenafil pharmacokinetics. However, in one study fluvoxamine was found to modestly increase the levels and vascular effects of sildenafil.

Clinical evidence

The manufacturer notes that population pharmacokinetic analysis of clinical study data indicate that inhibitors of cytochrome P450 isoenzyme CYP2D6 such as SSRIs and tricyclic antidepressants do not have any effect on the pharmacokinetics of sildenafil. However, in a double-blind, placebo-controlled study in healthy subjects, pre-treatment with fluvoxamine 50 mg daily for 3 days then 100 mg daily for 6 days increased the AUC of sildenafil 50 mg by 40%. This resulted in an increase in the vascular effects of sildenafil.

Mechanism

Sildenafil is principally metabolised by cytochrome P450 isoenzyme CYP3A4, and to a lesser extent by CYP2C9. Fluvoxamine probably raises sildenafil by inhibition of both of these isoenzymes. Grouping all SSRIs and tricyclics together in a retrospective analysis would not be a sensitive enough technique to have picked up this modest effect of fluvoxamine.

Importance and management

The increases in sildenafil levels with fluvoxamine are modest, and the authors concluded that they do not suggest a large clinically relevant interaction. Nevertheless, they suggest it may be prudent to consider a 25-mg starting dose of sildenafil in patients taking fluvoxamine. This may be sensible. Although retrospective analyses of clinical study data are useful to identify potentially important drug interactions, they are not sensitive enough to rule out interactions, and should not replace prospective pharmacokinetic studies.

Phosphodiesterase type-5 inhibitors; Sildenafil + Bosantan

Bosantan markedly reduces sildenafil levels.

Clinical evidence

In 10 patients with pulmonary hypertension, bosantan 62.5 mg twice daily for one month decreased the AUC of a single 100-mg dose of sildenafil by 53% and increased its clearance 2.3-fold. A second month of bosantan at an increased dose of 125 mg twice daily, the AUC of a single 100-mg dose of sildenafil was reduced by 69%, and the clearance increased 3.4-fold. The AUC of the primary metabolite, desmethyl-sildenafil, was also decreased in a dose-dependent manner by bosantan.

In a further study in healthy subjects, the concurrent use of bosantan 125 mg twice daily and sildenafil 80 mg three times daily for 6 days decreased the AUC of sildenafil by 63%.

Mechanism

Bosantan induces the cytochrome P450 isoenzyme CYP3A4 and CYP2C9, by which sildenafil is metabolised.

Importance and management

This pharmacokinetic interaction is established and potentially clinically important. The efficacy of sildenafil is likely to be reduced in patients taking bosantan, and should be closely monitored.
Phosphodiesterase type-5 inhibitors; Sildenafil + Dihydrocodeine

Two men using sildenafil had prolonged erections following orgasm while also taking dihydrocodeine.

Clinical evidence, mechanism, importance and management

Two men, successfully treated with 100-mg doses of sildenafil for erectile dysfunction, experienced prolonged erections after orgasm while also taking dihydrocodeine 30 to 60 mg every 6 hours for soft tissue injuries. One of them had two erections lasting 4 and 5 hours, and this did not occur on subsequent occasions when the dihydrocodeine was stopped. The other had 2 to 3 hour erections on three occasions during the first week of dihydrocodeine use, but no problems over the next 2 weeks while continuing to take the dihydrocodeine.\(^1\) The reasons are not understood.

According to the manufacturers of sildenafil, priapism (painful prolonged abnormal erection) associated with its use is rare, and there appear to be no other reports about an interaction between sildenafil and dihydrocodeine. Excessively prolonged erections can have serious consequences and may need urgent treatment. Therefore, the authors suggest it would now be prudent to warn patients about this possible (though remote) problem if opioids are being used, and advise them to contact the prescriber if priapism occurs.\(^1\)

Phosphodiesterase type-5 inhibitors; Sildenafil + Ecstasy

The abuse of sildenafil and ecstasy (MDMA, methylenedioxymethamphetamine) has been reported to result in serious headache and priapism requiring emergency treatment.

Clinical evidence, mechanism, importance and management

A journalist’s account, based purely on anecdotal reports, claims that the illicit use of sildenafil with ecstasy (MDMA, methylenedioxymethamphetamine) causes “hammerheading” because of the pounding headache and the prolonged and painful penis erections that require emergency medical treatment.\(^1\) The report does not say how much of each of these drugs is taken to produce these adverse effects. The outcome can clearly be unpleasant, painful and, the priapism, potentially serious.

Phosphodiesterase type-5 inhibitors; Sildenafil + Miscellaneous

No pharmacokinetic interaction appears to occur between sildenafil and a combined oral contraceptive or tolbutamide.

Clinical evidence, mechanism, importance and management

(a) Oral contraceptives

The pharmacokinetics of sildenafil were not altered by concurrent use of a combined oral contraceptive (ethinylestradiol/levonorgestrel), and the plasma levels of these contraceptive steroids were not altered by sildenafil.\(^1,2\)

(b) Tolbutamide

Sildenafil 50 mg did not alter the pharmacokinetics of tolbutamide 250 mg,\(^3,4\) probably because sildenafil is only a weak inhibitor of the cytochrome P450 isoenzyme CYP2C9 (consider also ‘warfarin’, (p.441)).

Phosphodiesterase type-5 inhibitors; Vardenafil + Miscellaneous

The manufacturers of vardenafil suggest the avoidance of class la and III antiarrhythmics because of fears of possible QT interval prolongation. No clinically significant interaction has been seen between vardenafil and food, glibenclamide (glyburide), metformin or sulphonylureas.

Clinical evidence, mechanism, importance and management

(a) Antiarrhythmics (class Ia and III)

Vardenafil 10 mg and 80 mg caused very small (8 and 10 millisecond) increases in the corrected QT interval in healthy subjects.\(^1,2\) This increase was similar to that seen with a single 400-mg dose of moxifloxacin,\(^2\) a drug known to cause moderate QT-prolongation. Because of this, the manufacturers recommend that vardenafil is not used in those taking class Ia antiarrhythmics (e.g. quinidine, procainamide) or class III antiarrhythmics (e.g. amiodarone, sotalol), which are also known to prolong the QT interval.\(^1,2\) Note that prolongation of the QT interval is associated with an increased risk of the potentially fatal torsade de pointes arrhythmia (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

(b) Antidiabetics

The manufacturers say that the pharmacokinetics of glibenclamide (glyburide) were not affected by a single 20-mg dose of vardenafil,\(^1\) and that vardenafil had no effect on glibenclamide pharmacodynamics (glucose and insulin levels).\(^2\) Also, although no specific pharmacokinetic study has been conducted, the manufacturers say that population pharmacokinetic analysis suggests that sulphonylureas (not named) and metformin have no effect on vardenafil pharmacokinetics. No additional precautions therefore seem necessary on concurrent use.\(^1\)

(c) Food

In a single-dose study, healthy subjects were given a single 20-mg dose of vardenafil on four occasions; after an overnight fast, on an empty stomach, following a high-fat breakfast (fat 58 g), or following a moderate-fat evening meal (fat 23 g). No pharmacokinetic changes were noted in the fasting or moderate-fat periods. Although the high-fat breakfast caused a slight decrease and a slight delay in the absorption of vardenafil this was not considered to be sufficient to warrant changing the dosing time or making dosage adjustments. Therefore vardenafil may be given without regard to meals.\(^3\)

Pseudoephedrine + Antacids or Antidiarrhoeals

Kaoïn does not appear to interact significantly with pseudoephedrine, but aluminium hydroxide may possibly cause a more rapid onset of action.

Clinical evidence

In a single-dose crossover study in 6 healthy subjects, 30 mL of aluminium hydroxide gel did not affect the total amount of pseudoephedrine absorbed from a single 60-mg dose over 24 hours, but the rate of absorption was significantly increased during the first 3 hours.\(^1\) Conversely, 30 mL of a 30% suspension of kaoïn reduced the amount of pseudoephedrine absorbed from a single 60-mg dose by just 10%. The rate of absorption was also decreased.\(^1\)
Mechanism

The increased rate of absorption of pseudoephedrine seen with aluminium hydroxide is probably also due to pH rises, which favour the formation of the lipid-soluble absorbable form of pseudoephedrine. The reduced absorption with kaolin is probably due to adsorption of the pseudoephedrine onto the surface of the kaolin.

Importance and management

Aluminium hydroxide may possibly cause a more rapid onset of pseudoephedrine activity (but this needs confirmation). Any interaction seems unlikely to be clinically significant. Similarly, the effects of kaolin on absorption are small and unlikely to be clinically important. For the effect of sodium bicarbonate on pseudoephedrine and ephedrine, see ‘urinary alkalinisers’, (p.1277).

Pseudoephedrine and related drugs + Caffeine

Phenylpropanolamine can raise blood pressure and in some cases this may be further increased by caffeine. Combined use has resulted in hypertensive crises in a few individuals. Ephedrine may interact similarly. Phenylpropanolamine can markedly raise plasma caffeine levels, and isolated reports describe the development of acute psychosis when caffeine was given with phenylpropanolamine or ephedrine.

Clinical evidence

(a) Ephedrine

In a single-dose, randomised study, 15 healthy subjects were given ephedrine 25 mg, caffeine 200 mg, both drugs together, or placebo. An assessment of systolic blood pressure found that ephedrine had no significant effect, caffeine caused a 9.1 mmHg increase, and the use of both drugs resulted in an 11.7 mmHg increase. Caffeine alone did not increase heart rate, but both ephedrine and ephedrine plus caffeine caused increases of roughly 11%. Subjective tests suggested that there was no significant difference in feelings of headache, chest pain, heart pounding or shortness of breath between the treatments. There was no significant pharmacokinetic interaction between the drugs.1 In another randomised study, investigating the combination of ephedrine 20 mg and caffeine 200 mg, both three times daily, for weight loss, did not find any significant hypertensive effects with the combination, although the authors suggested that this may have been due to the favourable effects of weight loss on blood pressure. However, one patient was withdrawn due to a rise in blood pressure, to 185/125 mmHg.2

A review of reports from the FDA in the US revealed that several patients have experienced severe adverse effects (subarachnoid haemorrhage, cardiac arrest, hypertension, tachycardia and neurosis) after taking tablets containing ephedrine or ephedra alkaloids and caffeine, or ephedra alkaloids alone.3 However, it is not possible to definitively say that these effects were the result of an interaction because none of the patients took either drug separately. Similarly, a meta-analysis assessing the safety of ephedrine and pseudoeaphrous (‘Vigueur Fit’) tablets, caffeine in ‘Red Bull’ and alcohol.4

In a placebo-controlled study, the mean blood pressure of 16 healthy subjects rose by 11/12 mmHg after they took caffeine 400 mg, by 12/13 mmHg after they took phenylpropanolamine 75 mg, and by 12/11 mmHg when both drugs were taken. Phenylpropanolamine 150 mg caused a greater rise of 36/18 mmHg. One of the subjects had a hypertensive crisis after taking phenylpropanolamine 150 mg and again 2 hours after taking caffeine 400 mg. This needed antihypertensive treatment.5 The same group of workers describe a similar study in which the AUC of caffeine 400 mg increased by more than threefold, and the mean peak caffeine concentration increased almost fourfold (from 2.1 to 8 micrograms/mL) after phenylpropanolamine 75 mg was given.6 Additive increases in blood pressure are described in another report.7

Importance and management

Phenylpropanolamine-containing decongestants (sometimes called ma huang) and therefore these preparations may pose a serious health risk to some users.8 The risk may be affected by individual susceptibility, the additive stimulant effects of caffeine, the variability in the contents of alkaloids in non-prescription dietary supplements, or pre-existing medical conditions.9 One study in healthy subjects found that no adverse clinical response to the enhanced cardiac effects of the combination concluded that the cardiac effects could be clinically significant in patients with compromised cardiac function.1 The authors of one report advised that likely users of phenylpropanolamine (those with allergies or the overweight) and those particularly vulnerable (elderly or hypertensive patients) should be warned about taking more than the recommended dose of phenylpropanolamine, and also about taking caffeine at the same time, because of the possible risk of intracranial haemorrhage.

Note that, phenylpropanolamine is no longer available in the US and UK and its use has been restricted in many other countries. In addition, because of the associated health risks, the FDA bans combinations of caffeine with ephedrine or pseudoephedrine, and also bans herbal products containing ephedra.

Pseudoephedrine and related drugs + Urinary acidifiers or alkalinisers

Alkalisation of the urine (e.g. by sodium bicarbonate) causes retention of ephedrine and pseudoephedrine by the kidneys, leading to the possible development of toxicity (tremors, anxiety, insomnia, tachycardia). Acidification of the urine (e.g. with ammonium chloride) has the opposite effect.

Clinical evidence

(a) Ephedrine

When the urine was made acidic (pH of about 5) with ammonium chloride, the excretion of ephedrine in the urine of three healthy subjects was two to fourfold higher than when the urine was made alkaline (pH of about 8) with sodium bicarbonate.1

(b) Pseudoephedrine

A patient with renal tubular acidosis and persistently alkaline urine developed unexpected toxicity (cachexia and personality changes) when given therapeutic doses (not stated) of pseudoephedrine for 2.5 months. She was found to have a very prolonged pseudoephedrine half-life of 50 hours (10 times normal). Therefore 8 subjects (adults and children) were studied, to establish the possible effects of changing the urinary pH on pseudoephedrine elimination. When the urinary pH was adjusted using ammonium chloride or sodium bicarbonate, within the approximate range of 5.7 to 7.8, the half-life of a single dose of pseudoephedrine (about 5 mg/kg) was found to increase from 1.9 hours at the lowest pH to 21 hours at the highest pH.2 This confirms an earlier study, in which it was found that at a urinary pH of 8, the half-life of pseudoephedrine was 16, 9.2, and 15 hours in 3 subjects, respectively. At a urinary pH of about 5, the half-life was 4.8, 3, and 2.3. Sodium bicarbonate was given to raise urinary pH and ammonium chloride to lower urinary pH.

Another study in 6 healthy subjects found that sodium bicarbonate 5 g initially increased the excretion rate of a single 60-mg dose of pseudoephedrine, but as the urinary pH increased the excretion of pseudoephedrine was reduced.4

Mechanism

Ephedrine and pseudoephedrine are basic drugs, which are mainly excreted unchanged in the urine. In acidic urine, most of the drug is ionised in the tubular filtrate and unable to diffuse passively back into the circulation, and is therefore lost in the urine. In alkaline urine, these drugs mostly exist in the lipid-soluble form, which are reabsorbed.

The increased rate of absorption of pseudoephedrine seen with sodium bicarbonate is probably also due to pH rises, which favour the formation of the lipid-soluble absorbable form of pseudoephedrine.

Importance and management

The interaction between ephedrine or pseudoephedrine and urinary alkalinisers is established but reports of adverse reactions in patients appear to be rare. Be aware that any increase in the adverse effects of these drugs (tremor, anxiety, insomnia, tachycardia, etc.) could be due to drug retention brought about by this interaction. Acetazolamide makes the urine alkaline and would be expected to interact with ephedrine and pseudoephedrine in the same way as sodium bicarbonate.

Acidification of the urine with ammonium chloride increases the loss of ephedrine and pseudoephedrine in the urine and could be exploited in cases of drug overdosage.

PUVA therapy + Herbal medicines or Foods

Two case reports describe photosensitivity, one in a patient taking rue (Ruta graveolens) and another in a patient who ate large amounts of celery soup.

Clinical evidence, mechanism, importance and management

A 35-year-old woman taking methoxsalen and undergoing PUVA for psoriasis unexpectedly developed increased photosensitivity. Over the previous weekend and on the morning of therapy she had been drinking a concoction of rue (Ruta graveolens).1 This plant naturally contains 5-methoxypsoralen so it would appear that a pharmacodynamic interaction occurred, which resulted in the photosensitivity.

The authors note that other herbal products contain photosensitising substances (e.g. those containing members of the Umbelliferae family, such as celery, or Chlorella species), and so suggest that patients undergoing PUVA should be warned about the potential interactions.1 This warning appears justified by the case of a woman taking methoxsalen and undergoing PUVA, who developed photosensitivity after eating a large quantity of soup containing celery, parsnip and parsley.2

Raloxifene + Miscellaneous

The absorption of raloxifene is reduced by colestyramine, and their concurrent use is not recommended. No clinically relevant changes in raloxifene pharmacokinetics occur with aluminium/magnesium hydroxide, amoxicillin, ampicillin or calcium carbonate. Raloxifene does not alter digoxin or methylprednisolone levels. Oral antibacterials, antihistamines, aspirin, benzodiazepines, H2-receptor antagonists, ibuprofen or paracetamol (acetaminophen) were used in clinical studies without any obvious effect on raloxifene levels. Smoking does not appear to alter the efficacy of raloxifene.

Clinical evidence, mechanism, importance and management

(a) Ampicillin and Amoxicillin

Ampicillin is reported to reduce the maximum serum levels of raloxifene by 28% and the extent of the absorption by 14% without affecting the elimination rate.1 This is thought to be because ampicillin reduces the number of enteric bacteria and so reduces enterohepatic recycling of raloxifene. These small changes are unlikely to be clinically relevant. In another clinical efficacy study, there was no discernible difference in plasma raloxifene levels when taken with amoxicillin.1

(b) Antacids

The manufacturers of raloxifene report that in studies, an antacid containing aluminium/magnesium hydroxide given 1 hour before and 2 hours after raloxifene had no effect on its absorption. Also, no interaction was seen with calcium carbonate.2 There would therefore appear to be no reason for avoiding concurrent use.

(c) Colestyramine

The manufacturers report that colestyramine reduced the absorption of raloxifene by about 60% due to an interruption in enterohepatic cycling.1 It is recommended that these two drugs should not be used concurrently.1,3

(d) Digoxin

Raloxifene is reported not to affect the steady-state AUC of digoxin, while the maximum serum levels of digoxin were increased by less than 5%.3
(e) Methylprednisolone

Steady state raloxifene had no effect on the pharmacokinetics of a single oral dose of methylprednisolone.1,3

(f) Tobacco

Retrospective analysis of data from a placebo-controlled study of raloxifene found that raloxifene was equally effective in current tobacco smokers as non-smokers, although smokers had a lower baseline bone mineral density.4

(g) Miscellaneous

Data from clinical efficacy studies revealed no clinically relevant differences in the plasma levels of raloxifene when stratified according to concurrent drug use. These drugs included oral antibacterials (not named), antihistamines (not named), aspirin, benzodiazepines (not named), H1-receptor antagonists (not named), NSAIDs (ibuprofen, naproxen), and paracetamol (acetaminophen).3 There would therefore appear to be no reason for avoiding the concurrent use of any of these drugs with raloxifene.

Retinoids + Food

Fatty foods increase the absorption of acitretin, etretinate and isotretinoin.

Clinical evidence

(a) Acitretin

The absorption of acitretin was increased by 90% and the peak plasma concentrations were increased by 70% when acitretin 50 mg was taken by 18 healthy subjects with a standard breakfast. The breakfast consisted of two poached eggs, two slices of toast, two pats of margarine and 8 oz (about 240 mL) of skimmed milk.1

(b) Etretinate

Studies have found that high-fat meals and milk cause about a two to fivefold increase in the absorption of etretinate, when compared with high-carbohydrate meals or when fasting.2,3

(c) Isotretinoin

In a study in 20 healthy subjects the AUC of a single 80-mg dose of isotretinoin was increased 1.4-fold, 1.7-fold, and 1.9-fold when taken one hour before a standard breakfast, during breakfast, and one hour after breakfast, respectively, when compared with the same dose of isotretinoin taken 4 hours before breakfast.4

Mechanism

It is thought that because these retinoids are lipid soluble they become absorbed into the lymphatic system by becoming incorporated into the bile-acid micelles of the fats in the food. In this way losses due to first-pass liver metabolism and gut wall metabolism are minimised, and bioavailability increased.

Importance and management

Established interactions of clinical importance. The manufacturers of acitretin recommend taking it with meals5,6 or with milk,7 and the manufacturers of isotretinoin recommend taking it with food.7,8 Similar recommendations were made with etretinate.9

Retinoids + Tetracyclines

The development of ‘pseudotumour cerebri’ (benign intracranial hypertension) has been associated with the concurrent use of acitretin or isotretinoin and tetracyclines.

Clinical evidence, mechanism, importance and management

The concurrent use of isotretinoin and a tetracycline has resulted in the development of ‘pseudotumour cerebri’ (i.e. a clinical picture of cranial hypertension with headache, dizziness and visual disturbances). By 1983, the FDA in the US had received reports of 10 patients with ‘pseudotumour cerebri’ and/or papilloedema associated with the use of isotretinoin. Four had retinal haemorrhages, and 5 of the 10 were also taking a tetracycline.1 The manufacturers also have similar reports on file of 3 patients given isotretinoin and either minocycline or tetracycline.2 The same reaction has been seen in a patient given etretinate with minocycline.3 It seems that the tetracyclines and retinoids have an additive effect in increasing intracranial pressure. The manufacturers of acitretin4 and isotretinoin5,6 contraindicate their use with tetracyclines.

Retinoids + Vitamin A (Retinol)

A condition similar to vitamin A (retinol) overdosage may occur if acitretin or isotretinoin are given with vitamin A.

Clinical evidence, mechanism, importance and management

Combined treatment with isotretinoin and vitamin A may result in a condition similar to overdosage with vitamin A. Concurrent use should therefore be avoided or very closely monitored because changes in bone structure can occur, including premature fusion of the epiphyseal discs in children.1

The manufacturers of acitretin2 say that the concurrent use of vitamin A should be avoided. In the UK2 they advise no more than 4000 to 5000 units daily, which is the recommended daily allowance, and in the US3 they advise doses of no more than the minimum recommended daily allowance. Similarly, the manufacturers of isotretinoin4 say that vitamin A should be avoided.5

Ritodrine + Miscellaneous

Supraventricular tachycardia developed in a woman given ritodrine when she was also given glycopyrronium (glycopyrrolate). Tachycardia has also been reported in two patients when atropine was used with ritodrine. Hypertension has been reported when cyclopropane was given to patients who had recently received ritodrine. The abuse of cocaine does not appear to increase the incidence of adverse effects in patients given ritodrine.
Clinical evidence, mechanism, importance and management

(a) Anaesthetics

In an analysis of 43 women who had a caesarean section under cyclopropane anaesthesia, all of the 6 who had previously been given ritodrine developed unacceptably high blood pressure (185/103 mmHg) after cyclopropane was started. Arrhythmias were reported in 2 of these patients.1

(b) Antimuscarinics

Premature labour in a 39-year-old woman who was 28 weeks pregnant was arrested with an intravenous infusion of ritodrine hydrochloride. Two weeks later, while she was on the maximum dose of ritodrine (300 micrograms/minute), her uterine contractions began again and she was scheduled for emergency caesarean section. The ritodrine was discontinued 40 minutes before the operation. It was noted in the operating room that she had copious oral secretions so she was given 100% oxygen by mask and 200 micrograms of intravenous glycopyrronium (glycopyrrolate). Shortly afterwards she developed a supraventricular tachycardia (a rise in heart rate from 80 to 180 to 180 bpm), which was converted to sinus tachycardia of 130 bpm when she was given intravenous propanolol 500 micrograms, in divided doses over several minutes.2

The reason for this reaction is not understood. Ritodrine alone has been responsible for tachyarrhythmias and one possible explanation for this interaction is that the effects of these two drugs were additive. Two other patients given intravenous ritodrine 6 mg over 3 minutes developed tachyarrhythmias when they were premedicated with atropine.3 Information is very limited and the interaction is not well established but some caution is clearly appropriate if both drugs are used. The authors of the first report advise avoidance.

Other sympathomimetics have also been seen to interact with antimuscarinics, see ‘Inotropes and Vasopressors + Antimuscarinics’, p.889.

(c) Cocaine

A study in 51 pregnant patients given ritodrine for premature labour found no evidence of an increase in adverse effects in 17 of the patients who had been abusing cocaine.4

Sodium oxybate + Miscellaneous

Patients taking sodium oxybate should not drink alcoholic beverages with sodium oxybate. Additive CNS depressant effects are predicted with other CNS depressant drugs, and concurrent use of sedative hypnotics should be avoided. No pharmacokinetic interaction occurs with omeprazole, protriptyline, zolpidem or modafinil, but a pharmacodynamic interaction cannot be ruled out. Food markedly delays and modestly reduces the absorption of sodium oxybate.

Clinical evidence, mechanism, importance and management

(a) Alcohol and other CNS depressants

Sodium oxybate is the sodium salt of gamma hydroxybutyrate (GHB) a CNS depressant substance with well known abuse potential. When used clinically it is predicted to have additive effects with alcohol and other CNS depressants and the manufacturers specifically say it should not be used with these.1,2 Patients should be warned not to drink alcoholic beverages while taking sodium oxybate.1,2

1. Antidepressants. The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and protriptyline, but that the possibility of a pharmacodynamic interaction was not assessed.1,2 The UK manufacturer states that the rate of adverse effects was increased when sodium oxybate was given with tricyclic antidepressants.1

2. Barbiturates. The UK manufacturer specifically contraindicates the use of sodium oxybate in patients taking barbiturates.1

3. Benzodiazepines and related hypnotics. The manufacturer states that sodium oxybate should not be given in combination with sedative hypnotics,1,2 and the UK manufacturer specifically cautions against the concurrent use of benzodiazepines because of the possibility of increased risk of respiratory depression.1

The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and zolpidem, but that the possibility of a pharmacodynamic interaction was not assessed,1 and cannot be ruled out.2

4. Opioids. The UK manufacturer specifically contraindicates the use of sodium oxybate in patients taking opioids.1

(b) Food

In a study in 34 healthy subjects 4.5 g of sodium oxybate solution was given after a high-fat meal. It was found that food delayed the time to maximum level from 0.75 to 2 hours, reduced the maximum level by 58% and reduced the AUC by 35%, when compared with the fasted state.3 The first dose of sodium oxybate should be taken at least 2 hours after the evening meal, and patients should always try to keep the same timing of dosing in relation to meals.1,2

(c) Modafinil and other CNS stimulants

The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and modafinil, but that the possibility of a pharmacodynamic interaction was not assessed.1,2 About 80% of patients in clinical studies were also taking CNS stimulants.1

(d) Proton pump inhibitors

In a crossover study in 44 healthy subjects pretreatment with omeprazole 40 mg daily for 5 days did not alter the pharmacokinetics of a single 3-g dose of sodium oxybate. There was no difference in the frequency and severity of adverse events.3 No sodium oxybate dose adjustment is therefore expected to be needed in patients taking proton pump inhibitors.1

1. Xyrem (Sodium oxybate). UCB Pharma Ltd. UK Summary of product characteristics, March 2007.

Sodium polystyrene sulfonate + Antacids

The concurrent use of antacids with sodium polystyrene sulfonate can result in metabolic alkalosis. Use with aluminium hydroxide has resulted in intestinal obstruction.

Clinical evidence, mechanism, importance and management

A man with hyperkalaemia developed metabolic alkalosis when given 30 g of sodium polystyrene sulfonate with 30 mL of magnesium hydroxide mixture three times daily.1 Alkalosis has also been described in a study in a number of patients given this cation exchange resin with Maalox (magnesium/aluminium hydroxide) and calcium carbonate.2 The suggested reason is that the breakdown of the magnesium hydroxide usually requires equal amounts of bicarbonate and hydrogen ions, and so does not cause any acid-base disturbance. However, when sodium polystyrene sulfonate is given, it binds the magnesium, while the hydroxide is neutralised by the hydrogen ions. This results in a relative excess of bicarbonate ions, which are absorbed, leading to metabolic alkalosis. This interaction appears to be established. Concurrent use should be undertaken with caution and serum electrolytes should be closely monitored. Administration of the resin rectally as an enema can avoid the problem.

In addition to alkalosis, the manufacturer also notes that concurrent use of aluminium hydroxide and the resin has resulted in intestinal obstruction due to ‘concretions’ of aluminium hydroxide.3 Caution is advised.

**Sodium polystyrene sulfonate + Sorbitol**

Potentially fatal colonic necrosis may occur if sodium polystyrene sulfonate is given as an enema with sorbitol.

**Clinical evidence**

Five patients with uraemia developed severe colonic necrosis after being given enemas containing sodium polystyrene sulfonate and sorbitol for the treatment of hyperkalaemia. Four of the 5 died as a result. Associated studies in uraemic rats found that all of them died over a 2-day period after being given enemas of sodium polystyrene sulfonate with sorbitol. Extensive haemorrhage and transmural necrosis developed. No deaths occurred when enemas without sorbitol were given.1

**Mechanism**

Not understood.

**Importance and management**

Information is very limited and the interaction is not firmly established, nevertheless its seriousness indicates that sodium polystyrene sulfonate should not be given as an enema in aqueous vehicles containing sorbitol. More study is needed. Note that the manufacturer advises against the concurrent use of both oral and rectal sorbitol with sodium polystyrene sulfonate, because of the risk of colonic necrosis.2

**St John’s wort (Hypericum perforatum) + Cimetidine**

Cimetidine does not significantly alter the metabolism of the constituents of St John’s wort, hypericin and pseudohypericin.

**Clinical evidence, mechanism, importance and management**

A placebo-controlled study in healthy subjects taking St John’s wort (LI160, Lichtwer Pharma) 300 mg three times daily found that, apart from a modest 25% increase in the AUC of pseudohypericin, cimetidine 1 g daily (in divided doses) did not significantly affect the pharmacokinetics of either the hypericin or pseudohypericin constituents of St John’s wort. The available evidence therefore suggests that cimetidine is unlikely to affect the dose requirements of St John’s wort.1

**Strontium ranelate + Miscellaneous**

Food, dairy products and calcium compounds markedly reduce the absorption of strontium ranelate, and administration should be separated by at least 2 hours. Aluminium and magnesium antacids only slightly reduce strontium ranelate absorption. Strontium ranelate is predicted to reduce the absorption of the quinolones and the tetracyclines, and strontium should be stopped during courses of these antibacterials. Vitamin D does not affect strontium ranelate bioavailability.

**Clinical evidence, mechanism, importance and management**

**(a) Antacids**

The manufacturer notes that aluminium/magnesium hydroxide slightly reduced the absorption of strontium ranelate (AUC decreased by 20 to 25%) when given either at the same time or 2 hours before the strontium. However, when the antacid was given 2 hours after strontium, absorption was barely affected.1 Therefore, the manufacturers recommend that antacids should be taken 2 hours after strontium ranelate. However, because it is also recommended that strontium ranelate is taken at bedtime, they say that, if this is impractical, concurrent intake is acceptable.1 Note that calcium-containing antacids would have a greater effect, see (b) below, and concurrent intake would not be recommended.

**(b) Food, Dairy products, and Calcium compounds**

The manufacturers note that food, milk, dairy products, and calcium supplements reduce the bioavailability of strontium ranelate by about 60 to 70%, when compared with administration 3 hours after a meal.1 This is because divalent cations such as calcium form complexes with strontium ranelate so preventing its absorption. Therefore, strontium ranelate should not be taken within 2 hours of eating, or presumably within 2 hours of any calcium compound. The manufacturer recommends that strontium ranelate should be taken at bedtime, at least 2 hours after eating.1

**(c) Quinolones and Tetracyclines**

The manufacturer predicts that strontium will complex with quinolones and tetracyclines, so preventing their absorption. Because of this, they recommend that when treatment with quinolones or tetracyclines is required, strontium ranelate therapy should be temporarily suspended.1

**(d) Vitamin D**

The manufacturer notes that vitamin D supplements had no effect on strontium ranelate bioavailability.1

**Sulfinpyrazone + NSAIDs**

The uricosuric effects of sulfinpyrazone are not opposed by the concurrent use of flufenamic acid, meclofenamic acid or mefenamic acid.1,2 Consider also ‘Aspirin or other Salicylates + Sulfinpyrazone’, p.138).

**Sulfinpyrazone + Probencid**

Probencid reduces the urinary excretion of sulfinpyrazone, but the overall uric acid clearance remains unaltered.

**Clinical evidence, mechanism, importance and management**

A study in 8 patients with gout showed that while probencid was able to inhibit the renal tubular excretion of sulfinpyrazone, reducing it by about 75%, the maximal uric acid clearance was about the same as when either drug was given alone.1 There would therefore seem to be no advantage in using these drugs together. The possibility of an increase in the adverse effects of sulfinpyrazone does not seem to have been studied.

**Thyroid hormones + Antacids**

A few reports describe reduced levothyroxine effects in patients given aluminium or magnesium-containing antacids.
Clinical evidence, mechanism, importance and management

A man with hypothyroidism corrected with levothyroxine 150 micrograms daily developed high serum TSH levels (a rise from 1.1 up to 36 mU/L) while taking an aluminum/magnesium hydroxide antacid (Silain-Gel), and on two subsequent occasions when rechallenged. The reasons are not understood. Although he remained asymptomatic throughout, the rise in the levels of TSH indicated that the dosage of the levothyroxine was halved. The reason for this effect is not known, but it seems possible that in this case these two barbiturates acted in the same way, probably by enzyme induction. The general importance of this interaction is almost certainly small, but be alert for any evidence of changes in thyroid status if barbiturates are added or withdrawn from patients taking levothyroxine. Consider also ‘Thyroid hormones + Antiepileptics’, above.

Thyroid hormones + Antiepileptics

An isolated report describes a patient, previously stable taking levothyroxine, who developed clinical hypothyroidism when phenytoin was given. Both carbamazepine and phenytoin can reduce endogenous serum thyroid hormone levels, but clinical hypothyroidism caused by an interaction seems to be rare.

Clinical evidence

A patient with hypothyroidism had been successfully managed with 150 micrograms of levothyroxine daily for 4 years, developed hypothyroidism when given 300 mg of phenytoin daily. Doubling the levothyroxine dosage proved to be effective. Later this interaction was confirmed when stopping and restarting the phenytoin produced the same effect. A number of other reports describe very significant reductions in endogenous markers of thyroid function in subjects and patients taking phenytoin or carbamazepine, but not sodium valproate. However, there seems to be only two cases in which reversible hypothyroidism was seen, one with carbamazepine and phenytoin, and the other with carbamazepine alone. There is also a report of an arrhythmia in a patient with hypothyroidism and rheumatic heart disease given phenytoin; this was attributed to the displacement of protein bound levothyroxine by phenytoin leading to an increase in free levothyroxine in the plasma. This report was later criticised by others, who suggested that the arrhythmia, if indeed there was one, was caused directly by the cardiac actions of phenytoin.

Mechanism

Both phenytoin and carbamazepine can increase the metabolism of endogenous thyroid hormones, thereby reducing their plasma levels. Phenytoin can also displace levothyroxine and triiodothyronine from thyroxine binding globulin.

Importance and management

Despite very clear evidence that both carbamazepine and phenytoin can cause a marked reduction in endogenous serum thyroid hormone levels, the development of clinical hypothyroidism seems to be very rare, and there seems to be only one case on record of an interaction between levothyroxine and phenytoin. There seems to be little reason for avoiding concurrent use, but the outcome should be monitored. Increase the levothyroxine dosage if necessary. Consider also ‘Thyroid hormones + Barbiturates’, below.

Thyroid hormones + Barbiturates

An isolated report describes a reduction in the response to levothyroxine when a woman also took a barbiturate. See also ‘Thyroid hormones + Antiepileptics’, p.1281.

Clinical evidence, mechanism, importance and management

An elderly woman taking 300 micrograms of levothyroxine daily for hypothyroidism complained of severe breathlessness within a week of reducing her nightly dose of Tuinal (secobarbital 100 mg with amobarbital 100 mg) from two capsules to one capsule. She was subsequently found to be thyrotoxic. She became symptom-free again when the dosage of the levothyroxine was halved. The reason for this effect is not known, but phenobarbital has been shown to reduce the serum levels of endogenous thyroid hormones in some studies, and it seems possible that in this case these three barbiturates acted in the same way, probably by enzyme induction. The general importance of this interaction is almost certainly small, but be alert for any evidence of changes in thyroid status if barbiturates are added or withdrawn from patients taking levothyroxine. Consider also ‘Thyroid hormones + Antiepileptics’, above.

Thyroid hormones + Calcium carbonate

The efficacy of levothyroxine can be reduced by calcium carbonate.

Clinical evidence

Twenty patients with hypothyroidism were given levothyroxine, to which calcium carbonate 1.2 g daily was then added for 3 months. While taking the calcium carbonate their mean free thyroxine levels fell from 16.7 to 5.4 picoM/L and rise again to 18 picoM/L when it was stopped. The mean total thyroxine levels over the same period were about 118, 111 and 120 nanomol/L, respectively, and the mean TSH levels were 1.6, 2.7 and 1.4 mU/L, respectively.

A woman with thyroid cancer taking levothyroxine 125 micrograms daily to suppress serum TSH levels had a reduced response (fatigue, weight gain) when she took Tums containing calcium carbonate, for the prevention of osteoporosis. She often took the two together. Over a 5-month period her serum TSH levels rose from 0.08 mU/L to 13.3 mU/L. Within 3 weeks of stopping the calcium carbonate, her serum TSH levels had fallen to 0.68 mU/L. Other reports have described 4 patients who had elevations in their TSH levels while taking calcium carbonate concurrently with levothyroxine. All levels returned to normal when administration was separated by about 4 hours.

Mechanism

In vitro studies indicate that levothyroxine is adsorbed onto calcium carbonate when the pH is low (as in the stomach), which would reduce the amount available for absorption.

Importance and management

An established interaction, which seems to be of limited clinical significance. The study cited shows that the mean reduction in the absorption of levothyroxine is quite small, but the case reports show that some individuals can experience a reduction in the absorption that is clinically im-
important. Since it is impossible to predict which patients are likely to be affected significantly, the cautious approach would be to advise all patients to separate the dosages of the two preparations by at least 4 hours to avoid admixture in the gut. This interaction would be expected to occur with calcium carbonate in any form but it is not known whether other thyroid hormone preparations interact in the same way as levothyroxine.

2. Schneyer CR. Calcium carbonate and reduction of levothyroxine efficacy. JAMA (1998) 279, 750.

**Thyroid hormones + Ciprofloxacin**

There is a report of unexplained hypothyroidism in two patients taking levothyroxine who had also been taking oral ciprofloxacin for 3 to 4 weeks.

**Clinical evidence, mechanism, importance and management**

An 80-year-old patient with advanced thyroid cancer taking levothyroxine 125 micrograms daily required treatment with oral ciprofloxacin 750 mg twice daily and intravenous dicloxacillin for osteomyelitis complicating a fracture. After 4 weeks of treatment she complained of increasing tiredness, and was found to have a markedly raised TSH level (10 times of the upper limit of normal). Increasing the levothyroxine dose to 200 micrograms daily did not have any effect on TSH, so the dose was reduced to 125 micrograms. The ciprofloxacin was then stopped, and the thyroid function tests normalised.

Another women stable taking levothyroxine 150 micrograms daily had a more than 10-fold increase in TSH levels after taking ciprofloxacin 500 mg twice daily for 3 weeks. When administration of levothyroxine and ciprofloxacin was separated by 6 hours, thyroid function tests normalised, which suggests that concurrent administration somehow reduces the absorption of levothyroxine.

This interaction is not established, but the two cases suggest that long-term ciprofloxacin should be considered as a possible cause of hypothyroidism in patients taking levothyroxine. Further study is needed.

**Thyroid hormones + Colestyramine**

The absorption of thyroid extract, levothyroxine, and tri-iodothyronine from the gut is reduced by the concurrent use of colestyramine.

**Clinical evidence**

A patient with hypothyroidism, taking levothyroxine, had a fall in his basal metabolic rate when given colestyramine: this prompted a further study in two similar patients taking thyroid extract 60 mg daily or levothyroxine sodium 100 micrograms daily, and 5 healthy subjects. Colestyramine 4 g four times daily reduced their absorption of levothyroxine, the amount recovered in the faeces being roughly doubled. One of the patients had a worsening of her hypothyroidism. Giving the levothyroxine 4 to 5 hours after the colestyramine reduced but did not completely prevent the interaction.

Another report describes a patient taking levothyroxine whose TSH levels rose when colestyramine was taken, and fell again when it was stopped, indicating an impairment of levothyroxine absorption.

**Mechanism**

Colestyramine binds to levothyroxine in the gut, thereby reducing its absorption. Since levothyroxine probably also undergoes enterohepatic circulation, continued contact with the colestyramine is possible and separating administration may not entirely eliminate the interaction.

**Thyroid hormones + Grapefruit juice**

In a pharmacokinetic study, grapefruit juice had little effect on the absorption of levothyroxine, suggesting a clinically relevant interaction is unlikely. However, there is one case of unexplained hypothyroidism in a patient taking levothyroxine, which resolved when grapefruit juice consumption was reduced.

**Clinical evidence, mechanism, importance and management**

A 36-year-old woman previously stable taking levothyroxine 100 micrograms daily and with a marked consumption of grapefruit juice (specific volumes not stated) had a very high TSH level even after an increase in her levothyroxine dose to 150 micrograms daily. When she was advised to drink less grapefruit juice, her TSH fell to within the normal range.

This case prompted a crossover study in 10 healthy subjects; however, grapefruit juice caused only a slight 11% reduction in the maximal increase in thyroxine after a single 600-microgram dose of levothyroxine.

In this study, normal-strength grapefruit juice 200 mL was taken 3 times a day for 2 days, then on the third day, grapefruit juice 200 mL was taken one hour before, simultaneously with, and one hour after, levothyroxine.

The pharmacokinetic study established that grapefruit juice appears to have only small effects on levothyroxine levels, which suggests that a clinically relevant interaction is unlikely. However, consider this case in the event of an unexpected decreased response to levothyroxine.

**Thyroid hormones + H₂-receptor antagonists**

Cimetidine, but not ranitidine, causes a small reduction in the absorption of levothyroxine.

**Clinical evidence, mechanism, importance and management**

When 10 women with simple goitre were given 400 mg of cimetidine 90 minutes before a single capsule of levothyroxine, the absorption of levothyroxine was reduced over the first 4 hours by about 21%. The reasons are not understood. A single 300-mg dose of ranitidine was found not to affect the levothyroxine absorption in a matched group of 10 women.

The clinical importance of this interaction with cimetidine awaits assessment, but it seems unlikely to be generally significant.

**Thyroid hormones + HRT**

HRT appears to increase the requirement for levothyroxine in some patients.

**Clinical evidence**

In 25 postmenopausal women taking stable doses of levothyroxine (for hypothyroidism or TSH suppression), the addition of hormone replacement therapy (conjugated estrogens 0.625 mg daily with or without medroxyprogesterone acetate 5 mg daily for 12 days each month)
decreased serum free thyroxine levels and increased TSH levels. The changes in TSH were clinically important in 10 of the 25 women, requiring increased doses of levothyroxine, although only one woman had symptoms of hypothyroidism.1

**Mechanism**

Estrogens increase thyroxine binding-globulin. In women with normal thyroid function this does not alter free thyroxine levels or TSH levels, as the thyroxine secretion can increase to accommodate the changes. However, in women with hypothyroidism who cannot compensate for the increased thyroxine binding, decreased free thyroxine and therefore increased TSH can result.

**Importance and management**

Although this study appears to be the only evidence of an interaction, it would now be prudent to monitor thyroid function several months after starting or stopping HRT to check levothyroxine requirements.

### Thyroid hormones + Imatinib

Imatinib appears to cause hypothyroidism in thyroidectomy patients taking levothyroxine.

**Clinical evidence, mechanism, importance and management**

Retrospective analysis of 11 patients taking levothyroxine and with thyroid cancer found that 8 patients who had previously undergone a total thyroidectomy developed markedly elevated TSH levels and were clinically hypothyroid after receiving treatment with imatinib. Despite a mean increase in the dose of levothyroxine of about 200%, hypothyroidism was reversed in only 3 patients. Thyroid function tests normalised on discontinuing imatinib. Conversely, no effect on thyroid status was seen in the 3 patients who had not had their thyroid gland removed.1

The authors postulated that imatinib might increase the clearance of the thyroid hormones thyroxine and tri-iodothyronine by induction of glucuronosyltransferases (UGTs).1 Patients who have undergone a thyroidectomy cannot respond to these changes and therefore become hypothyroid. The findings from this study appear to be established. TSH levels should be closely monitored in thyroidectomy patients taking levothyroxine if they are given imatinib, anticipate the need to increase the levothyroxine dose. The authors suggest that in thyroidectomy patients the dose of levothyroxine should be doubled before starting imatinib.1

1. de Groot JWB, Zonnenberg BA, Plukker JTM, van Der Graaf WTA, Links TP. Imatinib induction of glucuronosyltransferases (UGTs).1 Patients who have undergone a thyroidectomy cannot respond to these changes and therefore become hypothyroid. The findings from this study appear to be established. TSH levels should be closely monitored in thyroidectomy patients taking levothyroxine if they are given imatinib, anticipate the need to increase the levothyroxine dose. The authors suggest that in thyroidectomy patients the dose of levothyroxine should be doubled before starting imatinib.1

### Thyroid hormones + Iron compounds

Ferrous sulfate causes a reduction in the effects of levothyroxine in patients with hypothyroidism.

**Clinical evidence**

Fourteen patients with primary hypothyroidism had an increase in TSH levels from 1.6 to 5.4 mU/L when given ferrous sulfate 300 mg daily for 12 weeks along with their usual levothyroxine dose. The symptoms of hypothyroidism in 9 patients worsened.1 In another report a woman with hypothyroidism, taking levothyroxine, had a very marked rise in TSH levels when she took ferrous sulfate. Her levothyroxine dosage needed to be raised from 175 to 200 micrograms daily.2

**Mechanism**

The addition of iron to levothyroxine in vitro was found to produce a poorly soluble purple iron-levothyroxine complex suggesting that this might also occur in the gut.1

---

**Thyroid hormones + Proton pump inhibitors**

A man needed to have his levothyroxine dosage doubled when he took saquinavir/ritonavir, and another woman possibly had a similar reaction when given indinavir then nevirapine. Conversely, another woman needed a markedly reduced dose of levothyroxine when given indinavir.

**Clinical evidence, mechanism, importance and management**

An HIV-positive man, taking levothyroxine for autoimmune thyroiditis, developed an enlarged thyroid gland and marked lethargy about a month after his HIV treatment was changed to include stavudine, lamivudine, saquinavir and ritonavir. It became necessary to double his maintenance dose of levothyroxine to re-stabilise him. When the ritonavir and saquinavir were withdrawn and replaced by indinavir, the patient was able to go back to the original dose of levothyroxine. It is thought that this interaction occurred because ritonavir increases the activity of the glucuronosyl transferases, which are concerned with the metabolism (conjugation) of levothyroxine.1

Although this case suggested that indinavir did not interact with levothyroxine, a further case suggests the opposite. A 36-year-old HIV-positive woman taking levothyroxine 750 micrograms daily (following partial thyroid gland destruction for Grave’s disease) was started on stavudine, lamivudine and indinavir. After about 7 weeks she presented with symptoms of hyperthyroidism (including nervousness, palpitations and weight loss). Her serum TSH was low and thyroxine was high. After stopped dose decreases she was finally restabilised on levothyroxine 120 micrograms daily, with normal thyroid indices. The authors postulated that indinavir reduces the activity of glucuronosyl transferases in contrast to ritonavir.2

Conversely, in another woman a 4-week course of antiretroviral prophylaxis, including 2 weeks of indinavir then 2 weeks of nevirapine, tended to reduce the efficacy of levothyroxine 125 micrograms daily. She was fatigued and had elevated TSH and hypercholesterolaemia, which resolved after the antiretroviral therapy was stopped.3

Direct information of the interactions of protease inhibitors and thyroid hormones seems limited. Whether or not an interaction occurs seems to depend on the individual protease inhibitor, how it affects glucuronidation, and how much remaining thyroid function a patient has.1 Until more is known about this interaction it would seem prudent to monitor thyroid function more closely if a protease inhibitor is given to a patient with pre-existing hypothyroidism.

---

**Thyroid hormones + Proton pump inhibitors**

In one study, patients who had been taking levothyroxine and omeprazole for a least 6 months required a modest 37% increase in the median levothyroxine dose required to suppress TSH levels to those seen before starting omeprazole. Conversely, in a pharmacokinetic study, pantoprazole did not alter the absorption of a single dose of levothyroxine.
Clinical evidence

In a randomised, crossover study in 20 healthy subjects, pre-treatment with pantoprazole 40 mg daily for one week had no effect on the AUCs of TSH or thyroxine after a single 4-micrograms/kg dose of levothyroxine.1

In contrast, in a non-randomised study in 10 women with multinodular goitre and gastroesophageal reflux disease taking a stable dose of levothyroxine to suppress thyroid growth, the use of omeprazole 40 mg daily for at least 6 months caused a variable increase in TSH levels (median 1.7 mU/L versus 0.1 mU/L before treatment). At that time, the dose of levothyroxine was increased to suppress TSH levels: this required a median dose of levothyroxine of 2.16 micrograms/kg compared with 1.58 micrograms/kg before starting omeprazole (a 37% increase).2

Mechanism

A decrease in gastric acidity might decrease levothyroxine absorption. Supporting this is the finding that in patients with impaired gastric acid secretion the required dose of levothyroxine was 22 to 34% higher than in patients free of gastric disease.2 However, this effect could be due to the disease rather than gastric acid per se.3

Importance and management

An interaction between levothyroxine and proton pump inhibitors is not established. The pharmacokinetic study with pantoprazole did not reveal a change in levothyroxine absorption, whereas the study in patients who had been taking omeprazole for 6 months suggested that patients may need a modest increase in levothyroxine dose. Bear in mind the possibility of an interaction if a patient starting a proton pump inhibitor shows signs of reduced levothyroxine efficacy. Any interaction may take several months to develop. Further study is needed.

Thyroid hormones + Raloxifene

There are two reports of patients who developed increased levothyroxine requirements after taking raloxifene for a number of months.

Clinical evidence

A 79-year-old woman taking levothyroxine 150 micrograms daily developed elevated TSH levels and symptoms of hypothyroidism within 2 to 3 months of starting to take raloxifene 60 mg daily. Over the next 6 months the levothyroxine dose was progressively increased to 300 micrograms daily without normalising TSH levels. This patient took the raloxifene early in the morning at the same time as the levothyroxine. Subsequently, separating the dose of raloxifene and levothyroxine by 12 hours led to a drop in TSH levels. In a single-dose study in this patient, serum thyroxine levels were reduced when levothyroxine 1 mg was given with raloxifene 60 mg, and separating the doses of raloxifene and levothyroxine by 12 hours was found to reduce TSH levels.1 Another very similar case has been reported in a 47-year-old woman, which also, resolved on separating administration by 12 hours.2

Mechanism

Raloxifene is known to increase levels of thyroxine binding globulin, which results in increased levels of total thyroxine, without altering free thyroxine.3 However, this is not likely to be the mechanism in the cases described, since separating the doses would not reduce any effect by this mechanism. It appears that raloxifene reduced the absorption of levothyroxine, but the mechanism for this is not known.

Importance and management

The interaction is not established, but the similar outcomes in both case reports suggest that an interaction may occur. Further study is needed, but until then it would be prudent to monitor TSH levels in patients taking levothyroxine and starting raloxifene, especially if they complain of tiredness. If TSH levels are raised, try separating administration by 12 hours before increasing the levothyroxine dose.

Thyroid hormones + Sertraline

Limited evidence suggests that the effects of levothyroxine can be opposed in some patients by sertraline.

Clinical evidence, mechanism, importance and management

Two case reports suggest that rifampicin might possibly reduce the effects of thyroid hormones.

Clinical evidence, mechanism, importance and management

A woman with Turner’s syndrome, who had undergone a total thyroidectomy and who was being treated with levothyroxine 100 micrograms daily, had a marked fall in serum levothyroxine levels and free levothyroxine index with a dramatic rise in TSH levels when given rifampicin. However, no symptoms of clinical hypothyroidism developed, and the drop in serum levothyroxine occurred prior to starting rifampicin, which may reflect the clinical picture of an acute infection.1 Another case describes a fall in TSH levels when rifampicin was discontinued.2

A possible reason for the changes is that rifampicin, a potent enzyme inducer, can markedly increase the metabolism of many drugs and thereby reduce their effects. Rifampicin has been found to reduce endogenous serum thyroxine levels in healthy subjects1 and possibly in patients.2

There seem to be no reports of adverse effects in other patients given both drugs and the evidence for this interaction is by no means conclusive. Although rifampicin can affect thyroid hormones, it appears that healthy individuals can compensate for this. Since hypothyroid patients may not be able to compensate in the same way, bear this interaction in mind if rifampicin is given to a patient taking levothyroxine.

Thyroid hormones + Sodium polystyrene sulfonate

A woman with hypothyroidism taking levothyroxine relapsed when she took sodium polystyrene sulfonate.

Clinical evidence

A woman taking levothyroxine 150 micrograms daily for hypothyroidism, following total thyroidectomy, later developed renal impairment and required dialysis. She was also taking digoxin, clofibrate, calcium carbonate, ferrous sulfate, nicotinic acid, folic acid, and magnesium sulfate. Because of persistent hyperkalaemia she started taking sodium polystyrene sulfonate 15 g daily. After 6 months, she developed lethargy, a hoarse voice, facial fullness and weight gain (all symptoms of hypothyroidism). These symptoms resolved within 6 weeks of raising the levothyroxine dosage to 200 micrograms daily and separating its administration from the sodium polystyrene sulfonate by 10 hours (previously taken at the same time as the levothyroxine).\(^1\)

Mechanism

Sodium polystyrene sulfonate is a cation-exchange resin that is used to bind potassium ions in exchange for sodium. An in vitro study found that when levothyroxine 200 micrograms was dispersed in 100 mL water with 15 g sodium polystyrene sulfonate, the concentration of the levothyroxine at pH 2 fell by 93% and at pH 7 by 98%.\(^1\) This drop in concentration would almost certainly occur in the gut as well, thereby markedly reducing the amount of levothyroxine available for absorption.

Importance and management

Information seems to be limited to this study, but the interaction would appear to be of general importance. Separate the dosages of levothyroxine and sodium polystyrene sulfonate as much as possible (10 hours seems to be effective) and monitor the thyroid function to confirm that this is effective.

---

Thyroid hormones + Sucralfate

An isolated report describes raised serum thyroid hormone levels and evidence of thyrotoxicosis in a man taking levothyroxine with lovastatin. In contrast another isolated case report describes hypothyroidism in a woman taking levothyroxine with lovastatin.

Another report describes reduced efficacy of levothyroxine in two patients taking simvastatin, one of whom was successfully treated with pravastatin.

Clinical evidence, mechanism, importance and management

(a) Lovastatin

A 54-year-old diabetic man taking 150 micrograms of levothyroxine daily for Hashimoto’s thyroiditis, and a number of other drugs (gemfibrozil, clofibrate, pranoprolol, diltiazem, quinidine, aspirin, dipyridamole, insulin) started taking lovastatin 20 mg daily. Weakness and muscle aches (with a normal creatinine phosphokinase) developed within 2 to 3 days and over a 27-day period he lost 10% of his body weight. His serum levothyroxine levels rose from 11.3 to 27.2 micrograms/dL. The author of the report postulated that the lovastatin may have displaced the thyroid hormones from their binding sites, thereby increasing their effects and causing this acute thyrotoxic state. It was suggested that the patient did not have any cardiac symptoms because of his pre-existing drug regimen.\(^1\)

In contrast, a woman with goitrous hypothyroidism due to Hashimoto’s thyroiditis, which was being treated with 125 micrograms of levothyroxine sodium daily, developed evidence of hypothyroidism (elevated TSH) on two occasions while takingLovastatin 20 or 60 mg daily. No clinical signs of hypothyroidism developed, apart from some increased fatigue, and possibly an increased sensitivity to insulin. The author suggested that lovastatin may have influenced the absorption or clearance of levothyroxine.\(^2\)

When the second report was published, the manufacturers of lovastatin reported that at that time (August 1989) more than 1 million patients had taken Lovastatin, and hypothyroidism had only been reported in 3 patients.\(^3\) It seems that any interaction is a very rare event and consequently unlikely to happen in most patients. No special precautions would therefore seem to be necessary.

(b) Simvastatin

A 75-year-old woman who had been stable taking levothyroxine 800 micrograms weekly for many years had a gradual increase in TSH levels and increasing tiredness after starting to take simvastatin 10 mg daily. After 4 months the levothyroxine dose was increased to 900 micrograms daily, but the patient’s symptoms had not improved in 2 weeks and the simvastatin was stopped. The patient’s symptoms gradually resolved, and the dose of levothyroxine was reduced back to the previous level.\(^4\)

Another patient, who had recently started taking levothyroxine 50 micrograms daily, because of rising TSH levels, was also given simvastatin 10 mg daily. TSH levels continued to increase, so the simvastatin was stopped, and the TSH levels decreased to the normal range within 4 weeks without the need for an alteration in the levothyroxine dose. This patient was subsequently treated with pravastatin without a change in thyroid status.\(^5\)

The authors conclude that any interaction must be extremely rare given the frequent use of simvastatin and levothyroxine.\(^6\) No special precautions would appear to be required on concurrent use, but bear the possibility of this interaction in mind in the event of an unexpected response to treatment.

---

be prudent not to take sucralfate until a few hours after the levothryroxine. Patients should be advised accordingly and the response well monitored.

**Tizanidine + Antihypertensives**

Tizanidine may increase the effects of antihypertensive drugs. There are two case reports of severe hypotension with lisinopril. The manufacturer of tizanidine contraindicates the concurrent use of α2-adrenergic agonists (e.g. clonidine).

**Clinical evidence**

A 10-year-old child taking lisinopril developed severe hypotension within a week of starting to take tizanidine.1 Similarly, a 48-year-old stroke patient taking amlodipine, nimodipine, lisinopril, and labetalol, which had been added sequentially to control hypertension, had a dramatic reduction in blood pressure (from 130/85 to 66/42 mmHg) within 2 hours of her first dose of tizanidine 2 mg. She was given dopamine to maintain her blood pressure, and tizanidine and all the antihypertensives were withdrawn. Later labetalol, amlodipine, nimodipine and tizanidine were successfully resumed without producing similar problems.2

**Mechanism**

Tizanidine is a centrally acting α2-adrenergic agonist structurally related to clonidine and can cause dose related hypotension (66% of patients given a single 8-mg dose of tizanidine had a 20% reduction in blood pressure). This can result in bradycardia, dizziness or light-headedness, and rarely syncope. The antihypertensive effects of tizanidine are said to be less than one-tenth of those of clonidine.3 These effects are expected to be additive with other antihypertensive drugs. However, in the cases with lisinopril, it was suggested that ACE inhibition, combined with the alpha-agonist effects of tizanidine prevented the usual sympathetic response to hypotension (that is, it was not thought to be due to simple additive hypotensive effects).1,2

**Importance and management**

Tizanidine alone can cause hypotension, an effect which is usually minimised by titration of the dose. Patients should be warned about this effect. Because of this, the manufacturers caution that tizanidine might increase the effects of antihypertensive drugs, including diuretics, and recommend caution on concurrent use. This is a prudent precaution. The US manufacturer specifically states that tizanidine (an α2-adrenergic agonist that is structurally related to clonidine) should not be used with other α2-adrenergic agonists [e.g. clonidine, methyldopa].3

The UK manufacturers also say that the concurrent use of beta blockers may potentiate bradycardia and hypotension.4

**Tizanidine + CYP1A2 inhibitors**

Fluvoxamine causes a very marked 33-fold increase in tizanidine levels with a consequent increase in hypertensive and sedative effects. The combination is potentially hazardous and should be avoided. Ciprofloxacin markedly increases tizanidine levels and adverse effects, and particular caution is required if this combination is considered essential. Combined oral contraceptives increase tizanidine levels fourfold and might increase adverse effects. Other inhibitors of CYP1A2 are predicted to interact similarly.

**Clinical evidence**

(a) Ciprofloxacin

In a placebo-controlled, crossover study in 10 healthy subjects ciprofloxacin 500 mg twice daily for 3 days markedly increased the AUC of a single 4-mg dose of tizanidine by tenfold and the maximum level by 12-fold, without significantly affecting the half-life. The hypotensive and sedative effects of tizanidine were also markedly increased by ciprofloxacin.1

A 45-year-old Japanese woman with multiple sclerosis taking tizanidine 3 mg daily had a reduction in blood pressure (from 124/88 to 102/74 mmHg) and heart rate (from 86 to 58 bpm) shortly after starting to take ciprofloxacin 400 mg daily. After 2 days she complained of drowsiness and her blood pressure was 92/54 mmHg.2 Retrospective analysis revealed 8 patients who had received tizanidine and ciprofloxacin concurrently. In these patients, the mean reduction in blood pressure on starting ciprofloxacin was 21.3/15.4 mmHg, and the heart rate reduction was 14.9 bpm. Adverse effects attributable to tizanidine occurred in three of the patients.2

(b) Fluvoxamine

In a placebo-controlled, crossover study in 10 healthy subjects fluvoxamine 100 mg once daily for 4 days very markedly increased the AUC of a single 4-mg dose of tizanidine by 33-fold and the maximum level by 12-fold. The elimination half-life was prolonged from 1.5 to 4.3 hours. The hypotensive and sedative effects of tizanidine were also markedly increased by fluvoxamine, with all of the 10 subjects somnolent and dizzy for 3 to 6 hours.3

A 70-year-old Japanese woman started taking tizanidine 3 mg daily 15 days after starting fluvoxamine 100 mg increased to 150 mg daily. Her heart rate dropped from about 85 bpm to a range of 56 to 60 bpm. After tizanidine was stopped, the symptoms improved immediately.4 Retrospective analysis revealed 23 patient who had received tizanidine with fluvoxamine. Of these patients, 6 had adverse effects including low heart rate, dizziness, drowsiness and hypotension. The patients with adverse effects were, on average, taking higher doses of fluvoxamine and tizanidine than those without adverse effects.4

(c) Oral contraceptives

In a study in 15 healthy women taking a combined oral contraceptive (ethinylestradiol/gestodene), the AUC of a single 4-mg dose of tizanidine was 3.9-fold higher than in 15 healthy women not taking an oral contraceptive, without any difference in the elimination half-life. In addition, the blood pressure-lowering effect of tizanidine was increased by 12/8 mmHg in the oral contraceptive users.5 The manufacturer also notes that retrospective analysis of population pharmacokinetic data showed that the clearance of tizanidine is about 50% lower in women taking oral contraceptives.6,7

(d) Rofecoxib

In a placebo-controlled, crossover study in 9 healthy subjects rofecoxib 25 mg daily for 4 days markedly increased the AUC of a single 4-mg dose of tizanidine by 13.6-fold and the maximum level by 6.1-fold. The hypotensive and sedative effects of tizanidine were also markedly increased by rofecoxib. There was no evidence of QT prolongation in this study.8

An otherwise healthy 59-year-old woman developed extreme sinus bradycardia (30 bpm) with chest pain and acute right heart failure while taking tizanidine, diclofenac and rofecoxib. This resolved promptly after stopping the medication.9 Note that rofecoxib was generally withdrawn worldwide in 2004 because of its cardiovascular adverse effects, but these data are included here for completeness.

**Mechanism**

Tizanidine is a substrate of the cytochrome P450 isoenzyme CYP1A2, which undergoes substantial presystemic metabolism by this isoenzyme. Ciprofloxacin appears to inhibit mainly the presystemic metabolism leading to increased absorption, as reflected by the increase in maximum level without a change in elimination half-life. Rofecoxib and fluvoxamine inhibited both presystemic metabolism and the elimination phase. Fluvoxamine, which is a known potent inhibitor of CYP1A2, had the most marked effect. The contraceptive steroids were modest inhibitors of CYP1A2 by comparison.
Importance and management

These pharmacokinetic interactions are well established, and clinically important. The common adverse effects of tizanidine, such as hypotension and sedation, are dose related, and consequently the manufacturers recommend starting with a low dose of tizanidine (2 or 4 mg) and carefully titrating to the usual maximum of 24 mg daily, and not exceeding 36 mg daily.6,7 This represents a maximum 18-fold variation in dosage. Fluvoxamine increases the exposure to tizanidine by a mean of 33-fold, which, broadly speaking, changes a 2 mg dose into a 66 mg dose, which is far higher than the maximum recommended dose. For this reason, the authors of one of the studies conclude that the combination is potentially hazardous and should be avoided.3 The US manufacturer also contraindicates the combination.5 Given the available data this is sensible advice. Note that other SSRIs are generally not considered to inhibit CYP1A2, see ‘Theophylline + SSRIs’, p.1197, and may therefore be suitable alternatives to fluvoxamine.

For ciprofloxacin, there is a marked tenfold increase in exposure to tizanidine, with a consequent increase in adverse effects. Some authors recommend that this combination be avoided,2 whereas others recommend caution.1 The US manufacturer contraindicates the combination,1 whereas the UK manufacturer mention this potential interaction.6 If ciprofloxacin is considered the most appropriate antibacterial to use in a patient already taking tizanidine, anticipate the need to reduce the tizanidine dose before starting the ciprofloxacin, and closely monitor adverse effects: starting ciprofloxacin may cause marked hypotension, bradycardia, and sedation. Other quinolones also inhibit CYP1A2, but to varying degrees, see ‘Table 33.4’, (p.1193).

For combined oral contraceptives, the increase in exposure to tizanidine is a more moderate fourfold. The manufacturer states that clinical response or adverse effects might occur at lower doses of tizanidine in patients taking oral contraceptives,5 and that during dose titration, individual doses should be reduced.7 Care is needed.7 In addition, the US manufacturer also recommends caution if tizanidine is given with other inhibitors of CYP1A2, of which they mention amiodarone, mexiletine, propafenone, cimetine, and ticlopidine.7 For a list of clinically important CYP1A2 inhibitors, see ‘Table 1.2’, (p.4).

Tizanidine + Rifampicin

Rifampicin moderately decreases the plasma concentrations of tizanidine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study in 10 healthy subjects, pre-treatment with rifampicin 600 mg daily for 5 days moderately reduced the AUC and peak level of a single 4-mg dose of tizanidine given on day 6 by about 50%, without altering the half-life.1 Rifampicin appears to be only a weak inducer of the cytochrome P450 isoenzyme CYP1A2, by which tizanidine is metabolised.1 Rifampicin moderately reduces the levels and effects of tizanidine. Because tizanidine dose is titrated to effect, this is probably not that clinically important. A small increase in dose might be required.1,2

Tizanidine + Miscellaneous

The sedative effects of tizanidine and other sedative drugs and alcohol are additive. Increased bradycardia might occur with digoxin. It is unclear whether tizanidine prolongs the QT interval in humans. No interaction occurs with paracetamol (acetaminophen).

Clinical evidence, mechanism, importance and management

(a) CNS depressants

One of the most common adverse effects of tizanidine is somnolence or drowsiness (occurring in up to 50% of patients) for which reason the manufacturers warn about the possibility of increased sedation with other sedative drugs, and alcohol.6,7 In addition to additive sedative effects, alcohol increased the AUC of tizanidine by about 20% and its maximum level by 15%, which was associated with an increase in adverse effects of tizanidine.5 Patients should be warned.

(b) Digoxin

Tizanidine alone can cause bradycardia.2,3 The UK manufacturers say that the concurrent use of digoxin may potentiate bradycardia.2

(c) Drugs that prolong the QT interval

The US manufacturer information states that prolongation of the QT interval and bradycardia were noted in chronic toxicity studies in dogs at doses equal to the maximum dose.5 The UK information states that caution should be exercised when tizanidine is prescribed with drugs known to increase the QT interval.2 In one pharmacological interaction study in healthy subjects, there was no evidence of QT prolongation either with tizanidine 4 mg, or almost 14-fold increased tizanidine levels caused by ‘rofecoxib’, (p.1286), despite increased bradycardia and hypotension.5 This suggests that a clinically significant interaction resulting in QT-prolongation is unlikely.

(d) Paracetamol

In 20 healthy subjects, no clinically significant interaction occurred between 325 mg of paracetamol (acetaminophen) and 4 mg of tizanidine.1

Importance and management

Although the clinical relevance of these pharmacokinetic interactions have not been assessed, the manufacturers recommend that the daily dose of darifenacin is limited to 7.5 mg if it is given with ketoconazole or other potent inhibitors of CYP3A4. They specifically name clarithromycin, itraconazole, miconazole, nefazodone, neflinavir and ritonavir. They say that dose adjustments are not required for moderate CYP3A4 inhibitors of which they list erythromycin, fluconazole, diltiazem and verapamil. The UK manufacturers of darifenacin say that the concurrent use of potent CYP3A4 inhibitors is contraindicated. They specifically name grapefruit juice, clarithromycin, erythromycin, telithromycin and fluconazole. For a list of CYP3A4 inhibitors, see ‘Table 1.4’, (p.6).

Urinary antimuscarinics; Darifenacin + Miscellaneous

Paroxetine and cimetidine cause small, clinically irrelevant, increases in darifenacin levels. Darifenacin increases imipramine levels, and caution is required with this and other tricyclics. Darifenacin does not significantly affect the pharmacokinetics of midazolam or combined oral contraceptives.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

The manufacturers note that, in a study in healthy subjects, cimetidine 800 mg twice daily increased the steady-state AUC of darifenacin 30 mg once daily by 34%,1,2 This change is unlikely to be clinically relevant. However, the UK manufacturers recommend that the dose of darifenacin should be started at 7.5 mg daily and, if well tolerated, titrated to 15 mg daily in the presence of cimetidine.1 This seems a cautious approach.

(b) CYP2D6 inhibitors

They then recommend a cautious approach. For a list of CYP2D6 inhibitors, see ‘Table 1.3’, (p.6).

(c) CYP3A4 substrates

The manufacturers note that steady-state darifenacin 30 mg once daily increased the AUC of imipramine by 70% and increased the AUC of its active metabolite, desipramine, 2.6-fold in a study in healthy subjects.1 Because of these changes, the manufacturer recommends caution with tricyclic antidepressants and other CYP2D6 substrates that have a narrow therapeutic window.3 They name flecainide and thioridazine (see ‘Table 1.3’, (p.6), for a list).

(d) Midazolam

The manufacturers note that darifenacin 30 mg daily increased the AUC of a single 7.5-mg dose of midazolam by just 17% in a study in healthy subjects.1,2 This change is not clinically important.3

(e) Oral contraceptives

The manufacturers note that steady-state darifenacin 10 mg three times daily had no effect on the pharmacokinetics of a combined oral contraceptive (ethinylestradiol/levonorgestrel) in a study in 22 healthy women.1,2

Tyramine + Cimetidine

A woman taking cimetidine experienced a severe headache and hypertension when she drank Bovril and ate some cheese.

Clinical evidence, mechanism, importance and management

A 77-year-old woman with hiatus hernia, who had been taking cimetidine 400 mg four times daily for 3 years, experienced a severe frontal headache and hypertension, which appeared to be related to the ingestion of a cup of Bovril and some English cheddar cheese, both of which contain substantial amounts of tyramine.1 Although the authors point out the similarity between this reaction and that seen in patients on MAOIs who eat tyramine-rich foods (see ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153), there is no satisfactory explanation for what occurred. They note that she was also taking salbutamol (another sympathomimetic) but rule out any contribution from this drug.

This is an isolated report and there is no reason why in general patients taking cimetidine should avoid tyramine-rich foods.

Urinary antimuscarinics; Darifenacin + CYP3A4 inhibitors

Ketoconazole markedly increases darifenacin levels, whereas erythromycin and fluconazole have only a modest effect on darifenacin levels.

Clinical evidence

(a) Azoles

The manufacturers note that, in a study in 16 healthy subjects, ketoconazole 400 mg daily for 6 days markedly increased the steady-state AUC of darifenacin 30 mg once daily by about tenfold.1,5 The UK manufacturers also note that ketoconazole 400 mg caused a fivefold increase in the AUC of a 7.5-mg dose of darifenacin.1

Fluconazole 200 mg then 100 mg daily had much less effect, causing an 84% increase in the steady-state AUC of darifenacin 30 mg once daily.1,2

(b) Erythromycin

The manufacturers note that erythromycin 500 mg daily increased the steady-state AUC of darifenacin 30 mg once daily by 95% in a study in healthy subjects.1,2

Mechanism

Darifenacin is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a potent inhibitor, and erythromycin and fluconazole are moderate inhibitors.

Importance and management

Although the clinical relevance of these pharmacokinetic interactions have not been assessed, the manufacturers recommend that the daily dose of darifenacin is limited to 7.5 mg if it is given with ketoconazole or other potent inhibitors of CYP3A4. They specifically name clarithromycin, itraconazole, miconazole, nefazodone, neflinavir and ritonavir. They then recommend a 7.5 mg dose of darifenacin in those taking moderate CYP3A4 inhibitors (they specifically name grapefruit juice, clarithromycin, erythromycin, telithromycin and fluconazole). For a list of CYP3A4 inhibitors, see ‘Table 1.4’, (p.6).

Urinary antimuscarinics; Oxybutynin + CYP3A4 inhibitors

Itraconazole and ketoconazole double the serum levels of oxybutynin. The clinical relevance of this is uncertain.

Clinical evidence

A single 5-mg dose of oxybutynin was given to 10 healthy subjects after they had taken itraconazole 200 mg daily or placebo for 4 days. The peak serum levels and the AUC of the oxybutynin were approximately doubled, while the pharmacokinetics of the active metabolite of oxybutynin were...
unchanged. The sum of the oxybutynin and its metabolite concentrations were on average about 13% higher than with the placebo. No increase in adverse effects was seen. Similarly, some manufacturers note that ketocnazole increases oxybutynin levels about twofold.\(^1,2\)

**Mechanism**

This interaction is almost certainly due to itraconazole and ketoconazole inhibiting the metabolism of oxybutynin by the cytochrome P450 isoenzyme CYP3A4, in the intestinal wall and liver.

**Importance and management**

The authors of this report consider that this interaction is only of minor importance, but note that this was only a single-dose study and may not necessarily reflect the full picture in practice. Nevertheless, because itraconazole is a known and potent enzyme inhibitor, they predict that other CYP3A4 inhibitors that are less potent (they name erythromycin, diltiazem, and verapamil) are unlikely to interact with oxybutynin significantly.\(^3\) Nevertheless, some manufacturers recommend caution with concurrent use,\(^1,2\) and until more is known this seem prudent. Bear in mind the possibility of an interaction if antimuscarinic effects (dry mouth, constipation, drowsiness) are increased.

---

**Urinary antimuscarinics; Solifenacin + CYP3A4 inhibitors**

Ketoconazole markedly increases solifenacin levels, and the solifenacin dose should be limited if ketoconazole or other potent inhibitors of CYP3A4 are used.

**Clinical evidence**

In a crossover study in healthy subjects, ketoconazole 200 mg daily for 20 days increased the AUC of a single 10-mg dose of solifenacin given on day 7 twofold.\(^3\) Moreover, the manufacturer notes that a higher dose of ketoconazole 400 mg daily increased the AUC threefold.\(^2,3\)

**Mechanism**

Solifenacin is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a known, potent inhibitor.

**Importance and management**

Although the clinical relevance of this interaction has not been assessed, the manufacturers recommend that the daily dose of solifenacin succinate is limited to 5 mg if it is given with ketoconazole or other potent inhibitors of CYP3A4.\(^2,3\) The UK manufacturer specifically names itraconazole, nelfinavir and ritonavir.\(^2\) In addition, in patients with severe renal impairment or moderate hepatic impairment, the combined use of solifenacin and potent CYP3A4 inhibitors is contraindicated.\(^2\) For a list of clinically significant CYP3A4 inhibitors, see “Table 1.4”, (p.6).

---

**Urinary antimuscarinics; Tolterodine + CYP3A4 inhibitors**

Ketoconazole can increase tolterodine levels in those who are deficient in the cytochrome P450 isoenzyme CYP2D6 (poor metabolisers). The manufacturers of tolterodine currently say that potent CYP3A4 inhibitors such as clarithromycin, erythromycin, itraconazole and ketoconazole, and protease inhibitors should be used with caution or avoided because of a risk of increased tolterodine effects.

**Clinical evidence**

A study\(^1\) in 8 healthy subjects who were deficient in the cytochrome P450 isoenzyme CYP2D6 (poor metabolisers) found that after taking ketoconazole 200 mg daily for 4 days the clearance of a single 2-mg dose of tolterodine was reduced by 61% and its AUC was increased 2.5-fold. A subsequent multiple-dose study in 6 of the original subjects given tolterodine 1 mg twice daily (half the usual dose) found similar increased levels: ketoconazole 200 mg once daily caused a 2.1-fold increase in tolterodine AUC, and a 2.2-fold increase in the AUC of the active moiety (unbound tolterodine plus metabolite).\(^1\)

**Mechanism**

Although tolterodine is normally metabolised to its active metabolite by CYP2D6, in those with low levels of this isoenzyme (about 5 to 10% of the population), metabolism by CYP3A4, becomes more important. It should be noted that tolterodine levels are already higher in poor CYP2D6 metabolisers than extensive metabolisers\(^2\) but are likely to rise even further when a potent CYP3A4 inhibitor such as ketoconazole blocks this other route of metabolism.

**Importance and management**

The UK manufacturers\(^3\) consider that this increase in levels represents a risk of overdose in poor CYP2D6 metabolisers. Consequently, they do not recommend the use of potent CYP3A4 inhibitors (they name clarithromycin, erythromycin, ketoconazole, and itraconazole, and protease inhibitors) with tolterodine in any patient (note that metaboliser status is rarely known). However, the US manufacturers\(^2\) recommend only that the dose of tolterodine be reduced to 1 mg twice daily in patients currently taking drugs that are potent inhibitors of CYP3A4, and this seems the more sensible advice. It may be prudent to assess experience of adverse effects in these patients, and to reduce the dose further or withdraw the drug if it is not tolerated.

---

**Urinary antimuscarinics; Tolterodine + Duloxetine**

Duloxetine increased the maximum levels of tolterodine by 64%, but this was not considered to be clinically significant.
Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 14 healthy subjects received duloxetine 40 mg twice daily and tolterodine 2 mg twice daily for 5 days. Duloxetine increased the steady-state AUC of tolterodine by 71% and its maximum level by 64%. However, duloxetine had no effect on the pharmacokinetics of 5-hydroxymethyl-tolterodine the active metabolite of tolterodine.1

Duloxetine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, by which tolterodine is metabolised. The increases in tolterodine levels were not considered to be clinically relevant, and no routine dosage adjustment of tolterodine dosage was considered necessary when given with duloxetine. Consider also ‘Urinary antimuscarinics; Tolterodine + Fluoxetine’, p.1290.

Urinary antimuscarinics; Tolterodine + Fluoxetine

Although fluoxetine can markedly inhibit the metabolism of tolterodine in some patients this is unlikely to cause a clinically important increase in the effects of tolterodine.

Clinical evidence, mechanism, importance and management

Thirteen psychiatric patients with symptoms of urinary incontinence were given tolterodine 2 mg twice daily for 5 doses, followed by fluoxetine 20 mg daily for 3 weeks, and then both drugs for a further 3 days. Nine of the 13 completed the study, the other 4 withdrew because of fluoxetine-related adverse effects. Fluoxetine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, the main enzyme involved in the metabolism of tolterodine. However, levels of this enzyme can vary between individuals and in the 7 patients with high CYP2D6 levels (extensive metabolisers) there was a 4.8-fold increase in the AUC of tolterodine and a minor reduction in its active and equipotent metabolite. In contrast the AUC of tolterodine increased by about 25% in 2 patients with low levels of CYP2D6 (poor metabolisers). These changes in AUC represent an increase of about 25% in active moiety (unbound tolterodine plus metabolite) for both poor and extensive metabolisers, a figure within normal variation.1

In practical terms this means that the antimuscarinic (anticholinergic) effects of the tolterodine are only moderately increased, and it seems unlikely that any tolterodine dosage changes are likely to be needed. Consider also ‘Antimuscarinics + Antimuscarinics’, p.674.

Ursodeoxycholic acid (Ursodiol) + Bile-acid binding resins

The absorption of ursodeoxycholic acid can be more than halved by colestil or colestyramine given simultaneously, and efficacy might be reduced.

Clinical evidence

(a) Colestil

Following a test meal with an overnight fast, 5 healthy subjects were given 200 mg of ursodeoxycholic acid alone or with 1.5 g of colesital granules. It was found that the ursodeoxycholic acid serum levels at 30 minutes were reduced by the colesital by more than 50% in 4 out of the 5 subjects, and the mean level was decreased from 9.2 to 3.4 micromol/L.1

(b) Colestyramine

Simultaneous administration of colestyramine 4 g daily with ursodeoxycholic acid reduced the fasting serum levels of ursodeoxycholic acid by about 60% in a study in 5 healthy subjects. Separation of administration by 5 hours tended to diminish the reduction (serum levels reduced by less than 40%).2

Mechanism

The mechanism of this interaction would appear to be that the bile-acid binding resins bind with ursodeoxycholic acid (a bile acid) in the intestine and thereby reduce its absorption.

Importance and management

These interactions would appear to be established, and are probably clinically important. One UK manufacturer actually advises that colestipol and colestyramine should be avoided when ursodeoxycholic acid is given, as they may limit the effectiveness of therapy.3 The authors of the reports recommend that in order to reduce the effects of this interaction, these two drugs should be separated,1,2 by at least 2 hours.1

Valerian + Cytochrome P450 isoenzyme substrates

Valerian root extract does not affect the metabolism of caffeine, chlorzoxazone, debrisoquine and metoprolol.

Clinical evidence, mechanism, importance and management

In a study 12 non-smoking healthy subjects were given valerian root extract 125 mg three daily for 28 days before receiving single doses of caffeine, chlorzoxazone, debrisoquine and midazolam. Valerian root extract caused no significant changes in the metabolism of these drugs, and it is therefore unlikely that other drugs metabolised by the cytochrome P450 isoenzymes CYP1A2, CYP2E1, CYP2D6 or CYP3A4 will be affected by the use of valerian.1 See tables ‘Table 1.2’, (p.4), ‘Table 1.3’, (p.6), and ‘Table 1.4’, (p.6), for a list of substrates for these isoenzymes.

Vinpocetine + Antacids

Aluminium/magnesium hydroxide gel (1 sachet four times daily) had no significant effects on the serum levels of vinpocetine (20 mg three times daily) in 18 healthy subjects.1 No special precautions seem necessary if they are taken together.

Vitamin A (Retinol) + Neomycin

Neomycin can markedly reduce the absorption of vitamin A (retinol) from the gut.

Clinical evidence, mechanism, importance and management

Neomycin 2 g markedly reduced the absorption of a test dose of vitamin A in 5 healthy subjects. It is suggested that this was due to a direct chemical interference between the neomycin and bile in the gut, which disrupted the absorption of fats and fat-soluble vitamins.1 The extent to which...
long-term treatment with neomycin (or other aminoglycosides) would impair the treatment of vitamin A deficiency has not been determined.

**Vitamin B<sub>12</sub> + Miscellaneous**

Neomycin, aminosalicylic acid and the H<sub>2</sub>-receptor antagonists can reduce the absorption of vitamin B<sub>12</sub> from the gut, but no interaction is likely when B<sub>12</sub> is given by injection.

**Clinical evidence, mechanism, importance and management**

Neomycin causes a generalised malabsorption syndrome, which has been shown<sup>1</sup> to reduce the absorption of vitamin B<sub>12</sub>. Colchicine has also been shown to decrease B<sub>12</sub> absorption.<sup>1</sup> Aminosalicylic acid reduces vitamin B<sub>12</sub> absorption for reasons that are not understood, but which are possibly related to a mild generalised malabsorption syndrome.<sup>2</sup> Review of the literature<sup>3</sup> suggests that H<sub>2</sub>-receptor antagonists (such as cimetidine and ranitidine) can also reduce vitamin B<sub>12</sub> absorption, primarily because they reduce gastric acid production. The acid is needed to aid the release of B<sub>12</sub> from dietary protein sources. There is therefore a possibility that on long-term use patients could become vitamin B<sub>12</sub> deficient.

Within the context of adverse drug interactions, none of these drugs is normally likely to be clinically important, because for anaemia, vitamin B<sub>12</sub> should be given parenterally for convenience and to avoid well-established problems with absorption.

1. Faloon WW, Chodos RB. Vitamin B<sub>12</sub> absorption studies using colchicine, neomycin and continuous 75C<sub>14</sub>B<sub>12</sub> administration. Gastroenterology (1969) 56, 1251.

**Vitamin D substances; Alfacalcidol + Danazol**

An isolated report describes hypercalcaemia when a woman taking alfacalcidol also took danazol.

**Clinical evidence, mechanism, importance and management**

A woman with idiopathic hypoparathyroidism, treated with alfacalcidol, developed hypercalcaemia when she was given danazol 400 mg daily for endometriosis. She needed a reduction in the dosage of alfacalcidol from 4 to 0.75 micrograms daily. When the danazol was stopped 6 months later, the alfacalcidol dosage was raised to 4 micrograms daily and she remained normocalcaemic. The reasons for this interaction are not understood and the general importance is limited as this appears to be an isolated case.

1. Falooin WW, Chodos RB. Vitamin B<sub>12</sub> absorption studies using colchicine, neomycin and continuous 75C<sub>14</sub>B<sub>12</sub> administration. Gastroenterology (1969) 56, 1251.

**Vitamin D substances + Phenytoin and Barbiturates**

The long-term use of phenytoin, phenobarbital, or primidone can disturb vitamin D and calcium metabolism and may result in osteomalacia. There are a few reports of patients taking vitamin D supplements who responded poorly to vitamin replacement while taking phenytoin or barbiturates. Serum phenytoin levels are not altered by vitamin D.

**Clinical evidence**

(a) Effect on vitamin D

A 16-year-old with grand mal epilepsy and idiopathic hypoparathyroidism did not adequately respond to daily doses of alfacalcidol 10 micrograms and 6 to 12 g of calcium, apparently because phenytoin 200 mg and primidone 500 mg daily were also being taken. However, when dihydroetchysterol 0.6 to 2.4 mg daily was given normal calcium levels were achieved.<sup>1</sup>

Other reports describe patients whose response to usual doses of vitamin D was poor, because of concurrent anticonvulsant treatment with phenytoin and phenobarbital or primidone.<sup>2</sup> Other reports clearly show low serum calcium levels,<sup>3,4</sup> low serum vitamin D levels,<sup>5</sup> osteomalacia,<sup>6</sup> and bone structure alterations<sup>5,7</sup> in the presence of phenytoin.

(b) Effect on phenytoin

A controlled study in 151 epileptic patients taking phenytoin and calcium showed that the addition of 2000 units of vitamin D<sub>2</sub> daily over a 3-month period had no significant effect on serum phenytoin levels.<sup>3</sup>

**Vitamin K substances + Antibacterials**

Seven patients in intensive care did not respond to intravenous vitamin K for hypoprothrombinemia while receiving gentamicin and clindamycin.

**Clinical evidence, mechanism, importance and management**

Some patients, particularly those in intensive care who are not eating, can quite rapidly develop acute vitamin K deficiency, which leads to prolonged prothrombin times and possibly bleeding.<sup>1,2</sup> This can normally be controlled by giving vitamin K parenterally. However, one report describes 7 such patients, all with normal liver function, who unexpectedly did not respond to intravenous phytomenaden. Examination of their records showed that all were receiving gentamicin and clindamycin.<sup>2</sup> Just why, or if, these two antibacterials might have opposed the effects of intravenous vitamin K is not understood. More study is needed.

**Vitamins + Orlistat**

Orlistat decreases the absorption of supplemental beta-carotene and vitamin E. There is some evidence to suggest that some patients may have low vitamin D levels while taking orlistat, even if they are also taking multivitamins.

**Clinical evidence**

Studies in healthy subjects have found that about two-thirds of a supplemental dose of beta-carotene<sup>1</sup> and roughly half the dose of vitamin E (<i>α</i>-tocopherol)<sup>2</sup> was absorbed in the presence of orlistat, while the absorp-
tion of vitamin A was not affected. In the first study, beta-carotene was given within about 30 minutes of the orlistat, whereas in the second, the vitamin supplement was given at the same time as orlistat. In another study, 17 obese adolescents were given orlistat 120 mg three times daily with meals and a daily multivitamin (containing vitamins A, D, E, and K) to be taken at night. Levels of vitamins A, E, and K were not significantly altered over 6 months of orlistat use, but vitamin D concentrations dropped after the first month, but had returned to baseline by 3 months. Three subjects (all African-Americans) required additional vitamin D supplementation, but all had a low dietary intake of vitamin D.

**Mechanism**

Orlistat reduces dietary fat absorption by inhibiting gastrointestinal lipase. Consequently, it reduces the absorption of fat soluble vitamins.

**Importance and management**

To maximise vitamin absorption, the manufacturers recommend that any multivitamin preparations should be taken at least 2 hours before or after orlistat, such as at bedtime. The US manufacturers suggest that patients taking orlistat should be advised to take multivitamins, because of the possibility of reduced vitamin levels. Note that the authors of the study in adolescents suggest that monitoring of vitamin D may be required, even if multivitamins are given.

---

**Calcium compounds reduce the absorption of zinc.**

**Clinical evidence, mechanism, importance and management**

Elemental calcium in doses of 600 mg (either as calcium carbonate or calcium citrate) was given to 9 healthy women with a single 20-mg oral dose of zinc sulphate. The AUC of zinc was reduced by 72% by calcium carbonate and by 80% by calcium citrate. The reason for this interaction is not understood, nor is the clinical importance of this interaction known, but it would seem prudent to separate the administration of zinc from the administration of any calcium compound. Two to three hours separation is often sufficient to achieve maximal absorption with interactions like this. More study of this interaction is needed to confirm the extent and to determine if separation of the doses is an adequate precaution.

Index

All of the pairs of drugs included in this book, whether interacting or not, are listed in this index. They may also be listed under the group names if the interaction is thought to apply to the group as a whole, or if several members of the group have been shown to interact. Note that in some circumstances, broad terms (e.g. analgesics) have been used, where the information is insufficient to allow more specific indexing. It is therefore advisable to look up both the individual drug and its group to ensure all the relevant information is obtained. It may also be advisable to look up both drugs of interest if you don’t initially find what you are looking for as drug name synonyms are also included as lead-ins. You can possibly get a lead on the way unlisted drugs behave if you look up those which are related, but bear in mind that none of them are identical and any conclusions reached should only be tentative.

Look up the names of both individual drugs and their drug groups to access full information.
Aprepitant

+ Hypericum (+ Rifampicin, 1249
+ Pimozide, 1250
+ Phenytoin, 1249
+ Primidone, 715
+ Protease inhibitors, 715
+ Quinidine, 715
+ Rifabutin, 715
+ Rifampicin, 715
+ Selective serotonin re-uptake inhibitors (see SSRIs), 715
+ Semisodium valproate (see Valproate), 715
+ Sertraline, 715
+ Sodium valproate (see Valproate), 715
+ SSRIs, 715
+ St John’s wort, 715
+ Valproate, 715
+ Venlafaxine, 715
+ Warfarin, 385

Aprindine

+ Aminodarone, 250

Aprobarbital

+ Bishydroxycoumarin (see Dicoumarol), 390
+ Dicoumarol, 390
+ Dicumarol (see Dicoumarol), 390

Aprotinin

+ ACE inhibitors, 14
+ Captopril, 14
+ Enalapril, 14
+ Heparin, 460
+ Neurornuscular blockers, 117
+ Succinylcholine (see Succinumethanol, 117)
+ Succinumethanol, 117
+ Tretinoin, 668
+ Tubocurarine, 117

Areca (Betel; Betel nuts)

+ Anti-asthma drugs, 1160
+ Anticholinergics (see Antimuscarinics), 674
+ Antimuscarinics, 674
+ Procyclidine, 674

Arecoline

+ Anti-asthma drugs, 1160

Argatroban

+ Abcinambah, 465
+ Acenocoumarol, 465
+ Acetylsalicylic acid (see Aspirin), 465
+ Alteplase, 465
+ Antiplaetelet drugs, 465
+ Aspirin, 465
+ CYP3A4 inhibitors, 465
+ Diginox, 910
+ Epifibatide, 465
+ Erythromycin, 466
+ Indanediones, 465
+ Lidocaine, 466
+ Lysine acetylsalicylate (see Aspirin), 465
+ Paracetamol, 466
+ Phenprocoumon, 465
+ Recombinant tissue-type plasminogen activator (see Alteplase), 465
+ rt-PA (see Alteplase), 465
+ Streptokinase, 465
+ Thrombolytics, 465
+ Tissue-type plasminogen activator (see Alteplase), 465
+ Vitamin K antagonists, 465
+ Warfarin, 465

Aripiprazole

+ Azoles, 715
+ Carbamazepine, 715
+ Citalopram, 715
+ Dextromethorphan, 715
+ Diphenylhydantoin (see Phenytoin), 715
+ Divalproex (see Valproate), 715
+ Efavirenz, 715
+ Escitalopram, 715
+ Famotidine, 715
+ Fluoxetine, 715
+ Foods, 715
+ Fosphenytoin (see Phenytoin), 715
+ HIV-protease inhibitors (see Protease inhibitors), 715
+ Hypericum (see St John’s wort), 715
+ Itraconazole, 715
+ Ketoczoonase, 715
+ Lithium compounds, 714
+ Nevirapine, 715
+ Omeprazole, 715
+ Paroxetine, 715
+ Phenoabarbital, 715
+ Phenobarbital, 715
+ Prindime, 715
+ Protease inhibitors, 715
+ Quinidine, 715
+ Rifabutin, 715
+ Rifampicin, 715
+ Selective serotonin re-uptake inhibitors (see SSRIs), 715
+ Semisodium valproate (see Valproate), 715
+ Sertraline, 715
+ Sodium valproate (see Valproate), 715

+ St John’s wort, 715
+ Valproate, 715
+ Venlafaxine, 715
+ Warfarin, 715

Arsenic trioxide, see QT-interval prolongers

Artemether, see also QT-interval prolongers

+ Antiabetics, 477
+ Cimetidine, 224
+ CYP3A4 inhibitors, 224
+ Erythromycin, 224
+ Foods, 224
+ Foods: Grapefruit juice, 224
+ Grapefruit juice (see Foods: Grapefruit juice), 224
+ HIV-protease inhibitors (see Protease inhibitors), 224
+ Hypoglycaemic agents (see Antiabetics), 477
+ Itraconazole, 224
+ Ketoconazole, 224
+ Mefloquine, 224, 231
+ Protease inhibitors, 224
+ Pyrimethamine, 239
+ Quinine, 225

Artemether/Lumefantrine see Co-artemether and individual ingredients

Artemisinin, see also QT-interval prolongers

+ Caffeine, 1163
+ Mefloquine, 231
+ Omeprazole, 969

Artemisinin derivatives, see also individual drugs and QT-interval prolongers

+ Antiabetics, 477
+ Hypoglycaemic agents (see Antiabetics), 477
+ Mefloquine, 231

Arsenenate

+ Atovaquone, 215
+ Mefloquine, 231
+ Proguanil, 215

Ascorbic acid, see Vitamin C substances

Asian ginseng, consider also Ginseng and Siberian ginseng
+ Diginox, 926

Asparaginase (Colaspase)

+ Antiabetics, 478
+ Hypoglycaemic agents (see Antiabetics), 478
+ Mefloquine, 231

Aspartame see Warfarin, 406

Aspirin (Acetylsalicylic acid; Lysine acetylsalicylate)

+ ACE inhibitors, 14
+ Acenocoumarol, 385
+ Acetaminophen (see Paracetamol), 152
+ Acetazolamide, 135
+ Alcohol, 51
+ Alendronate, 1251
+ Aluminium hydroxide, 135
+ Anaesthetics, general, 95
+ Anaegrelide, 698
+ Anastrozolone, 611
+ Angiotensin II receptor antagonists, 34
+ Antacids, 51
+ Anticholinesterases, 354
+ Antiplatelet drugs, 698
+ Arugatoban, 465
+ Ascorbic acid (see Vitamin C substances), 1250
Look up the names of both individual drugs and their drug groups to access full information.
Protease inhibitors, 734
Proton pump inhibitors, 735
Quinolones, 735
Raloxifene, 1277
Ranitidine, 727
Rifampicin, 736
Rifampin (see Rifampicin), 736
Saw palmetto, 736
Selectiv serotonin re-uptake inhibitors (see SSRI’s), 737
Semisodium valproate (see Valproate), 719
Serenoa repens (see Saw palmetto), 736
Sertraline, 737
Smoking (see Tobacco), 740
Sodium gamma-hydroxybutyrate (see Sodium oxybate), 1279
Sodium oxbate, 1279
Sodium valproate (see Valproate), 719
SSRIs, 737
St John’s wort, 739
Sucrose polyesters, 739
Sufentanil, 167
Tadalafil, 739
Tamsulosin, 84
Tea (see Xanthine-containing beverages), 740
Terbinafine, 740
Theophylline, 740
Tobacco), 740
Tobramadol, 166
Triamcinolone acetonide, 1231
Triamterene, 740
Venlafaxine, 737
Vinpocetine, 740
Xanthine-containing beverages, 740
Zidovudine, 808

Benztiazide
Antidiabetics, 487
Hypoglycaemic agents (see Antidiabetics), 487

Benzydamine
Prophenocoumon, 428

Benzylpenicillin (Penicillin G)
Acetylsalicylic acid (see Aspirin), 324
Aspirin, 324
Chloramphenicol, 299
Chlorothiazide, 324
Chlorothiazide, 326
Cimetidine, 324
Contraceptives, hormonal, 981
Foods: Milk, 323
Gamma globulin (see Normal immunoglobulins), 292
Hormonal contraceptives (see Contraceptives, hormonal), 981
Immunoglobulin (see Normal immunoglobulins), 292
Indometacin, 324
Lysine acetylsalicylate (see Aspirin), 324
Methotrexate, 643
Milk (see Foods: Milk), 323
Normal immunoglobulins, 292
Oxetatracycline, 326
Phenybutazone, 324
Probencid, 325
Sulfaethidole, 324
Sulfamethizole, 324
Sulfamethoxypyridazine, 324
Sulfaphenazole, 324
Sulfapyrazine, 324
Tetracycline, 326
Warfarin, 372

Bepridil
Digoxin, 914
Noricarandil, 899

Berberine
Saw palmetto, 736

Beta-2 agonist bronchodilators, 1158

Beta agonists, see also individual drugs
Adrenergic neuromon blockers, 891
Diuretics, thiazide (see Thiazides), 1162
Montelukast, 1160
Thiazide diuretics (see Thiazides), 1162
Thiazides, 1162

Beta-2 agonists (Beta-agonist bronchodilators), see also individual drugs
Antihypersensitivities, 880

Beta blockers, see also individual drugs
ACE inhibitors, 18
Acetaminophen (see Paracetamol), 197
Adrenaline, 848
Albuterol (see Salbutamol), 1160
Alcohol, 55
Alpha blockers, 84
Aminophylline, 1175
Amiodarone, 246
Beta blockers, 1160
Beta blockers, 1160
Beta-agonist bronchodilators (see Beta-2 agonist bronchodilators), 1160
Bile-acid binding resins, 838
Caffeine, 856
Cimetidine, 846
Formoterol, 1160
Flucainide, 844
Fluvastatin, 1094
Foods, 844
Foods: Grapefruit juice, 844
Formoterol, 1160
General anaesthetics (see Anaesthetics, general), 97
Halothane, 97
HMG-CoA reductase inhibitors (see Statins), 1094
Hormonal contraceptives (see Contraceptives, hormonal), 847
Hydralazine, 847
Hydroxychloroquine, 842
Hypoglycaemic agents (see Antidiabetics), 481
Ibuprofen, 852
Icosapent (see Eicosapentenoic acid), 843
Indomethacin, 841
Insulin, 841
Iodinated contrast media, 857
Isosorbide, 847
Isoprenaline, 1160
Isotretinoin (see Isoprenaline), 1160
Itraconazole, 849
Ketanserin, 894
L-DOPA (see Levodopa), 684
Lercanidipine, 838
Levadopa, 848
Levosimendan, 895
Lidocaine, 263
Lithium compounds, 1128
Local anaesthetics (see Anaesthetics, local), 110
Looestrin, 1094
MAOIs, 1131
Mefloquine, 232
Mexiletine, 268
Monoamine oxidase inhibitors (see MAOIs), 1131
Morphine, 850
Moxonidine, 899
Naproxen, 835
Naratriptan, 602
Nefazodone, 858
Neostigmine, 834
Neuro muscular blockers, 119
Noricarandil, 899
Nifedipine, 838
Nizatidine, 846
Nonsteroidal anti-inflammatory drugs (see NSAIDs), 835
NSAIDs, 835
Omega-3 marine triglycerides), 843
Omega-3 marine triglycerides, 843
Ondansetron, 1260
Orlistat, 31
Paracetamol, 197
Penicillins, 850
Peppermint (see Xanthine-containing beverages), 856
Phenolthiazines, 851
Phenylephrine, 848
Phenytoin, 835
Propafenone, 852
Propofol, 97
Propoxyphene (see Dextropropoxyphene), 842
Proton pump inhibitors, 853
Pyridostigmine, 834

Oxybutynin
+ Fosphenytoin (see Phenytoin), 545
+ Haloperidol, 707
+ Hormonal contraceptives (see Contraceptives, hormonal), 987
+ Lamotrigine, 545
+ Levetiracetam, 543
+ Levovalternest, 987
+ Lanzapine, 755
+ Phenobarbital, 545
+ Phenytoin, 545
+ Propoxyphene, see Dextropropoxyphene, 527
+ Risperidone, 764
+ Semisodium valproate (see Valproate), 545
+ Sodium valproate (see Valproate), 545
+ Verapamil, 525
+ Viloxazine, 538
+ Warfarin, 395

Oxiconazole, interactions overview

- Antacids, 1257
- Tobacco, 856
- Terbutaline, 1160
- Sulfinpyrazone, 856
- Pyridostigmine, 834
- L-Dopa, 684
- Isoprenaline, 1160
- Indometacin, 835
- Ethanol, 55
- Hormonal contraceptives, see Contraceptives, 983
- Coumarins, 434
- SSRIs, 1225
- Smoking, 1225
- Smoking (see Tobacco), 186

Oxygen
- Acetazolamide, 1266
- Aminodarone, 249
- Barbiturates, 1266
- Bleomycin, 618
- Narcotics (see Opioids), 1266
- Opiates (see Opioids), 1266
- Opioids, 1266

Oxybutynin
+ Antacids, 1257
+ Carbamazepine, 527
+ Ciclosporin, 1042
+ Clonipramine, 1245
+ Cyclosorpin (see Ciclosporin), 1042
+ CYP3A4 inhibitors, 1288
+ Diltiazem, 1288
+ Divalproex (see Valproate), 527
+ Erythromycin, 1288
+ Haloperidol, 707
+ Ketocazone, 1288
+ Omeprazole, 1257
+ Semisodium valproate (see Valproate), 527
+ Sodium valproate (see Valproate), 527
+ Tricyclic antidepressants, 1245

- Valproate, 527
- Verapamil, 1288

Oxycodeone
+ Acetaminophen (see Paracetamol), 196
+ Alcohol, 72
+ Amitriptyline, 187
+ Benzodiazepines, 166
+ Carisoprodol, 169
+ Erythromycin, 174
+ Escitalopram, 1220
+ Ethanol (see Alcohol), 72
+ Fluoxetine, 1220
+ Fluvoxamine, 1220
+ Foods, 169
+ Gatifloxacin, 338
+ Ibuprofen, 177
+ Ketocazone, 164
+ Levofloxacin, 338
+ Methylphenidate, 161
+ Paracetamol, 196
+ Pregabalin, 570
+ Quinidine, 184
+ Rifampicin, 185
+ Rifampin (see Rifampicin), 185
+ Ritonavir, 180
+ Sertraline, 1220
+ Smoking (see Tobacco), 186
+ Tobacco, 186

Oxyhemophore
+ Acenocoumarol, 364
+ Phenindione, 364
+ Acetaminophen, 196
+ Dicoumarol, 377
+ Phenobarbital, 346
+ Phenothiazines, 187
+ Phenytoin, 551

Oxyphenbutazone
+ Bisphosphonates, 521
+ Methotrexate, 521
+ Nefluramine, 521
+ Penicillin, 521
+ Phenobarbital, 521
+ Phenytoin, 521
+ Polyoxyx castor oils, 521
+ Protease inhibitors, 521
+ Quinupristin/Dalfopristin, 343
+ Ritonavir, 521
+ Semaxanib, 521

Paclitaxel
+ Amifostine, 660
+ Aprepitant, 614
+ Captopril, 635
+ Carbamazepine, 662
+ Carboquat, 662
+ Cyclosporin, 660
+ Cimetidine, 663
+ Cisplatin, 660
+ Crescophor, 663
+ Cyclophosphamide, 661
+ Cyclosporine (see Ciclosporin), 660
+ Dalfopristin/Quinupristin (see Quinupristin/Dalfopristin), 343
+ Deferasirox, 1261
+ Delavirdine, 661
+ Dexamethasone, 663
+ Diphenhydramine, 663
+ Diphenylhydantoin (see Phenytoin), 662
+ Doxorubicin, 612
+ Eprinubin, 612
+ Fosphenytoin (see Phenytoin), 662
+ Ganciclovir, 636
+ Granisetron, 614
+ HIV-protease inhibitors (see Protease inhibitors), 661
+ Ifosfamide, 628
+ Indinavir, 661
+ Ketocazone, 662
+ Lopinavir, 661
+ Methotrexate, 663
+ Nelfinavir, 661
+ Nelfinavir, 661
+ Phenytoin, 662
+ Protease inhibitors, 661
+ Quinupristin/Dalfopristin, 343
+ Ritonavir, 661
+ Semoxanib, 661

Paeonia lactiflora, see Paeoniae radix

Paeoniae radix (Paeonia lactiflora)
+ Divalproex (see Valproate), 521
+ Semisodium valproate (see Valproate), 521
+ Sodium valproate (see Valproate), 521
+ Valproate, 521

Palonosetron
+ Antiarrhythmics, 1260
+ Aprepitant, 1259
+ Dexamethasone, 1260
+ Diuretics, 1260
+ Metoclopramide, 1261
+ QT-interval prolongers, 1260
+ Rifaxpinic, 1260
+ Rifaxpin (see Rifampicin), 1260

Panax ginseng
+ Warfarin, 416

Panax quinquefolius
+ Warfarin, 416

Pancreatic enzymes
+ Ciprofloxacin, 342

Pancreatin
+ Acarbose, 470
+ Alpha-glucosidase inhibitors, 470
+ Ciclosporin, 1042
+ Cyclosporine (see Ciclosporin), 1042
+ Miglitol, 470
Look up the names of both individual drugs and their drug groups to access full information.
+ Ciclosporin, 1018
+ Cimetidine, 335
+ Cyclosporine (see Ciclosporin), 1018
+ Ketoprofen, 337
+ Magnesium hydroxide, 328
+ Metronidazole, 339
+ Piperacillin, 339
+ Rifampicin, 339
+ Rifampin (see Rifampicin), 339
+ Sucralfate, 341
+ Theophylline, 1192
+ Tobramycin, 339

**Peginterferon alfa. consider also Interferons**
+ Methadone, 173
+ Ribavirin, 786
+ Telbivudine, 831

**Pemt rested**
+ Acetylsalicylic acid (see Aspirin), 656
+ Aminoglycosides, 656
+ Aspirin, 656
+ Ciclosporin, 656
+ Cisplatin, 656
+ Folic acid, 656
+ Hydrocortisone (see Vitamin B12 substances), 656
+ Ibuprofen, 656
+ Loop diuretics, 656
+ Lysine acetylsalicylate (see Aspirin), 656
+ Nonsteroidal anti-inflammatory drugs (see NSAIDs), 656
+ NSAIDs, 656
+ Penicillamine, 656
+ Probenecid, 656
+ Vitamin B12 substances, 656

**Pemri n olast**
+ Theophylline, 1172

**Pemoline**
+ MAOIs, 1144
+ Monoamine oxidase inhibitors (see MAOIs), 1144

**Penbutolol**
+ Cimetidine, 845
+ Insulin, 481
+ Lidocaine, 263

**Penflu ridol**
+ Moclobemide, 1157

**Penicillamine**
+ Aluminium hydroxide, 1266
+ Antacids, 1266
+ Anticholinesterases, 354
+ Chloroquine, 1267
+ Cimetidine, 1267
+ Clorazepate, 746
+ Corticosteroids, 1267
+ Digoxin, 934
+ Ferrous fumarate, 1267
+ Ferrous sulfate, 1267
+ Foods, 1266
+ Gold compounds, 1267
+ Hormonal contraceptives (see Contraceptives, hormonal), 1267
+ Lidocaine, 263
+ Magnesium hydroxide, 1266
+ Nonsteroidal anti-inflammatory drugs (see NSAIDs), 1267
+ NSAIDs, 1267
+ Oxypenbutazone, 1267
+ Phenylbutazone, 1267
+ Simeticone, 1266

**Penicillins G, see Benzylpenicillin**

**Penicillin V, see Phenoxymethylpenicillin**

**Penicillins, see also individual drugs**
+ Acenocoumarol, 372
+ Alcohol, 45
+ Allergens, 322
+ Aminoglycosides, 289
+ Antacids, 323
+ Beta blockers, 850
+ Catha, 323
+ Catha edulis (see Catha), 323
+ Chloramphenicol, 299
+ Chlorquinine, 323
+ Ciclosporin, 1018
+ Contraceptive devices, intrauterine (see IUDs), 1007
+ Contraceptives, combined hormonal, 981
+ Contraceptives, hormonal, 981
+ Contraceptives, progesterone-only, 1007
+ Coumarins, 372
+ Cyclosporine (see Ciclosporin), 1018
+ Digoxin, 913
+ Diphenylhydantoin (see Phenytoin), 562
+ Divalproex (see Valproate), 327
+ Erythromycin, 316
+ Ethanol (see Alcohol), 45
+ Foods, 323
+ Fosphenytoin (see Phenytoin), 562
+ Genefacids, 464
+ Hormonal contraceptives (see Contraceptives, hormonal), 981
+ H2-receptor antagonists, 324
+ Indanediones, 372
+ Intrauterine contraceptive devices (see IUDs), 1007
+ IUDs, 1007
+ Khat (see Catha), 323
+ Macrolides, 316
+ Methotrexate, 643
+ Methoxyflurane, 107
+ Neuronal muscular blockers, 127
+ Omeprazole, 972
+ Pemetrexed, 656
+ Phenytoin, 562
+ Probenecid, 325
+ Progestogen-only contraceptives (see Contraceptives, progesterone-only), 1007
+ Progesterone, 372
+ Proinflammatory agents, 372
+ Sodium valproate (see Semisodium valproate), 1267
+ Theophylline, 1172
+ Thrombolytics, 372
+ Thiram, 325
+ Tocopherol, 634
+ Torsades de pointes, 325
+ Uracil, 325
+ Warfarin, 372
+ Warfarin, 372
+ Xanthine-containing beverages, 372

**Pentoxifylline**
+ Acenocoumarol, 440
+ Antibiotics, 499
+ Cimetidine, 900
+ Ciprofloxacin, 900
+ Coumarins, 440
+ Erythromycin, 45
+ Insulin, 499
+ Ketorolac, 153
+ Nonsteroidal anti-inflammatory drugs (see NSAIDs), 153
+ NSAIDs, 153
+ Phenprocoumon, 440
+ Theophylline, 1190
+ Warfarin, 440

**Peppermint**
+ Caffeine, 1165
+ Cardiac glycosides (see Digitalis glycosides), 926
+ Digitalis glycosides, 926

**Pepsi, see Xanthine-containing beverages**

**Perazine**
+ Moclobemide, 1141

**Pergolide**
+ Antipsychotics, 677
+ Dopamined, 677
+ L-DOPA (see L-DOPA), 684
+ Levodopa, 684
+ Lisinopril, 24
+ Metoclopramide, 677
+ Neuroleptics (see Antipsychotics), 677

**Perhexiline**
+ Citralopram, 900
+ Fluoxetine, 900
+ Paroxetine, 900
+ Selective serotonin re-uptake inhibitors (see SSRIs), 900
+ SSRIs, 900

**Pericyazine**
+ Fluoxetine, 712

**Perindopril**
+ Anaesthetics, general, 94
+ Digoxin, 904
+ Diuretics, loop (see Loop diuretics), 21
+ Diuretics, thiazide (see Thiazides), 21
+ Epoetins, 25
+ Erythropoetins (see Epoetins), 25
+ Foods, 26
+ General anaesthetics (see Anaesthetics, general), 94
+ Glibenclamide, 471
+ Glyburide (see Glibenclamide), 471
+ Indometacin, 28
+ Lithium compounds, 1112
+ Loop diuretics, 21
+ Spirnolactone, 23
+ Trazodone, 84
+ Thiazide diuretics (see Thiazides), 21
+ Thiazides, 21

**Perosproline**
+ Carbamazepine, 759
+ Itraconazole, 759
